**Abstract** – A total of 212 carnivorous coastal fish species from New Caledonia, represented by 7335 individuals, were analysed for their diet. Fifty two prey items were identified and later grouped into broader taxonomic categories referred as “prey types”. For each fish species 6 biological traits were defined: maximum adult size, major biotope, schooling behaviour, home range, nycthemeral behaviour, degree of crypticity. A general linear model was fit to the diet data taking into account these traits, and depth of capture and fish family. This model was applied to the average number of prey types/stomach and to the volume of 5 prey types: nekton, crustaceans, molluscs, echinoderms, worms. A second analysis was performed on the effect of observed size on diet composition, taking into account these traits and taxonomy. This analysis was restricted to species with at least five individuals, representing 113 species from 33 families. More detailed information is given for the three major families, Serranidae, Lutjanidae and Lethrinidae and intra-family variations are illustrated for Lethrinidae. All the factors tested had significant effects on diet, fish size and taxonomy being the two major factors. The five prey types analysed in detail displayed marked differences according to the factors studied. In particular nekton increased in importance with fish size, whereas crustaceans decreased and molluscs presented a dome shaped relationship. Nekton and crustaceans made the bulk of the diet of most species, with molluscs being at times important. Echinoderms and worms were never a major food item and were eaten only by a restricted range of species.

**Key words:** Coral reefs / Fish diet / Trophic level / Indian Ocean

**R sum ** – R gime alimentaire de poissons carnivores des r cifs coralliens de Nouvelle Cal donie. Un ensemble de 212 esp ces de poissons carnivores c tiers de Nouvelle Cal donie, repr sent es par 7335 sp cimens, ont  t  analys s pour  tudier leur r gime alimentaire. Cinquante-deux types de proies ont  t  identifi es et regroup es par la suite dans des cat gories plus vastes ou « type de proies ». Pour chaque esp ce, six caract ristiques biologiques ont  t  d finies : taille adulte maximale, principal biotope, gr garit , domaine vital, comportement nycth m ral, niveau de crypticit . Un mod le lin aire g n ral a  t  ajust    ces donn es, en prenant en compte ces caract ristiques ainsi que la profondeur de capture et la famille. Ce mod le est appliqu  au nombre moyen de proies par estomac ainsi qu'au volume de cinq types de proies : necton, crustac s, mollusques,  chinodermes et vers. Une seconde analyse porte sur les effets de la taille observ e sur la composition de l'alimentation, prenant en compte ces caract ristiques vitales et la taxonomie ; cette analyse est restreinte aux esp ces comportant au moins 5 sp cimens, ce qui repr sente 113 esp ces provenant de 33 familles. Une information plus d taill e est fournie pour les trois familles principales : Serranidae, Lutjanidae et Lethrinidae et les variations au sein d'une m me famille sont illustr es pour les Lethrinidae. Tous les facteurs test s ont un effet significatif sur l'alimentation ; la taille et la taxonomie  tant les deux facteurs principaux. Les cinq types de proies analys s en d tail pr sentent des diff rences importantes en fonction des facteurs  tudi s. En particulier, le necton augmente en importance avec la taille des poissons, alors que les crustac s ont une tendance inverse, et les mollusques pr sentent une courbe en cloche. Necton et crustac s constituent l'essentiel des proies pour la plupart des esp ces, les mollusques  tant parfois importants. Les  chinodermes et les vers ne constituent jamais un aliment majeur et ne sont consomm s que par un nombre restreint d'esp ces.

## 1 Introduction

The functioning of fish assemblages depends in great part on the trophic status of the species within the assemblages. The diet of most fishes will change with a number of factors, either intrinsic (e.g. size, behaviour, taxonomy) or extrinsic (e.g. biotope, region). Information on the diet of fishes is important to understand the basic functioning of fish assemblages and is widely used for ecological work and modelling and is becoming an increasingly important component in ecologically based management. The downward shift of the trophic composition of the catch world wide, which was formerly dominated by large carnivorous species (Pauly et al. 1998), has also attracted attention towards the trophic status of species. In areas with very high fish diversity, such as the South Pacific which hosts over 2000 species of coastal fishes, the level of the information on the diets of fishes is often low and difficult to access.

