**Abstract.** The VAHINE mesocosm experiment, conducted in the low-nutrient low-chlorophyll waters of the Noumea lagoon (coastal New Caledonia) was designed to trace the incorporation of nitrogen (N) fixed by diazotrophs into the food web, using large volume (50 m<sup>3</sup>) mesocosms. This experiment provided a unique opportunity to study the succession of different N<sub>2</sub>-fixing microorganisms (diazotrophs) and calculate in situ net growth and mortality rates in response to fertilization with dissolved inorganic phosphate (DIP) over a 23-day period, using quantitative polymerase chain reaction (qPCR) assays targeting widely distributed marine diazotroph lineages. Inside the mesocosms, the most abundant diazotroph was the heterocyst-forming *Richelia* associated with *Rhizosolenia* (Het-1) in the first half of the experiment, while unicellular cyanobacterial Group C (UCYN-C) became abundant during the second half of the experiment. Decreasing DIP concentrations following the fertilization event and increasing temperatures were significantly correlated with increasing abundances of UCYN-C. Maximum net growth rates for UCYN-C were calculated to range between  $1.23 \pm 0.07$  and  $2.16 \pm 0.07$  d<sup>-1</sup> in the mesocosms, which are among the highest growth rates reported for diazotrophs. Outside the mesocosms in the New Caledonia lagoon, UCYN-C abundances remained low, despite increasing temperatures, suggesting that the microbial community response to the DIP fertilization created conditions favorable for UCYN-C growth inside the mesocosms. Diazotroph community composition analysis using PCR targeting a component of the nitrogenase gene (*nifH*) verified that diazotrophs targeted in qPCR assays were collectively among the major lineages in the lagoon and mesocosm samples, with the

exception of *Crocospaera*-like phylotypes, where sequence types not typically seen in the oligotrophic ocean grew in the mesocosms. Maximum net growth and mortality rates for nine diazotroph phylotypes throughout the 23-day experiment were variable between mesocosms, and repeated fluctuations between periods of net growth and mortality were commonly observed. The field population of diazotrophs in the New Caledonian lagoon waters appeared to be dominated by Het-1 over the course of the study period. However, results from both qPCR and PCR analysis indicated a diverse field population of diazotrophs was present in the lagoon at the time of sampling. Two ecotypes of the *Braarudosphaera bigelowii* symbiont unicellular group A (UCYN-A) were present simultaneously in the lagoon, with the recently described *B. bigelowii*/UCYN-A2 association present at higher abundances than the *B. bigelowii*/UCYN-A1 association.

## 1 Introduction

Biological nitrogen fixation (BNF), the microbially mediated conversion of dinitrogen (N<sub>2</sub>) gas into bioavailable nitrogen (N), is a significant source of new N in oligotrophic oceanic regions where primary productivity is N limited (Gruber and Sarmiento, 1997; Karl et al., 1997), and has the potential to directly impact carbon sequestration (Karl et al., 2012; Karl and Letelier, 2008). BNF has historically been considered an important process in the oligotrophic ocean gyres, but primary productivity in oligotrophic tropical coastal regions can also be N limited (Torréon et al., 2010) and such environ-

ments have the potential to play a significant role in export production in the world's oceans due to the transfer of carbon from tidal and wind-generated currents (Hyndes et al., 2014; Gattuso et al., 1998).

The New Caledonian (Noumea) coral lagoon, located off the southwestern coast of New Caledonia (southwestern Pacific), is a tropical low-nutrient low-chlorophyll (LNLC) system and is bounded by one of the world's largest barrier reefs. Oligotrophic ocean water enters the lagoon from the south over the open shelf, then is driven north by the trade winds and tidal forces and exits through several deep inlets in the intertidal barrier reef that forms the western boundary of the lagoon (Ouillon et al., 2010). Primary productivity is N limited throughout the year (Torréton et al., 2010), giving microorganisms able to fix N<sub>2</sub> gas into bioavailable nitrogen (diazotrophs) a competitive edge over non-diazotrophic organisms. High rates of BNF during the austral summer have been reported, in both large size fractions (> 10 µm) and small size fractions (< 10 µm; Garcia et al., 2007; Biegala and Raimbault, 2008). Garcia et al. (2007) also reported that the percent of N<sub>2</sub> fixation measured in the large size fraction had high temporal variability. Large blooms of the most conspicuous and well-studied diazotroph, *Trichodesmium*, have been repeatedly detected in this region using both indirect (via satellite observation; Dupouy et al., 2000, 2011) and direct measurements (Renaud et al., 2005; Masotti et al., 2007; Rodier and Le Borgne, 2008, 2010). Both free-living and organism- and particle-associated unicellular picocyanobacterial diazotrophs are also suspected to be significant contributors to BNF in the lagoon (Garcia et al., 2007; Biegala and Raimbault, 2008), yet the phylogenetic identity of these picocyanobacteria has yet to be determined. Despite evidence that diverse diazotroph communities exist in the Noumea lagoon, there is very little quantitative diazotroph distribution data from this region (Luo et al., 2012), especially for diazotrophs other than *Trichodesmium*.

Marine unicellular cyanobacterial diazotrophs are phylogenetically divided into three groups: the uncultivated unicellular group A (UCYN-A; Zehr et al., 2008, 2001; Tripp et al., 2010), which live in association with strains of the prymnesiophyte *Braarudosphaera bigelowii* (Thompson et al., 2014, 2012; Hagino et al., 2013); the free-living *Crocosphaera* sp. (also referred to as unicellular group B or UCYN-B); and the presumably free-living unicellular group C (UCYN-C), which contains several cultivated cyanobacteria including *Cyanothece* sp. strain ATCC 51142 (Reddy et al., 1993) and group C TW3 (Taniuchi et al., 2012).

The marine filamentous cyanobacterial diazotrophs include the colonial, non-heterocyst-forming *Trichodesmium*, and the heterocyst-forming symbionts associated with diatoms (DDAs). DDAs form between different strains of *Richelia* sp. associated with diatoms of the genera *Rhizosolenia* (Het-1) and *Hemiaulus* (Het-2; Villareal, 1990, 1992). Het-2 is in an obligate symbiont of *Hemiaulus*, as evidenced by its reduced genome size (Hilton et al., 2013). Although the

genome of Het-1 shows evidence of some genome reduction, it remains unclear whether Het-1 is also an obligate symbiont of *Rhizosolenia* (Villareal, 1992; Hilton et al., 2013). The heterocyst-forming *Calothrix* (Het-3) has long been observed living as an epiphyte with *Chaetoceros* (Carpenter and Foster, 2002) but can also grow free from its host (Foster et al., 2010), and has a non-streamlined genome (Hilton et al., 2013).

Although *nifH* genes are regularly recovered from diverse non-cyanobacterial diazotrophs in oligotrophic ocean waters (Halm et al., 2012; Farnelid et al., 2011; Riemann et al., 2010; Langlois et al., 2005; Hewson et al., 2007; Bird and Wyman, 2012; Bonnet et al., 2013; Fong et al., 2008; Turk-Kubo et al., 2014), their activity and relative significance to BNF remains poorly understood (Turk-Kubo et al., 2014). The most widely studied non-cyanobacterial diazotroph,  $\gamma$ -24774A11, is an uncultivated putative gamma proteobacteria most closely related to *Pseudomonas stutzeri* that has been hypothesized to be a potentially important contributor to overall BNF in the South Pacific (Moisander et al., 2014).

Different diazotrophs have potentially different fates in the marine environment. For example, *Trichodesmium* is rarely recovered in sediment traps (Walsby, 1992), but *Trichodesmium*-derived N is efficiently transferred to non-diazotrophic plankton (mainly diatoms and bacteria) at short time scales (48 h) in the surface ocean (Bonnet et al., 2015b). In contrast, blooms of DDAs fuel an important summer export flux at the ALOHA station (Karl et al., 2012). This highlights the importance of characterizing the diazotroph community composition when performing biogeochemical studies on the fate of N<sub>2</sub> fixation in the ocean. Such studies are commonly performed on oceanographic cruises, where discrete samples are taken from multiple stations along a cruise track, which passes over many different water masses. This approach is of critical importance to describe the biogeographical distribution of diazotrophs with respect to environmental parameters over large oceanic provinces. However, in order to understand how diazotroph assemblages shift in response to rapid environmental perturbations inside the same water mass, and to track the incorporation of their newly fixed N into the food web, high-frequency sampling of a single water body is required, which is rarely accomplished.

We report here data from the VAHINE mesocosm experiment, detailed by Bonnet (2015), which was a large, multi-institute collaborative project conducted to determine which components of the food web were directly supported by newly fixed N. To answer this question, three large (50 m<sup>3</sup>) mesocosms were deployed in the New Caledonian (Noumea) lagoon to isolate a part of the water column from physical dispersion without disturbing light penetration and temperature. The same water masses were monitored for 23 days during austral summer conditions. In order to create conditions favorable for diazotrophs, the mesocosms were fertilized with dissolved inorganic phosphorus (DIP) on day 4 of the incubation. This experiment provided unique oppor-

tunities to (1) track rapid diazotroph assemblage shifts using quantitative techniques (quantitative PCR; qPCR) targeting known major marine diazotroph lineages for a long period of time (23 days) in a single water mass; (2) calculate in situ net growth and mortality rates for targeted diazotroph phylotypes in a complex community; (3) determine the abundances of targeted diazotrophs in a coastal LNLC environment, the Noumea lagoon, during the experimental period; and (4) characterize shifts in the diazotroph community composition in both the mesocosms and in the Noumea lagoon during the experimental period using next-generation sequencing of *nifH* gene amplicons.

## 2 Methods

### 2.1 Sampling

Three large volume mesocosms (50 m<sup>3</sup>), based on the design described in Guieu et al. (2010, 2014), were deployed at the exit of the Noumea lagoon (22°29.073 S–166°26.905 E), 28 km off the coast of New Caledonia, on 13 January 2013. Detailed descriptions of the mesocosm site selection, deployment and sampling strategy are provided in Bonnet (2015). Large volume samples (50 L) were collected from 1, 6, and 12 m depths from each mesocosm and outside the mesocosms (hereafter called the Noumea lagoon) once per day at 07:00 using a Teflon® PFA pump and PVC tubing. This daily sample was immediately transferred back to laboratories aboard the R/V *Alis*, and subsampled for a suite of stock and flux measurements. Samples for DNA analysis were immediately filtered onto 25 mm 0.2 µm Supor® filters (Millipore, Billerica, CA), using gentle peristaltic pumping. All filters were flash frozen in liquid nitrogen, and stored at –80 °C until shipment on dry ice from New Caledonia to the University of California, Santa Cruz.

### 2.2 Determining targeted diazotroph abundances and net growth rates using the quantitative polymerase chain reaction (qPCR)

DNA was extracted using a Qiagen DNeasy Plant kit (Valencia, CA), with modifications to the protocol optimized to recover high-quality DNA from cyanobacteria, including additional cell lysis steps of freeze–thaw cycles, agitation using a bead beater, as well as a proteinase K digestion (Moisander et al., 2008). The quality of DNA extracts was evaluated using a NanoDrop (Thermo Scientific, Waltham, MA), and concentrations were determined using a PicoGreen® dsDNA Quantitation Kit (Molecular Probes, Eugene, OR, USA), according to the manufacturer's guidelines.

Nine diazotrophic phylotypes were quantified in samples from the mesocosms and the Noumea lagoon, using quantitative PCR (qPCR), using Taqman® assays widely used in the marine environment. This study targeted representatives from known major marine diazotroph lineages: two unicel-

lular diazotrophic symbionts of different *Braarudosphaera bigelowii* strains, UCYN-A1 (Church et al., 2005a), UCYN-A2 (Thompson et al., 2014); two free-living unicellular diazotroph cyanobacterial phylotypes UCYN-B (*Crocospaera* sp.; Moisander et al., 2010), and UCYN-C (Foster et al., 2007); filamentous, colonial, non-heterocyst forming *Trichodesmium* spp. (Church et al., 2005a); three diatom-diazotroph associations (DDAs), *Richelia* associated with *Rhizosolenia* (Het-1; Church et al., 2005b), *Richelia* associated with *Hemiaulus* (Het-2; Foster et al., 2007), and *Calothrix* associated with *Chaetoceros* (Het-3; Foster et al., 2007); and a widespread  $\gamma$ -proteobacterial phylotype  $\gamma$ -24774A11 (Moisander et al., 2008).

Recombinant plasmids with the targeted organism *nifH* fragment were used as qPCR standards, and each 96 well plate was run with a serial dilution ( $10^0$ – $10^7$  *nifH* copies reaction<sup>-1</sup>) of the appropriate standard. All qPCR reactions were set up with 1 µL of DNA extract in a 15 µL volume with the following reagents and final concentrations: 1X Taqman® Master Mix (Applied Biosystems, Carlsbad, CA, USA), 0.4 µM each forward and reverse primers, and 0.2 µM probe (5'-FAM and 3'-TAMRA labeled). Thermocycle parameters were as described in Goebel et al. (2010) for all assays, with the exception of using a 64 °C annealing temperature for UCYN-A2. The qPCR reaction efficiencies were as follows: UCYN-A1 – 96.7 ± 2.8 %; UCYN-A2 – 94.9 ± 3.4 %; UCYN-B – 101.3 ± 2.2 %; UCYN-C – 95.4 ± 2.9 %;  $\gamma$ -24774A11 – 96.2 ± 3.2 %; *Trichodesmium* – 93.6 ± 1.4 %; Het-1 – 96.1 ± 4.7 %; Het-2 – 98.3 ± 2.0 %; and Het-3 – 97.5 ± 0.9 %. Based on the differences in sample volumes, the limits of detection (LOD) and quantification (LOQ) for all qPCR assays ranged between 11 and 56 *nifH* copies L<sup>-1</sup>, and between 87 and 444 *nifH* copies L<sup>-1</sup>, respectively. Samples were determined to be “detected, not quantified” (DNQ) when calculated abundances were greater than the LOD, but less than the LOQ. Abundances are reported as *nifH* copies L<sup>-1</sup> rather than cells L<sup>-1</sup> because there is currently little information about the number of *nifH* copies per genome in these diazotroph targets.

Preliminary analyses were conducted from three depth profiles on days 19 and 20, and very little vertical stratification was observed for most of the targeted diazotrophs, with abundances for most diazotrophs measured at the same order of magnitude throughout the 15 m mesocosm (Supplement Fig. S1). *Trichodesmium* and Het-3 were the only exceptions to this observation. Based on these findings, qPCR analyses focused on samples taken from the middle of the mesocosm (6 m), collected on odd days from inside the mesocosms, and even days from outside the mesocosms.

Growth and mortality rates were calculated for individual diazotrophs inside the mesocosms when abundances were higher than the LOQ on two consecutive sampling days, as described in Moisander et al. (2012), using the following formula:  $k = 2.303 \times (\log_{10}(N_{t2} - N_{t1})) / (t_2 - t_1)$ , where  $N_x$  = abundance at time  $x$ . This assumes that the organisms

were growing exponentially during the experiment, which cannot be easily verified in field populations. These rates implicitly include grazing, mortality and viral lysis, and thus are net growth and mortality rates.

### 2.3 Determination of diazotroph community composition using high-throughput sequencing of *nifH* amplicons

In order to evaluate whether the diazotrophs targeted via qPCR assays were representative of the phylotypes present in the lagoon and mesocosms, partial *nifH* fragments (ca. 360 base pairs) were amplified using a nested PCR assay and universal *nifH* primers *nifH1-4*, as described in Turk-Kubo et al. (2014). Two lagoon samples (day 1 and day 22) and three samples from each mesocosm (day 3, day 23, and the day where UCYN-C abundances were beginning to increase, i.e., days 11–15; see discussion below) were chosen for analysis. For each sample, triplicate PCR reactions were pooled. Internal primers were modified 5' common sequence (CS) linkers (CS1\_ *nifH1F*: 5'-ACACTGACGA CATG-GTTCTA CATGYGAYCC NAARGCNGA; CS2\_ *nifH2R*: 5'-TACGGTAGCA GAGACTTGGT CTADNGCCAT CATYTCNCC) to facilitate library preparation at the DNA Services (DNAS) Facility at the University of Illinois, Chicago, using the targeted amplicons sequencing (TAS) approach described in Green et al. (2015). These libraries were pooled with other libraries to achieve a target depth of ca. 40 000 sequences per sample. Sequencing of paired end reads was performed at the W.M. Keck Center for Comparative and Functional Genomics at the University of Illinois at Urbana-Champaign using Illumina MiSeq technology. De-multiplexed raw paired end reads were merged in the CLC Genomics workbench, and merged reads between 300 and 400 base pairs in length were selected. Quality filtering was performed in QIIME (Caporaso et al., 2010) using the *usearch* quality filter (*usearch\_qf*) pipeline script, which includes steps for denoising, de novo chimera removal using UCHIME (Edgar et al., 2011) and operational taxonomic unit (OTU) determination using *usearch6.1* at 97% nucleotide identity (Edgar, 2010). Representative nucleotide sequences from OTUs with greater than 100 reads (277 out of 2325 OTUs, representing 92% of all sequences that passed the *usearch* quality filter) were imported into ARB (Ludwig et al., 2004), translated into protein sequences, where non-*nifH* OTUs or those with frameshifts were discarded. QIIME script *exclude\_seqs\_by\_blast.py* was used to check for sequences with > 92% amino acid identity to known contaminants; none were found. OTUs targeted by each qPCR assay were determined in silico for each group of diazotrophs in ARB by identifying representative sequences that had zero to two mismatches in either primer or the probe binding region, without exceeding a total of four mismatches in all three regions (see Supplement Table S4).