The present article intends to yield information on the diet of large carnivorous fish species of New Caledonia, with attention drawn on some of the major factors affecting these diets. Despite the descriptive nature of this information, we feel it will be useful because:

- 1- Most coastal fish species have a very wide geographical range in the Indo-Pacific, e.g. more than 50% of the species observed in New Caledonia are found from the Reunion island (western Indian Ocean) all the way to Polynesia (central Pacific), spanning over 15 000 km (Letourneur et al. 1997). This applies in particular to the large carnivorous species which are dominated by a restricted number of families, four of them making the bulk of the commercial catch: Lethrinidae, Lutjanidae, Serranidae and Carangidae. These four families have a very low endemism and all the species found in New Caledonia occur in most of the South Pacific islands (Carpenter and Niem 2000).
- 2- In the tropical Pacific, the diversity of shallow water fish communities is dominated by carnivorous species, the relative importance of this trophic category increasing significantly (Kulbicki et al. 2004) from West (Great Barrier Reef) to East (Polynesia). More specifically, in the lagoon of New Caledonia carnivores dominate soft-bottoms (Wantiez 1994), algae and sea-grass beds (Rossier and Kulbicki 2000), mangroves (Thollot et al. 1999) and are dominant on reefs in terms of diversity and biomass (Kulbicki 1997).
- 3- Diet information for these carnivorous reef fish species is found in an array of articles, but usually the number of specimens analysed remains low for each species, and most of this literature is difficult to obtain and often old (based on a review of 286 articles on the diet of reef fishes, some of the most informative literature on this matter is: Hiatt and Strasburg 1960; Hobson 1974; Harmelin-Vivien 1979; Blaber 1980; Randall 1980; Sano et al. 1984; Norris 1985; Parrish 1987; Abu Khair et al. 1990; Salini et al. 1994; Blaber et al. 1990; Nakamura et al. 2003). This study covers a wide spectrum of species, as diet information could be retrieved for 7335 carnivorous fish representing 212 species
- 4- Most species display some plasticity in their diet, fish being rather opportunistic feeders (e.g. Walker 1978;

Harmelin-Vivien 1981; Harmelin-Vivien et al. 1989; Salini et al. 1994). Many factors play a role in this plasticity, such as size (e.g. Harmelin-Vivien et al. 1989; Kingsford 1992), season (e.g. Kingsford 1992; Salini et al. 1994) or region (Shpigel and Fishelson 1989). However, many other factors play a role and most have been so far poorly documented. The present article intends to investigate the effects of some intrinsic factors (size, schooling behaviour, home range, nycthemeral activity, crypticity and taxonomy) and extrinsic factors (biotope and depth).

- 5- Detailed diet information is useful to tropho-dynamic models (Cury et al. 2002; Pauly et al. 2002), to estimate trophic levels (Froese and Pauly 2000; Stergiou and Karpouzi 2002) which may enter in the composition of ecosystem indicators (Pauly et al. 1998 2001; Pinnegar et al. 2002; Laurans et al. 2004; Bozec et al. 2005; Gascuel et al. 2005).

## 2 Material and methods

### 2.1 Study area and fish collections

All the fish studied were caught in four areas of New Caledonia (Fig. 1): Chesterfield Islands, Uvea Atoll, the South-west lagoon (South Province) and the East, West and North lagoons (North Province). The study areas cover various biota (coral reefs, lagoonal sandy areas, soft-bottoms, bays, estuaries, mangroves). Fish were caught during several scientific and monitoring programs led by IRD between 1985 and 1997. A wide array of methods was used to catch these fish (hand lines, longlines, trawls, gill nets, rotenone). The weight and length were recorded for each specimen. Fish length was taken as fork length, except for species with a rounded tail for which total length was measured. Fish were usually examined fresh but in some cases, when dissection in the field could not be performed, the fish were frozen or preserved in alcohol for later study.

### 2.2 Stomach analysis

Each prey item was identified to the genus, family or order level. This resulted in a total of 52 prey items which were later allocated to broader taxonomic groups, hereafter referred to as prey types. The percentage volumetric contribution (%V) made by each prey type to the total volume of the stomach contents was estimated for each individual. Only the four most important prey types (in %V) in a stomach were noted, as in most cases, this allowed to include all the stomach content.

### 2.3 Data analysis

Many factors play a role in the diet of these carnivorous fishes. These factors are not independent, and it would be rapidly tedious to analyse each factor separately. For this reason, we first performed a general analysis in which as many factors as possible were analysed in the same statistical model, then we focused on two major aspects: size and taxonomy.

Fig. 1. Location of the major sampling areas of this study (extracted from Reef Base).