For the characterization of the overall diazotroph community composition in the lagoon and mesocosms, representative sequences from the most highly recovered OTUs (109 OTUs representing 85% of all post quality-filtering sequences) were considered. Translated amino acid sequences were aligned to the existing amino acid alignment in the curated database. Maximum likelihood trees were calculated using translated amino acid sequences from representative sequences and their closest relatives (determined via *blastp*) in MEGA 6.06 (Tamura et al., 2013), using the JTT-matrix-based model and bootstrapped with 1000 replicate trees. Distribution of read data across samples for each representative sequence was visualized in the Interactive Tree of Life online tool (Letunic and Bork, 2006).

Raw reads (fastq files) were deposited into the National Center for Biotechnology Information (NCBI) Sequence Read Archive (SRA) under BioProject ID PRJNA300416 and BioSample accessions SAMN04202524–SAMN04202534.

### 2.4 PCR amplification of *Cyanothece*-like organisms

Partial *nifH* gene fragments (233 base pairs) from *Cyanothece*-like organisms were PCR amplified using primers designed as part of this study to broadly target the UCYN-C group, including cultivated *Cyanothece* spp., *Gleocapsa* spp., the cyanobionts of diatoms *E. turgida*, and *R. gibba*, as well as many closely related uncultivated *Cyanothece*-like ecotypes. The oligonucleotide primers *Cyanothece\_nifH\_F* (5'-CTT AGC AGC AGA ACG GGG AA-3') and *Cyanothece\_nifH\_R* (5'-GCA TTG CGA AAC CAC CAC AA-3') were designed using NCBI's Primer BLAST, screened in silico for cross reactivity to non-target *nifH* phylotypes in a curated *nifH* ARB database (Heller et al., 2014) and synthesized by Sigma Oligos (St. Louis, MO, USA).

Duplicate PCR reactions were carried out in 20  $\mu$ L volumes with 1X Platinum<sup>®</sup> Taq PCR buffer (Invitrogen, Carlsbad, CA), 3.0 mM MgCl<sub>2</sub>, 400  $\mu$ M dNTP mix, 0.2  $\mu$ M of each forward and reverse primers, 1 U Platinum<sup>®</sup> Taq polymerase (Invitrogen), and 2  $\mu$ L of DNA extract. Thermocycle parameters were as follows: the initial denaturation step at 94 °C for 5 min was followed by 30 cycles of 94 °C for 30 sec, 58 °C for 30 sec, and 72 °C for 30 sec and a final elongation step at 72 °C for 10 min. PCR amplicons were cleaned using the Qi-aQuick Gel Extraction Kit (Qiagen), and sequenced directly using Sanger technology at the UC Berkeley DNA Sequencing Center using *Cyanothece\_nifH\_R* to prime the sequencing reaction.

Raw sequences were processed using Sequencher 5.2.4 (Gene Codes Corporation, Ann Arbor, MI) and phylogenetic analyses were conducted in ARB (Ludwig et al., 2004), using a curated database of all *nifH* sequences available in Genbank (Heller et al., 2014) and in MEGA 6.06 (Tamura et al., 2013).

Sequences were submitted to NCBI's Genbank database under accession numbers KU160532–KU160537.

## 2.5 Statistical analyses

Pearson correlation coefficients were calculated for each paired variable, after transformation to assure normality, and samples collected from the incubations and the Noumea lagoon were treated independently. Tables S1 and S2 detail linear associations and transformations required for each variable inside and outside the mesocosms, respectively. Diazotroph abundance and physico-chemical environmental data were analyzed in R (Team, 2012). Biplot form principal component analysis was used to examine the temporal and spatial variation in environmental parameters. Correspondence analysis of the abundance data in each mesocosm separately was performed with the *ca* package (Nenadic and Greenacre, 2007). Biplots of sampling days (rows) and organisms (columns) were compared to examine reproducibility across mesocosms. Least squares regression models were calculated to fit and predict the effect of temperature, salinity, and PO<sub>4</sub> on diazotroph abundance.

## 3 Results and discussion

### 3.1 Diazotroph community structure in the VAHINE mesocosms experiment and in the Noumea lagoon

In order to (1) characterize the diazotroph community composition in the mesocosms and the lagoon using a qualitative approach that is complementary to qPCR and (2) evaluate whether the qPCR assays used in this study, which are widely used in studies of the oligotrophic ocean, target the major lineages of diazotrophs in the Noumea lagoon, fragments of the *nifH* gene were amplified from a subset of samples using a well-established nested PCR approach (Zehr and Turner, 2001) and sequenced using Illumina MiSeq technology.

In total, 636 848 paired end reads were recovered from 11 samples, and 544 209 passed the quality filtering steps described above (Table S4). Clustering at 97 % nucleotide identity yielded 2325 OTUs with greater than 4 reads, and 334 OTUs with greater than 100 reads. 277 of these OTUs (representing 479 402 reads or 88 % of all reads that passed quality filtering; Table S4) remained after removing non-*nifH* reads or those with frameshifts, and were used in downstream analyses. A majority of these 277 OTUs (152 OTUs, representing 311 550 reads, or 65 % of the reads selected for analysis) were affiliated with *nifH* cluster 1B Cyanobacteria. Reads affiliated with *nifH* cluster 1G, which is composed primarily of  $\gamma$ -proteobacterial phylotypes, was the second most highly recovered group (88 OTUs, representing 120 586 reads, or 25.2 % of the reads selected for analysis). Reads that were closely related to *nifH* cluster 1J/1K, comprised primarily of  $\alpha$ - and  $\beta$ -proteobacteria, were also recovered, but only comprised 8.4 % of the reads selected for analysis (19 OTUs,

**Table 1.** In silico qPCR coverage analysis. Taxonomic assignment for all *nifH* amplicons reads that passed the quality filtering steps (first column), and the number of OTUs affiliated with each group that are successfully targeted by qPCR assays used in this study. Rows in bold are pooled results for the entire *nifH* subgroup or group. Partial *nifH* sequences were classified according to the convention defined in Zehr et al. (2003). OTU – operational taxonomic unit.

	No. of OTUs (no. of sequences)	targeted by qPCR	
		No. of OTUs (no. of sequences)	% OTUs (% sequences)
<b>1B</b>	<b>152 (311550)</b>

\* 61 % (85 %) when a third mismatch at the 5' end (probe) is allowed.

40 032 reads). Cluster 3 and cluster 1O affiliated reads were recovered, but together accounted for less than 2 % of the reads selected for analysis (Table 1).

The two OTUs with the highest relative abundance (OTU1890 and OTU2317), accounted for 31 % of the reads selected for analysis and were closely related to the prymnesiophyte symbiont UCYN-A2 (Table S5). Both OTUs were present in the lagoon in day 1 and day 22 samples, and were recovered at high relative abundances from all three mesocosms throughout the experiment (Fig. 1). The third most highly recovered OTU (OTU1) was a  $\gamma$ -proteobacteria closely related to  $\gamma$ -24774A11, a heterotrophic diazotroph with widespread occurrence (Moisander et al., 2014; Langlois et al., 2015), that is also preferentially amplified by the *nifH* primers used (Turk et al., 2011). This sequence type was present in the lagoon samples, and had high relative abundances in all three mesocosms in midpoint samplings (days 11, 13, and 15 for M1, M2, and M3, respectively; Fig. 1). OTU2280 (cluster 1J/1K) was the OTU with the fourth highest relative abundance. It does not have high sequence similarity to any uncultivated or cultivated organisms, with the closest relative, an uncultivated rhizosphere isolate (Genbank accession no. KC667160), sharing only 86 % nucleotide sequence similarity. This is true for all but one of the 1J/1K OTUs, OTU119, which is closely related (98 % nucleotide identity) to an environmental sequence recovered from Heron Reef (Genbank accession no. EF175779).

Also among OTUs that had high recovery were UCYN-A1 (OTU2008, OTU1754, and OTU2), other UCYN-A2

**Figure 1.** Maximum likelihood tree calculated using partial *nifH* amino acid sequences recovered from the Noumea lagoon (NL) and mesocosms (M1, M2, and M3). Relative abundances of *nifH* reads associated with each operational taxonomic unit (OTU) are indicated for each sample by shaded boxes, with intense shading indicating high relative abundances, and light shading indicating low relative abundances. Trees were bootstrapped using 1000 replicate trees, and nodes with values > 50 are displayed. Branch lengths were inferred using the JTT model, and the scale bar indicates the number of substitutions per site. OTUs that are targeted by qPCR assays used in this study are marked with a black diamond (◆), and two UCYN-C sequences that are likely to amplify are marked with a circle (○). *nifH* cluster designations according to the convention in Zehr et al. (2003) are notated at the right. d1 – day 1; d11 – day 11; d13 – day 13; d15 – day 15; d22 – day 22; d23 – day 23.

OTUs (OTU2325, OTU1548, and OTU664), *Trichodesmium* (OTU5 and OTU35), UCYN-C (OTU12) and two OTUs affiliated with cluster 1G (OTU2218 and OTU2199) (Fig. 1 and Table S5). 1G OTUs are recovered from the lagoon sample at day 22, and have high relative abundances in all three mesocosms by the end of the experiment. These sequence types are not closely related to  $\gamma$ -24774A11, and thus are not quantified using qPCR assays in the study, and their quantitative importance in the mesocosm environment cannot be determined based on this qualitative measure. It is important to note that high relative abundances in PCR-based libraries is not indicative of high abundances, as often these sequence types dominate PCR libraries yet are present at low abundances in the environment (Hewson et al., 2007; Bonnet et al., 2013; Turk-Kubo et al., 2014; Shizoaki et al., 2014; Bentzon-Tilia et al., 2015), presumably as a result of preferential amplification (Turk et al., 2011).

A majority of the OTUs with high relative abundances (159 out of 277, representing 380 556 out of 479 402 reads) is affiliated with the following lineages targeted by qPCR assays used in this study: UCYN-A1, UCYN-A2, UCYN-B, UCYN-C, *Trichodesmium*, and *Richelia* associated with *Rhizosolenia* (Het-1), and  $\gamma$ -24774A11. To determine whether the qPCR assays used would target the diazotrophs present, representative sequences were identified that contained between zero and two mismatches in the primer and probe binding regions, without exceeding a total of four mismatches for all three regions. For UCYN-A, *Trichodesmium*, Het-1, and  $\gamma$ -24774A11 lineages, nearly all of the sequence types present met these criteria (between 97 and 100 %), and thus would be quantified in the qPCR assays (Table 1). Only 26 % of the recovered *Cyanothece*-like sequences would successfully be targeted by the UCYN-C assay; however, this coverage increases to 85 % when including two of the most highly recovered OTUs that have a third mismatch at the 5' end of the probe binding region, and thus are still likely to be quantified. Together with the results of UCYN-C specific PCRs (see Sect. 3.3 below), these results indicate that qPCR assays targeting UCYN-C likely quantified most of the phylotypes present, but absolute abundances may be underestimated.

A group of 32 OTUs clustered within the *Chroococcales* and were closely related to both *Crocospaera watsonii* 8501 (93–97 % amino acid identity) and *Cyanothece* sp. WH8904 (93–97 % amino acid identity). These OTUs were not targeted by the UCYN-B qPCR assay, with four to eight total mismatches in the primer/probe binding regions. So despite being considered putative *Crocospaera* sp. for the purpose of this study, it is possible that they are actually from a *Cyanothece*-like organism (not targeted by the UCYN-C qPCR assay) or another member of the *Chroococcales*. These OTUs were most highly recovered at the final sampling day (day 23) in M2 and M3, but were not recovered in the lagoon libraries.

The heterocyst-forming symbionts of diatoms are conspicuously underrepresented in these libraries, with only two

Het-1 OTUs recovered, despite being one of the most abundant diazotrophs measured in the lagoon and mesocosms (see discussion below). Furthermore, there were no *Richelia* associated with *Hemiaulus* (Het-2) or *Calothrix* associated with *Chaetoceros* (Het-3) sequences recovered despite being detected using qPCR assays. These findings lend further support to previous reports that this degenerate PCR assay does not work well for these phylotypes (Foster and Zehr, 2006). This underscores a major limitation of characterizing community composition using solely qualitative PCR techniques.

### 3.2 Most abundant diazotrophs in VAHINE mesocosms experiment shift from *Richelia* to *Cyanothece*-like ecotypes

During the VAHINE mesocosm experiment, three periods could be roughly defined based on the identity of the most abundant diazotroph and biogeochemical parameters (described in detail in Berthelot et al., 2015). A diazotroph community similar to the Noumea lagoon field community and low DIP concentrations characterized the period prior to the DIP spike (hereafter referred to as P0). The second period, days 5–14 (hereafter referred as P1), was characterized by high abundances of Het-1, high DIP availability, as well as moderate  $N_2$  fixation rates ( $10.1 \pm 1.3 \text{ nmol NL}^{-1} \text{ d}^{-1}$ ; Bonnet et al., 2015a). In the second half of the experiment, days 15–23 (hereafter referred as P2), the UCYN-C population grew to high abundances, and was characterized by low DIP availability, and high  $N_2$  fixation rates ( $27.3 \pm 1.0 \text{ nmol NL}^{-1} \text{ d}^{-1}$ ; Bonnet et al., 2015a), with rates reaching  $> 60 \text{ nmol NL}^{-1} \text{ d}^{-1}$ , ranking among the highest reported in marine waters (Luo et al., 2012).

At the initiation of the mesocosm experiment, the most abundant diazotrophs in the Noumea lagoon were Het-1 ( $3.1 \times 10^4 \text{ nifH copies L}^{-1}$ ), and *Richelia* associated with *Hemiaulus* (Het-2;  $1.2 \times 10^4 \text{ nifH copies L}^{-1}$ ), as well as the *B. bigelowii*-associated UCYN-A2 ( $1.5 \times 10^4 \text{ nifH copies L}^{-1}$ ) and UCYN-A1 ( $5.6 \times 10^3 \text{ nifH copies L}^{-1}$ ). *Trichodesmium* and the uncultivated unicellular cyanobacterial group C (UCYN-C) were present but at lower abundances,  $2.8 \times 10^3 \text{ nifH copies L}^{-1}$  and  $7.8 \times 10^2 \text{ nifH copies L}^{-1}$ , respectively.  $\gamma$ -24774A11 and *Calothrix* associated with *Chaetoceros* (Het-3) were also present but at abundances too low to quantify (DNQ), and no *Crocospaera* sp. (UCYN-B) could be detected (Table S3).

During P0, evidence of shifts from the original Noumea lagoon diazotroph assemblage could be observed in all three mesocosms (Fig. 2b–e). In M1, M2 and M3, Het-1 remained the most abundant diazotroph, and the relative proportions of Het-2 and UCYN-A1 were similar to those measured outside the mesocosms. However, UCYN-A2 abundances decreased and *Trichodesmium* abundances increased over this 3-day period with respect to their abundances in the lagoon. These changes were most pronounced in M3. As in the la-

goon, UCYN-C and  $\gamma$ -24774A11 were present at low abundances (ca.  $10^2$  *nifH* copies  $L^{-1}$ ) in the day 3 sampling.

Diazotroph assemblages within each mesocosm remained relatively consistent throughout the first thirteen days of the experiment, with Het-1 the most abundant diazotroph (Fig. 2b–d). However, a significant shift in community composition began about halfway through the 23-day experiment, evidenced by the increasing abundances of UCYN-C and Het-3, and decreasing abundances of Het-1 and UCYN-A1 (Figs. 2b–d and 3). Increasing UCYN-C abundances were first seen in M1 (day 11), then M2 (day 13), followed by M3 (day 15), which reflected the time in each mesocosm when the DIP turnover time dropped below  $1 d^{-1}$ , signaling DIP limitation (Berthelot et al., 2015; Moutin et al., 2005). In all three mesocosms, which acted as biological replicates, UCYN-C abundances were not only strongly correlated with the decreasing DIP concentrations ( $p = 0.004$ ,  $r = -0.51$ ), but also increasing temperatures in the mesocosms ( $p = 0.000$ ,  $r = +0.86$ ) and could be weakly correlated with increasing salinity ( $p = 0.000$ ,  $r = +0.56$ ), decreasing Het-1 ( $p = 0.002$ ,  $r = -0.54$ ), Het-2 ( $p = 0.01$ ,  $r = -0.37$ ) and UCYN-A1 ( $p = 0.000$ ,  $r = -0.64$ ) abundances. A similar correlation between UCYN-C abundance and both increasing salinity and temperature was observed outside in the Noumea lagoon (although UCYN-C abundances in the lagoon remained low; see Sect. 3.4). Salinity in each of the three mesocosms and in the lagoon did increase gradually during the experimental period, but were elevated inside the mesocosms in P2, likely due to evaporative loss (Bonnet, 2015). Together, this suggests that temperatures below  $25.6^\circ C$  are not optimal temperatures for this group, and that it may tolerate slightly elevated salinities better than other diazotrophs present. This is consistent with the warmer temperatures required for growth for the UCYN-C isolate TW3 (Taniuchi et al., 2012), and the occurrence of the UCYN-C group in low latitude, warm waters ( $> 28^\circ C$ ) in the tropical North Atlantic (Langlois et al., 2008). However, changes in temperature and salinity alone cannot explain the high abundances of UCYN-C in these mesocosms, as similar increases were recorded in the lagoon without a corresponding increase in UCYN-C abundances, and other diazotrophs also can grow optimally at these temperatures (e.g., *Crocospaera* sp. (Webb et al., 2009) and *Trichodesmium* sp.; Breitbart et al., 2007).