2.3.1 General model

Six characteristics were attributed to each species: its maximum adult size, its major biotope, its schooling behaviour, its degree of crypticity, its home range type and its nycthemeral behaviour. Adult size is the largest size known to occur in New Caledonia. Only four biotopes were kept: reef, soft bottom, near shore (mangroves, estuaries and coastal areas) and pelagic. Species were attributed several biotopes if needed (e.g. most Lethrinidae frequent both reef and soft bottom). Depth of catch was also taken into account. Species were distributed amongst five schooling types: solitary, paired, small schools (2–20 fish on average), medium size schools (20–50 fish), large schools (>50 fish). Species were classified as very cryptic, cryptic or non cryptic. Species were classified as having a small, medium or large home range. Species were also classified as either diurnal, nocturnal or constantly active. Prey types were restricted to 10 categories (Table 1).

To determine which factors were significant on the types or numbers of prey, a multiple regression was performed. The dependent variable was either prey volume or number of prey types averaged per species (volume or numbers per fish would have biased results in favor of the most sampled species). The independent variables were family, biotope, depth, adult size, crypticity and schooling behaviour. As families were coded qualitatively and biotopes, crypticity, nycthemeral activity and schooling behaviour were coded as present/absent, a GLM procedure was chosen to perform the analyses (Muller and Fetterman 2003). Interactions between factors were not included in the model as there were too many empty cells. The models may be written as follows:

$$\text{Prey volume (or Number of prey types)} = a_0 + a_1 \text{ Depth} + a_2 \text{ Biotope} + a_3 \text{ Family} + a_4 \text{ Size (adult)} + a_5 \text{ SchoolSize} + a_6 \text{ HomeRange} + a_7 \text{ DielActivity} + a_8 \text{ Crypticity} + \epsilon.$$

Table 1. Prey groups definition for the size-based analysis (6 prey groups) the taxonomy-based analysis (10 prey groups).

Size-based analysis	General model and Taxonomy-based analyses	Major Components

2.3.2 Size-based (observed size) analysis of fish diets

Size-related changes in the diet compositions were analysed, using a limited number of size classes, in order to

**Table 2.** Average diet of carnivorous Caledonian reef fishes, expressed as mean percentages of the relative volume occupied by 10 prey types in the fish diets. <sup>(1)</sup> Squids/cuttlefish, <sup>(2)</sup> planktonic crustaceans, <sup>(3)</sup> octopi, <sup>(4)</sup> nudibranchs, <sup>(5)</sup> sponges, <sup>(6)</sup> corals.

produce a sufficient number of dietary samples. Hence, body size of each fish specimen was rounded up or down to the nearest 10 cm (e.g. 35–44 cm became 40 cm), except for fishes greater than 70 cm which were grouped into the 70-cm class.

In a first step, prey types were grouped into 6 major categories (Table 1). Then, the mean volumetric contribution (%V) of these 6 prey categories to the total stomach content was calculated for each species for all size classes. Only species, with at least five stomach contents, were selected in a given size class. In a second step, a mean diet composition was estimated for each size class by averaging all species within the size class.

The same approach was adopted for the three most sampled fish families, i.e., Lethrinidae, Lutjanidae and Serranidae, which diet compositions were first averaged by species, and then averaged by size class.

To analyse the effects of observed size on prey volume  $V$ , a linear model taking into account species and observed size groups was performed according to the model:

$$V = a_0 + a_1 \text{ Species} + a_2 \text{ Size} + \varepsilon.$$

### 2.3.3 Taxonomical analysis

Fish species represented by five or more stomach contents were selected for the taxonomy-based analysis at the species level. First, prey types were grouped into 10 major prey types (Table 1). The diet composition was then estimated for each species as the mean percentage volumetric contribution for each of these 10 prey types.

In a second step, the diet compositions of several fish families were estimated by averaging the mean diet of the various species in a family, in order to avoid biased results due to the most sampled species. Only fish families with three or more species were selected.

## 3 Results

In our data base, 7335 specimens of carnivorous species had a full stomach. This represented 212 species. The analysis of fish species represented by five or more stomach contents resulted in a mean diet composition for 113 species from 33 families which is presented in Appendix I. The mean diet composition for the selected fish families (three or more species) is presented in Table 2.

### 3.1 General model

All the factors included in the model had a significant effect on either the number of prey types or on the volume of these prey types (Table 3).

#### 3.1.1 Number of prey types

The only set of factor which had no significant effect on the number of prey types was crypticity (Table 3).

There is an increase in the number of prey types as one goes from the least complex biotope (pelagic) to the most complex (reef). There is a slight increase in the number of prey types with home range, mobile species having more prey types than sedentary ones. The number of prey types tends to decrease with school size, however, solitary species have also low number of prey types. Species which are active at night have larger numbers of prey types (Table 4).

#### 3.1.2 Prey volumes

##### General

The most important prey items were in decreasing order fish, crabs, shrimps, bivalves, and worms (Table 4), these five

items making 76.3% in occurrence and 82.5% in volume of all prey. Some food items are probably not eaten intentionally by carnivorous fishes. This could be the case of algae, coral and sponges. These items could be absorbed accidentally when a fish catches a prey living on these items. However, algae are mainly eaten by the smallest fish (Appendix II) which could be an indication that algae are actively eaten by some small specimens of otherwise carnivorous species.

### Biotope

There are some major differences in prey types according to biotope (Table 4). The relative importance of nekton in the diet is very significantly affected by biotope type (Table 3) except for the pelagic biotope. Nekton follows a strong gradient from pelagic to reefs, being dominant for pelagic and near shore species, i.e. the biotopes with the least refuges for prey. Crustaceans are a major item for nearshore, soft bottoms and reefs and are the second most important item in pelagic fish stomachs (17%, but far after nekton: 79%). Biotope is a significant factor in determining the level of crustacean in the diet for soft-bottom and mainly nearshore fishes (Table 3). Soft bottom and reef fish have nearly the same amount of crustaceans in their diets. Echinoderms are a minor diet item for all biotopes. Biotope is not a significant factor in determining

the level of echinoderm in the diet of coastal fishes (Table 3), but depth was significant, echinoderms being found mostly in stomachs of fish caught in shallow areas. Molluscs followed an increasing gradient according to biotope complexity. Surprisingly, bivalves which are mainly sand dwelling organisms are more important in the diet of reef fishes than those from soft bottoms or near shore. Biotope is very significant in determining the level of molluscs in the diet of fish except for pelagic species (Table 3). Worms are associated to soft sediments and are mainly eaten by soft bottom and nearshore species, but reef and soft-bottoms are the two biotopes which are the most significant in determining the level of this item in the diets (Table 3).

### Home range

The proportion of nekton in the diet tends to decrease with increasing home range (Table 4), worms displaying the opposite trend. The other food items do not show gradients linked to home range. Crustaceans are the major item of low and medium home range species, echinoderms are mainly eaten by medium home range species and molluscs are favored by medium to large home range species. Home range is especially significant in determining the level of molluscs in the diet (Table 3).

### School size

There is no gradient of prey volume with school size for any of the prey type studied (Table 4). School size plays however a very significant role in determining the level of molluscs and to a lesser extent nekton and crustacean (Table 3).

Species forming small or medium size schools tend to eat less nekton than other species. There is no specific trend for crustacean. Echinoderms are preferentially eaten by species forming medium size schools, this corresponding mainly to Lethrinidae. Molluscs are seldom eaten by pairing species or species forming large schools. Worms are more specifically eaten by species living in small schools (Table 4).

### Nycthemeral activity

Nycthemeral activity has a very significant contribution to the level of molluscs, nekton, and worms, less significant contribution for crustaceans or echinoderms (Table 3). Fish which are constantly active eat more nekton, echinoderms and molluscs (Table 4). Nekton is much less favored by species which are active during the day only, these species having on the opposite the largest volume of worms in their diet and the lowest of echinoderms (Table 4). Night time active species are characterized by a higher proportion of crustaceans in their diet (Table 4).

### Crypticity

This factor plays only a minor role in determining the volume of prey types (Table 3), being significant only for nekton and molluscs, though contrasted results occurred according to this variable (Table 4). In particular, non cryptic species are characterized by a much higher level of echinoderms, molluscs and worms in their diet, whereas cryptic species are characterized by the highest level of nekton (79%) and 0% of echinoderm. Very cryptic species seem to specialize on crustaceans (79% of their diet).