Het-3 was undetected in all mesocosms until day 7, and then remained at low abundances (usually below quantitation limits) until day fifteen of the incubation. After day 15, Het-3 abundances were on a similar order of magnitude to their abundances in the Noumea lagoon (ca.  $10^2$ – $10^3$  *nifH* copies  $L^{-1}$ ). Increases in Het-3 abundances after day 15 could be strongly correlated to increases in temperature ( $p = 0.000$ ,  $r = +0.82$ ) as well as salinity ( $p = 0.000$ ,  $r = +0.78$ ), total chl a ( $p = 0.000$ ,  $r = +0.71$ ), and UCYN-C abundances ( $p = 0.000$ ,  $r = +0.77$ ). Het-3 abundances could also be weakly corre-

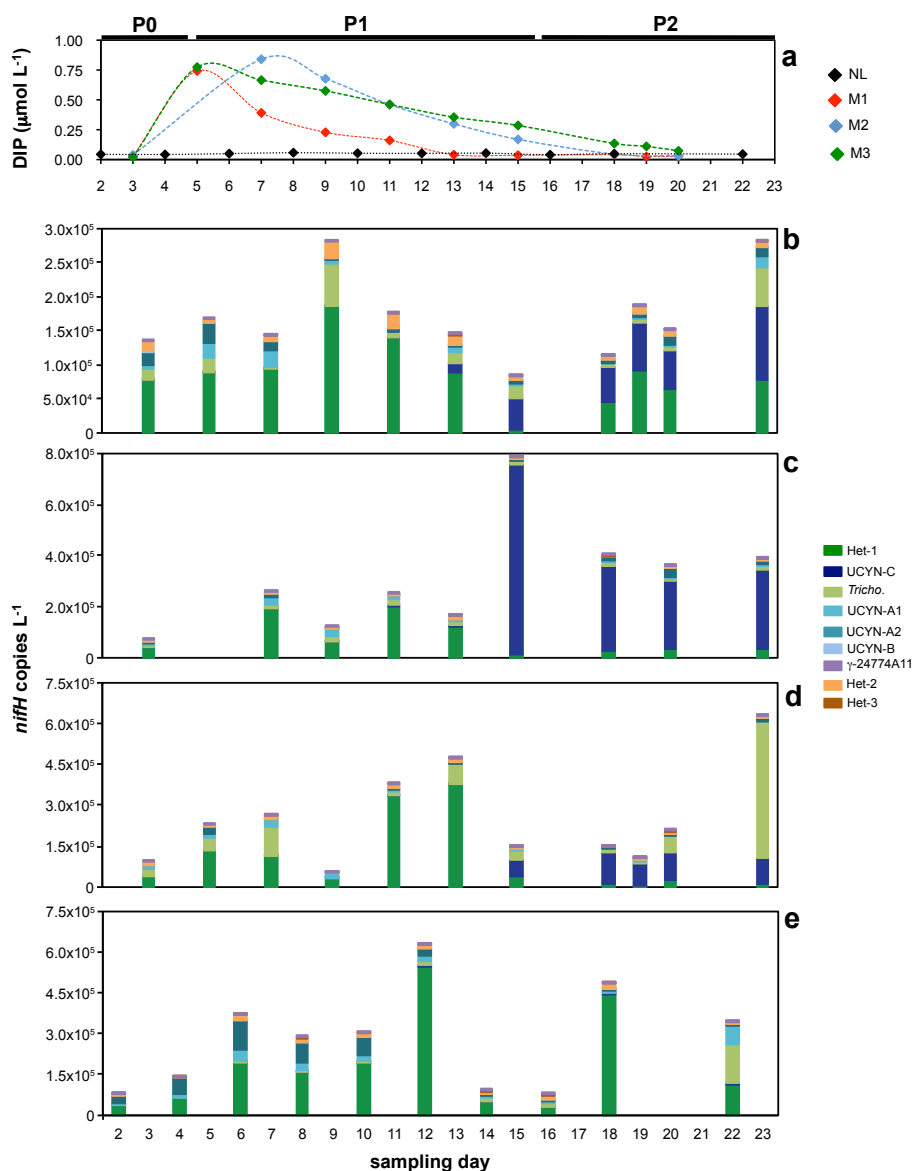

lated to increases in bulk  $N_2$  fixation rates ( $p = 0.01$ ,  $r = +0.49$ ), and decreases in  $PO_4$  concentrations ( $p = 0.003$ ,  $r = -0.54$ ), UCYN-A1 ( $p = 0.000$ ,  $r = -0.64$ ) and Het-1 ( $p = 0.03$ ,  $r = -0.38$ ) abundances. Het-3 abundances were never greater than  $5.8 \times 10^3$  *nifH* copies  $L^{-1}$ , however their distribution throughout the water column (Fig. S1) and their recovery in the sediment traps (Bonnet et al., 2015a) suggests that these diazotrophs are sinking out of the water column, and could possibly play a role in supplying fixed N to sediments in this shallow coastal system.

Both UCYN-A2 and UCYN-A1 abundances peaked early in the mesocosms, at days 5 and 7, respectively. UCYN-A2 abundances were not strongly correlated to any environmental factors, and were only weakly correlated to bulk  $N_2$  fixation rates ( $p = 0.008$ ,  $r = +0.49$ ) and  $N_2$  fixation rates associated with the  $< 10 \mu m$  size fraction ( $p = 0.045$ ,  $r = +0.38$ ). However, decreasing UCYN-A1 abundances could be strongly correlated to temperature increases ( $p = 0.000$ ,  $r = -0.75$ ), and decreasing  $PO_4$  concentrations ( $p = 0.000$ ,  $r = +0.69$ ). This implies that the *B. bigelowii*/UCYN-A1 association benefitted either directly or indirectly from the day 4 introduction of  $PO_4$  in the early part of the experiment. There is evidence that UCYN-A1 *nifH* transcription (a proxy for active  $N_2$  fixation) is limited by the availability of inorganic P (Turk-Kubo et al., 2012). UCYN-A1 is unable to directly utilize components of the dissolved organic phosphate (DOP) pool, such as phosphoesters and phosphonates (Tripp et al., 2010), but nothing is known about the capability of the *B. bigelowii* host to utilize DOP substrates. The correlation between UCYN-A1 abundances (thus assumed correlation between the symbiosis as a whole) and inorganic P concentrations in the VAHINE mesocosms provides further evidence that inorganic P may be the preferred P source for the *B. bigelowii* host.

Multiple regression models underscore the importance of a small number of environmental factors in the abundances of three of the diazotrophs targeted. The log abundances of UCYN-A1, UCYN-C and Het-3 in all three mesocosms and in the lagoon can be modeled well using only the temperature, salinity, and  $PO_4$  data, with  $R^2$  values between 0.77 and 0.85, and  $R^2$ -cv between 0.60 and 0.76 (Table 2), when the sample locations (M1–M3 and outside) are included as a variable. Although the three-predictor model provides the highest quality fit to the data, the goodness of prediction values ( $R^2$ -cv) are comparable between models that use all three predictors versus models using just T alone in the case of UCYN-A1 and UCYN-C, and just  $PO_4$  alone for all three diazotrophs (Table 2). These results from the linear regression model imply that the most important environmental factor best correlated with the dramatic increase in UCYN-C and Het-3 abundances was the decreasing concentration of  $PO_4$ .

Considering that UCYN-C maintained low population abundances in the Noumea lagoon during the time of the mesocosm experiment, despite changes in temperature and salinity that mirror changes in the mesocosms (Bonnet,

**Figure 2.** Abundances of targeted diazotrophs at the 6 m depth during the VAHINE mesocosm experiment and in the Noumea lagoon (NL) during the experimental period. Het-1 is the most abundant diazotroph in P0 and P1, while UCYN-C abundances become abundant during P2 in all three mesocosms, M1 (b), M2 (c), and M3 (d). In the NL (e), increasing abundances of UCYN-C during the experimental period are not observed. DIP concentrations (a) decreased steadily following the spike at day 4 (data from Bonnet, 2015).

2015), it follows that UCYN-C may have benefitted either indirectly from the DIP fertilization, or directly from a physical aspect of the mesocosms themselves. A biofilm had accumulated on the sides of the mesocosm bags, and although this was not sampled for molecular analysis, it is possible that the UCYN-C ecotype was a component of this biofilm community, and thus dependent on a physical environment not representative of water column conditions. Another explanation may be that the decreased turbulence in the mesocosm environment created favorable conditions for this ecotype. Finally, it is possible that the inverse cor-

relation between UCYN-C abundances and DIP concentrations may be a result of UCYN-C being able to outcompete other diazotrophs for organic P substrates, under low DIP conditions. *Cyanothece* sp. strains PCC 8801 and 8802 have genes used in phosphonate metabolism (Bandyopadhyay et al., 2011), which strongly implies that some strains are able to use this organic P substrate to meet cellular P requirements. The strain most closely related to the UCYN-C ecotype, *Cyanothece* sp. CCY0100, also has genes for phosphonate metabolism and transport (JGI website). It is evident that some component of the microbial community in the

**Figure 3.** Correspondence analysis biplot of diazotroph abundances for each mesocosm. The horizontal axis is representative of time, evidenced by the progression of time points projected onto the  $x$  axis. Variances covered by the two axes are 61 % + 18 % in M1, 88 % + 5 % in M2, and 56 % + 30 % in M3.

**Table 2.** Results from multiple regression models predicting diazotroph abundances from environmental parameters. Abundances from both the Noumea lagoon and the VAHINE mesocosms experiments are included in the linear regression models.  $R^2$ -cv is the cross-validated fit of the model, and when similar to the  $R^2$  value, indicates a high predictive ability for future data sets.

	Temp., sal. and PO <sub>4</sub>		Temp. and PO <sub>4</sub>		Temp.		PO <sub>4</sub>	
	$R^2$	$R^2$ -cv	$R^2$	$R^2$ -cv	$R^2$	$R^2$ -cv	$R^2$	$R^2$ -cv
UCYN-A1	0.85	0.76	0.84	0.76	0.70	0.59	0.73	0.63
UCYN-C	0.84	0.72	0.79	0.68	0.71	0.60	0.75	0.66
Het-3	0.77	0.60	0.70	0.57	0.55	0.39	0.70	0.60

mesocosms was utilizing DOP, as DOP stocks were drawn down to levels seen in the lagoon ( $0.105 \pm 0.011 \mu\text{mol L}^{-1}$ ) in the second half of the experiment (Berthelot et al., 2015), however, UCYN-C abundances could not be correlated to this drawdown (data not shown). *Trichodesmium erythraeum* IMS101 and *Calothrix rhizosoleniae* SC01 (Het-3) are the only two other diazotrophs targeted in this study known to possess the metabolic capability to utilize phosphonates (Dyhrman et al., 2006; Hilton et al., 2013). *Richelia* associated with *Hemiaulus* (Het-2) do not have any genes for the metabolism of phosphonates (Hilton et al., 2013), but it remains unclear whether the symbiont of *Rhizosolenia* (Het-1) is able to use phosphonates, as four genes related to phosphonate metabolism were identified in the genome (Hilton, 2014). However, as with UCYN-C, no correlations between DOP concentration and *Trichodesmium*, Het-1 or Het-3 abundances were seen (data not shown). This may be in part due to shortcomings in our understanding of the chemical composition of the DOP pool (Dyhrman et al., 2007), and which organic P compounds are bioavailable to which organisms.

### 3.3 Phylogenetic identity of diazotrophs targeted with UCYN-C qPCR assay

The UCYN-C qPCR assay used in this study was designed to target a *nifH* sequence type recovered from Amazon-

influenced waters in the tropical North Pacific (Foster et al., 2007). In addition to uncultivated sequences of marine origin, this assay also targets cultivated members of the UCYN-C group including *Cyanothece* sp. strains AT51142, AT51472, CCY 0110, as well as some freshwater cyanobacterial symbionts of diatoms (Fig. 4). Due to the importance of this group in the mesocosm experiment, and the uncertainty about exactly which organism(s) were targeted with the qPCR assay, PCR amplification of a partial *nifH* fragment was used to specifically characterize the identity of the *Cyanothece*-like organisms. Two closely related sequence types were recovered from 6 m samples on days 15 and 20, represented by 60341CB and 60343CB (Fig. 4), which shared 95 % nucleotide similarity. The *Cyanothece*-like sequences recovered from the mesocosms were most closely related to *Cyanothece* sp. CCY0100 (92–93 % nucleotide identity; Fig. 4), which was isolated from coastal waters in Chwaka Bay, Zanzibar. They shared only 90–91 % nucleotide identity with the sequences used to design the oceanic UCYN-C primer of Foster et al. (2007) and the UCYN-C isolate TW3 (Taniuchi et al., 2012). Thus the ecotypes that reached such high abundances in the mesocosms were more closely related to an ecotype reported in a coastal environment than those recovered from open water regimes.

It is important to note that the sequences amplified using this *Cyanothece*-specific PCR are targeted by the UCYN-C qPCR assay, and the phylotypes with three mismatches in the probe binding region were not recovered with this assay. This may be due to differences in primer efficiency, the number of amplification steps, and/or depth of sequencing, but these results lend further support to the assertion that important UCYN-C phylotypes were quantified with qPCR assays.

### 3.4 In situ net growth and mortality rates

The VAHINE mesocosm experiment provided a rare opportunity to repeatedly sample the same water mass for an extended period of time, and thus the ability to empirically determine in situ net growth or mortality rates for individ-

**Figure 4.** Maximum likelihood tree of *Cyanothecae*-like diazotrophs based on partial *nifH* nucleotide sequences. Sequences that are targeted by the UCYN-C qPCR assay (Foster et al., 2007) with no more than two mismatches in each primer and probe sequence are green, and the original sequence used for sequence design is marked with an asterisk (\*). *Cyanothecae*-like sequences recovered from the VAHINE mesocosms are bold. Bootstrap trees were calculated using 1000 replicate trees, and nodes with values > 50 are displayed. Branch lengths were inferred using the Tamura–Nei model, and the scale bar indicates the number of substitutions per site.

ual diazotroph phylotypes, based on the change in *nifH* gene copies  $L^{-1}$  between sampling days. Growth (and mortality) rates are critical input parameters for mathematical models of oceanic N budgets. Culture-based rates or estimates are often employed because there have been so few measurements of in situ rates from natural populations of diazotrophs, and some species such as UCYN-A remain uncultivated. However, due to the lack of competition and grazing in culture, these rates may be overestimated compared to in situ rates.

Surprisingly, maximum net growth rates for each diazotroph phylotype were among the highest reported for oceanic diazotrophic organisms (even when considering culture-based growth rates), yet showed substantial variability between mesocosms, both in terms of the absolute rates and the patterns of growth and mortality across time (Table 3). For example, maximum growth rates for UCYN-A2 ranged between 0.52 and 1.71  $d^{-1}$ , but occurred early in the experiment in M3 (day 5), in the middle of the experiment

in M2 (day 11) and at the end of the experiment in M1 (day 20). The two phylotypes with consistent timing of maximum growth rates across mesocosms were UCYN-C and Het-3. UCYN-C had the highest maximum growth rates of all phylotypes, which ranged between 1.23 and 2.16  $d^{-1}$  and occurred within a 4-day period (day 11–15) in all mesocosms. Het-3, which was virtually absent for the first half of the experiment in all three mesocosms, had maximum net growth rates between 0.57 and 1.09  $day^{-1}$  that occurred within a 5-day period (day 15–20) in all mesocosms.

Moisander et al. (2012) reported maximum net growth rates from nutrient amendment experiments conducted in the southwestern Pacific close to New Caledonia for UCYN-A1 (0.19  $d^{-1}$ ), UCYN-B (0.61  $d^{-1}$ ) and  $\gamma$ -24774A11 (0.52  $d^{-1}$ ). The maximum net growth rates calculated for these phylotypes during the VAHINE project were considerably higher, at 0.73, 1.38, and 1.07  $d^{-1}$  for UCYN-A1, UCYN-B and  $\gamma$ -24774A11, respectively. These results are unexpected considering that the rates determined by Moisander et al. (2012) were from a series of nutrient amendable incubations in 4.5 L bottles, where presumably favorable conditions for the growth of diazotrophs were present.