## 3.2 Effect of size

### 3.2.1 Number of prey types (Table 5)

The number of prey types tends to first increase with fish size then stabilises after 50 cm (Fig. 2). There are important variations from species to species. An analysis of all the relationships at the species level shows that only 25 species had a significant relationship between size and number of prey items (out of 122 species tested). The lack of correlation is due to the high dispersion of the values and also to the fact that some species (especially nekton feeders) tend to have only one item on average in their stomach (resulting in a nearly constant value of one item for all sizes). Fitting a parabolic curve resulted in only 22 significant relationships, but the fit was improved for only 9 species compared to a linear fit.

The increase of the number of prey types with size is more important for reef and soft-bottom species, and is nearly absent for pelagic species. The increase of prey types with size is accentuated by the increase in home range. This trend is little affected by school size, with however a steeper increase in

**Fig. 2.** Variations of the diversity of prey types with fish size. Data are estimated from species averages. The bars represent the 95% confidence intervals.

the number of prey types with size for species forming small schools. This relationship between size and prey types is significant for non cryptic species, but cryptic or very cryptic species do not show this trend. Nycthemeral activity has no influence on this relationship.

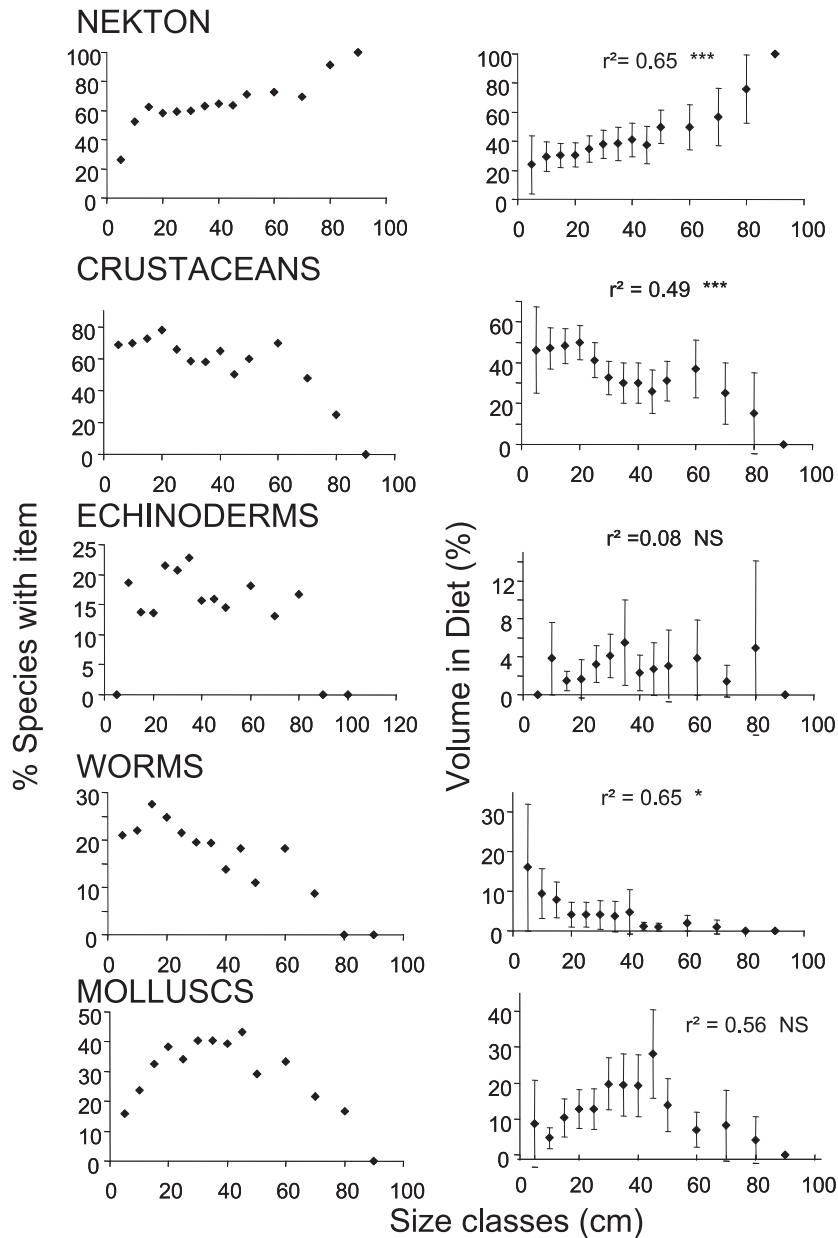

### 3.2.2 Relative volume of prey (Table 5)

#### Nekton

The relative number of species eating nekton increases with fish size and the relative volume of this item increases significantly with fish size (Fig. 3). The relationship between the importance of nekton in the diet and fish size varies according to most of the factors tested (Table 5). Nekton is the major prey items for the largest fish (>80 cm) in all biotopes. The difference with smaller size classes is striking, except for pelagic species for which there is a gradual increase of the importance of this item with size. If one excepts the largest sizes (>80 cm) there is not a constant pattern for the importance of nekton with size according to home range. Medium range species tend to display a decrease in the importance of nekton with size, opposite to species with small and large home ranges, for which nekton increases with size. Except for the species with medium size schools, school size has no effect on the relationship between the volume of nekton and fish size. Similarly only species active during the day display an increase in the importance of nekton with size. Cryptic species not only eat more nekton on average than other species, but this is true for all size classes.

#### Crustaceans

The relative number of species eating crustaceans tends to decrease with fish size and similarly the volume of this item tends to decrease in stomachs as fish size increases (Fig. 3). This decrease is more marked for reef species and soft bottom species, and is not observed for pelagic species. Species with a small home range tend to have very high levels of crustaceans in their stomachs when they are small (<20 cm). The decrease of crustaceans in stomach with fish size is however most marked for species with a large home range. School size does not have a clear influence on the relationship between