The maximum net growth rates determined in situ for UCYN-A2 and UCYN-C were among the highest measured at 1.71, and 2.16  $d^{-1}$ , respectively, and represent the only reported growth rates for these uncultivated diazotrophs. Very little is known about the newly described uncultivated *B. bigelowii*/UCYN-A2 association, but the difference between UCYN-A1 and UCYN-A2 net growth rates and their patterns within the same mesocosm indicate that the growth rates of each association are likely dependent upon different environmental variables. It also seems plausible, due to the difference in size between the two *B. bigelowii* hosts (Thompson et al., 2014), that they are grazed by different protists.

Experimental growth rates as high as 1.92  $d^{-1}$  have been reported for batch cultures of *Cyanothecae* sp. ATCC 51142 (Vu et al., 2012), and Taniuchi et al. (2012) measured rates up to 0.85  $d^{-1}$  in the presumably oligotrophic UCYN-C TW3 isolated from the Kuroshio Current. Thus, rates calculated for UCYN-C in the VAHINE mesocosms experiment are similar in magnitude. However, such high rates in culture are a direct result of the lack of competition with other organisms for nutrients important for growth and the lack of grazing pressure. Despite high growth rates in culture, TW3 is found at low abundances in the Kuroshio Current, presumably due to these factors (Taniuchi et al., 2012). Although the factors behind such high growth rates for UCYN-C in the mesocosms are not clear, it is possible that UCYN-C was free from significant grazing in these experiments.

Maximum net growth rates for the filamentous diazotrophs were also generally higher than previously reported growth rates. *Trichodesmium* sp. maximum net growth rates for were as high as 1.46  $\pm$  0.05 (M1) and 1.55  $\pm$  0.02  $d^{-1}$  (M3), and microscopic analyses indicated (data not shown) that both *T. erythraeum* and *T. thiebautii* were present in the

**Table 3.** Diazotroph net growth and mortality rates ( $\text{d}^{-1}$ ) during the VAHINE mesocosms experiment. Rates in bold are the maximum rates measured in each mesocosm. “–” denotes periods where no rates could be calculated due to missing data, and “na” denotes missing rates due to abundances being “detected, not quantified” (DNQ) or undetected (UD). Standard error ( $\pm$ ) reported for each growth rate is derived from qPCR measurements for replicate amplifications.

mesocosms, the former being the dominant *Trichodesmium* species. These calculated rates are much higher than the specific growth rate previously reported for cultures of *T. erythraeum* ( $0.29 \pm 0.04 \text{ d}^{-1}$ ; Hutchins et al., 2007) and net growth rates for *T. thiebautii* populations in the Noumea lagoon ( $0.11\text{--}0.38 \text{ d}^{-1}$ ; Rodier and Le Borgne, 2008). Maximum growth rates for the DDAs Het-1, Het-2, and Het-3 were 1.28, 2.24, and  $1.09 \text{ d}^{-1}$ , respectively. Although these are the first reported growth rates for these DDAs determined using in situ cellular abundances, Foster et al. (2011) determined maximum net growth rates to be much lower when using nanoSIMS-based techniques to quantify  $^{15}\text{N}$  incorporation in biomass, which is to be expected if the DDAs are using other N sources (e.g., dissolved organic N and/or recycled N) in addition to fixing N.

For many diazotrophs, the pattern of net growth and mortality rates indicated a very dynamic process that appeared specific to each mesocosm. Most diazotrophs experienced multiple transitions between net growth and net mortality within a single mesocosm throughout the 23-day incubation (Table 3). For example, in M1, net growth rates for *Trichodesmium* were observed approximately every other sam-

pling period (on days 9, 13, 15, 19, and 23), and in some intervening periods experienced mortality rates similar in magnitude to growth rates (e.g., days 7 and 11). In contrast, net growth occurred on days 7, 11, 13, 20, and 23 in M3, and one of the largest net mortality rates was measured at day 9 ( $-2.16 \pm 0.18 \text{ d}^{-1}$ ). There are no aspects of the experimental design that can be invoked to explain this variability; in fact biogeochemical parameters and picoplankton population dynamics were well replicated in all three mesocosms (Bonnet, 2015). Therefore the dynamic nature of diazotroph growth and mortality rates in each mesocosm most likely results from a combination of grazing pressure and viral lysis, which can be expected to reflect natural variations in the grazers and virus present.

### 3.5 Symbiotic *Richelia* and UCYN-A ecotypes are abundant in the Noumea lagoon during the VAHINE mesocosms experiment

The VAHINE mesocosm experiment provided an additional opportunity to characterize the abundances of targeted diazotrophs in the Noumea lagoon using quantita-

tive techniques. As described above, the diazotroph assemblage at the onset of the VAHINE mesocosms experiment was dominated by Het-1, Het-2, UCYN-A2 and UCYN-A1 (see Sect. 3.1). Het-1 remained the most abundant of the targeted diazotrophs for most of the sampling days ( $3.1 \times 10^4$ – $5.5 \times 10^5$  *nifH* copies L<sup>-1</sup>) during the period of study (Fig. 2e, Table S3). Het-2 abundances were consistently lower than Het-1, and variable throughout the period of study, ranging between  $4.0 \times 10^3$  and  $1.6 \times 10^4$  *nifH* copies L<sup>-1</sup>, and reaching peak abundances on day 10 and again on day 18 (Table S3). Bonnet et al. (2015a) discusses the BNF rates in detail; however, it should be noted that in the lagoon, only Het-2 abundances had a significantly strong positive correlation with bulk N<sub>2</sub> fixation rates ( $p = 0.01$ ,  $r = +0.78$ ).

Although *Richelia* living in association with *Rhizosolenia* (Het-1) and *Hemiaulus* (Het-2) are known to be widely distributed and potentially significant N<sub>2</sub> fixers in oligotrophic oceans (Carpenter et al., 1999; Subramaniam et al., 2008; Karl et al., 2012), reports of their presence in coastal waters in the southwestern Pacific are rare, and previous studies during the austral summer in the Noumea lagoon reported very low abundances of heterocystous symbionts (Rodier and Le Borgne, 2010; Biegala and Raimbault, 2008). This is the first report on quantitative abundances of *Richelia* in the Noumea lagoon, which are comparable to abundances reported from the tropical North Atlantic (Foster et al., 2007; Goebel et al., 2010) and the North Pacific Subtropical Gyre (Church et al., 2008; Foster and Zehr, 2006), where the DDAs are thought to have a significant impact on C sequestration due to their productivity and rapid sinking (Subramaniam et al., 2008; Karl et al., 2012; Villareal et al., 2012), and may play a role in supporting the benthic community (Houlbreque and Ferrier-Pagès, 2009).

UCYN-A2 was the second most abundant member of the targeted diazotrophic assemblage in the lagoon for the first 10 days of the experiment (Fig. 2e), and was present at abundances as high as  $1.1 \times 10^5$  *nifH* copies L<sup>-1</sup> (day 6; Table S3). UCYN-A2 abundances declined steadily throughout the period of the 23-day experiment ( $p = 0.04$ ,  $r = -0.63$ ), and had a significantly strong negative correlation with sea temperature ( $p = 0.003$ ,  $r = -0.82$ ) and salinity ( $p = 0.03$ ,  $r = -0.89$ ), both of which were increasing in the Noumea lagoon throughout the VAHINE deployment (Bonnet, 2015). UCYN-A1 abundances were consistently lower than those of UCYN-A2, ranging between  $2.8 \times 10^3$  and  $6.4 \times 10^4$  *nifH* copies L<sup>-1</sup> with peaks in abundance at day 6 and again at day 22 (Table S3). Interestingly, UCYN-A1 abundances had a significant positive correlation with total chl *a* in the >10 μm size fraction ( $p = 0.03$ ,  $r = +0.72$ ). The significant inverse relationship between UCYN-A2 abundances and water temperatures in the Noumea lagoon suggests that the *B. bigelowii*/UCYN-A2 association may thrive at lower temperatures than other diazotrophs (e.g.,

*Trichodesmium*), similar to the *B. bigelowii*/UCYN-A1 association (Moisander et al., 2010).

The coexistence of the *B. bigelowii*/UCYN-A1 and *B. bigelowii*/UCYN-A2 ecotypes in the Noumea lagoon, both present at reasonably high abundances, indicates that the ecological niches of these cryptic symbioses overlap. Very little information currently exists about the ratio of UCYN-A1 to UCYN-A2 in tropical oligotroph oceanic regimes, but UCYN-A1 is typically found at higher relative abundances (as inferred from clone-library based studies; Thompson et al., 2014) in oligotrophic regions. The Noumea lagoon is the first location where the co-occurrence of each ecotype has been verified using quantitative techniques, but it must be noted that the difference in abundances may be a result of the number of UCYN-A2 cells associated with each *B. bigelowii* host, which has been reported to be as high as 11 : 1 (Thompson et al., 2014).

*Trichodesmium* spp. have been routinely observed in the Noumea lagoon using satellite observations (e.g., Dupouy et al., 2000, 2011) and direct field measurements (Renaud et al., 2005; Masotti et al., 2007; Rodier and Le Borgne, 2008, 2010). Conspicuous blooms that occur in the austral spring and summer months have been associated with warm sea surface temperatures (>26 °C) and recent NO<sub>3</sub><sup>-</sup> and soluble reactive P (SRP) enrichments in the lagoon (Rodier and Le Borgne, 2008). Although *Trichodesmium* was present at relatively low abundances during the first 8 days of the experiment ( $3.4 \times 10^2$ – $6.5 \times 10^3$  *nifH* copies L<sup>-1</sup>; Table S3), abundances increased steadily throughout the experiment ( $p = 0.01$ ,  $r = +0.73$ ). *Trichodesmium* reached peak abundances of  $1.4 \times 10^5$  *nifH* copies L<sup>-1</sup> on the final sampling day (day 22; Fig. 2e). The only environmental parameter with which changes in *Trichodesmium* abundances could be strongly correlated was NH<sub>4</sub><sup>+</sup> ( $p = 0.02$ ,  $r = +0.81$ ).

The UCYN-C group comprised a minor part of the Noumea lagoon diazotroph community, and was detected at abundances between  $3.2 \times 10^2$  and  $4.8 \times 10^3$  *nifH* copies L<sup>-1</sup> (Table S3) during the experimental period. However, UCYN-C abundances did show a linear increase over the duration of the experiment ( $p = 0.01$ ,  $r = +0.74$ ), and significant positive correlations with changes in salinity ( $p = 0.02$ ,  $r = +0.80$ ), and NH<sub>4</sub><sup>+</sup> ( $p = 0.03$ ,  $r = +0.76$ ). The unicellular UCYN-C group was first described when *nifH* sequences with 90 % nucleotide identity to the cultivated *Cyanothece* sp. PCC 51142 were recovered from surface waters in the tropical North Atlantic (Langlois et al., 2005; Foster et al., 2007). This phylotype has rarely been quantified in the oligotrophic ocean, and when present, abundances are low (Foster et al., 2007; Langlois et al., 2008; Needoba et al., 2007; Goebel et al., 2010; Ratten et al., 2014); therefore, very little is known about its distribution or importance. The qPCR assay used in this study (Foster et al., 2007) amplifies not only the uncultivated Atlantic phylotype, but also many cultivated *Cyanothece*- and *Gloeothece*-like isolates, which are ex-

pected to be present in an environment like the Noumea lagoon, as *Cyanothece*- and *Gloeothece*-like organisms have been reported in shallow marine sediments (Hunter et al., 2006; Bauer et al., 2008) and intertidal sands (Reddy et al., 1993; Ohki et al., 2008).

$\gamma$  – 24774A11 was also consistently detected at low abundances (ca.  $10^2$ – $10^3$  *nifH* copies  $L^{-1}$ ; Table S3), which increased throughout the duration of the experiment ( $p = 0.03$ ,  $r = +0.65$ ). Despite being the most widely studied marine heterotrophic diazotroph, very little is known about this phylotype. Recent studies suggest that this  $\gamma$ -proteobacterial diazotroph is likely to be free-living and may be able to survive in a broad range of environmental conditions, as evidenced by low but uniform abundances throughout the photic zone in the South Pacific (Moisander et al., 2014).

The epiphytic *Chaetoceros* symbiont, *Calothrix* (Het-3), was also consistently detected at low abundances (ca.  $10^2$ – $10^3$  *nifH* copies  $L^{-1}$ ; Table S3). *Chaetoceros* can often be found as part of the neritic diatom assemblage; therefore, this association is generally observed in coastal or coastal transition zone regions (Gómez et al., 2005). This is the first report of Het-3 in the coastal oligotrophic waters surrounding New Caledonia.

*Crocospaera* sp. (UCYN-B), previously reported to be members of the unicellular diazotroph community in the Noumea lagoon (Biegala and Raimbault, 2008), were not initially detected, but were present at low abundances that increased over the 23-day period ( $p = 0.04$ ,  $r = +0.63$ ) to abundances as high as  $2.7 \times 10^3$  *nifH* copies  $L^{-1}$ , and had a significant strong correlation with total chl *a* ( $p = 0.02$ ,  $r = +0.81$ ). It must be noted that the *Crocospaera*-like sequences that were recovered from the mesocosm libraries would not likely amplify efficiently with the qPCR assay used. Therefore, it is not clear whether these abundances included a *Crocospaera* population not recovered in the PCR-based *nifH* libraries, or were in part the result of cross-reactivity with the *Crocospaera*-like population that were amplified from mesocosm samples during P1 and P2, and possibly present in the lagoon as well.

#### 4 Conclusions

The VAHINE mesocosm experiment was conducted to trace the incorporation of  $N_2$  fixed by diazotrophs into the food web (Bonnet, 2015). Despite a lack of sampling replication within each mesocosm, consistent patterns in both the relative abundances of targeted diazotrophic phylotypes, as well as shifts in diazotrophic community composition, were reproducibly seen in all three mesocosms. Although the timing of the increases was specific to an individual mesocosm, UCYN-C and Het-3 abundances increased over time, while UCYN-A1 and Het-1 abundances decreased over time in all three mesocosms (Fig. 3). The experimental conditions selected for the growth of UCYN-C during P2, an ecotype

never before quantified at high abundances in the marine water column, which enabled the calculation of growth rates of this uncultivated ecotype, and provided insight into its dynamics with respect to environmental parameters. Although the data strongly suggest that the drawdown of DIP provided an environment favorable for high UCYN-C growth rates, further studies are required to better understand the environmental conditions that stimulated this bloom, and whether such blooms are seen in the Noumea lagoon itself.

The experimental setup provided a rare opportunity to calculate in situ net growth rates for natural populations of diazotrophs, including the uncultivated UCYN-A. This study provided the first growth rates for the UCYN-C phylotype and for UCYN-A2, both of which were surprisingly high, implying not only favorable conditions, but also a lack of grazing pressure. Maximum net growth rates were high for all diazotroph ecotypes, but most also experienced intermittent periods of growth and mortality within the 23-day experiment, which was also an unexpected finding. Along with net rates recently reported by Moisander et al. (2012), we anticipate that these data will be important for future modeling efforts.

The analysis of the diazotroph assemblage outside the mesocosms represents both the first quantitative data on targeted diazotroph phylotypes, as well as the first *nifH*-based diversity libraries on the populations in the Noumea lagoon. Not previously considered to be a significant diazotrophs in this region, DDAs must now be considered a potentially important contributor to BNF in these waters, especially in the austral summer. Although the presence of UCYN-A in the lagoon has long been suspected due to the relative importance of daytime nitrogen fixation in the small size fraction (Biegala and Raimbault, 2008), we report the first quantitative data on UCYN-A abundances in the Noumea lagoon. Furthermore, the co-occurrence of the two UCYN-A ecotypes revealed in this study provides an important insight into the overlap in environmental niches for these two ecotypes.

**The Supplement related to this article is available online at doi:10.5194/bg-12-7435-2015-supplement.**

*Author contributions.* S. Bonnet designed and executed the experiments, and S. Bonnet and A. Desnues sampled the experiments for molecular analyses. M. E. Hogan extracted DNA samples, and K. A. Turk-Kubo conducted all qPCR and PCR analysis and analyzed the data. I. E. Frank performed statistical analyses. K. A. Turk-Kubo and J. P. Zehr prepared the manuscript with input from all co-authors.

*Acknowledgements.* Funding for this research was provided by the Agence Nationale de la Recherche (ANR starting grant VAHINE

ANR-13-JS06-0002), the INSU-LEFE-CYBER program, GOPS and IRD. The authors thank the captain and crew of the R/V *Alis*. We also thank the SEOH divers service from Noumea, as well as the technical support and the divers of the IRD research center of Noumea. We gratefully acknowledge C. Guieu, J.-M. Grisoni and F. Louis for the mesocosm design and their useful advice. We would also like to thank five anonymous reviewers for their time and critiques. The molecular component of this work was funded by a Gordon and Betty Moore Foundation Marine Investigator award (JPZ) and the National Science Foundation Science Center for Microbial Oceanography Research and Education (C-MORE, grant no. EF-0424599).