**Fig. 3.** Variations of the proportion of species feeding on the major diet items according to fish size (graphs on left) and corresponding variations of the volume in the diet of the major items according to size (graphs on right). Each point is the average of all species within a size class (5 cm) (not the average of all individuals).  $r^2$ : correlation coefficient for the whole model (Volume =  $a_0 + a_1$  Species +  $a_2$  Size +  $\epsilon$ ), and the significance of the “Size” variable is given by: NS: not significant; \*:  $p < 0.05$ ; \*\*:  $p < 0.01$ ; \*\*\*:  $p < 0.001$ .

crustacean volume in stomachs and fish size, however, the decrease is marked for both solitary species and species forming medium size schools. There is no relationship of crustacean with fish size for species which are constantly active and on the opposite this relationship is highly significant for species which are either active during day time or night time. Crypticity has no influence on this relationship.

**Echinoderms**

There is no pattern in the relative number of species eating echinoderms as size increases (Fig. 3), one notices however that echinoderms are not eaten by the largest fish. Similarly

the volume of echinoderms shows no significant trend as fish size increases (Fig. 3). This lack of relationship is confirmed when analysing biotope, home range, school size, nycthemeral activity or crypticity (Table 5). One notices however, that the largest values are observed for medium size fishes (20–80 cm)

**Worms**

The relative number of species eating worms tend to decrease with fish size and similarly there is a significant decrease in the importance of the volume of worms in the stomachs as fish size increases (Fig. 3). This decrease is only found for soft bottoms (Table 5), species eating worms in the

**Table 5.** Average diet composition (%) according to the combination of observed size with home range, school size, nycthemeral activity, level of crypticity and biotope. other biotopes showing no specific trend of worm volume in stomachs as fish size increases. This trend is also very significant for non cryptic species, species with a large home range, species which are daytime active and species with small to medium school size (Table 5).

### Molluscs

The relationship between the relative number of species feeding on molluscs and fish size is not linear but dome shaped, the same being true for the relationship between the volume of molluscs in stomachs and fish size (Fig. 3). The importance of molluscs for medium size fish (20–80 cm) is

mainly marked for reefs and soft bottoms. This dome shaped curve is observed for all home ranges and nycthemeral activities but restricted to small schooling species and non cryptic species (Table 5).

### 3.3 Taxonomic level

#### 3.3.1 All families

Families play a very significant role in determining the number of prey types and the volume of the various food

items (Table 3). Fish is the major food item of three of the studied families: Synodontidae, Sphyraenidae and Carangidae, this item representing more than 70% on average of the stomach content within these families (Table 2). All species within these three families have fish as their major food item (Appendix I). As the level of piscivory decreases, the importance of crustaceans increases, this prey group making more than 60% of the diet of Mullidae and Haemulidae (Table 2). Crustaceans represent the major item for all 9 species of Mullidae studied, whereas crustaceans represent a major item for only 3 out of the five species of Haemulidae studied (Appendix I). Molluscs are an important item (more than 25% of the diet) for only three of the studied families (Table 2): Lethrinidae (31%), Tetraodontidae (41%) and Balistidae (50%). The importance of molluscs within these three families is however very uneven, with some species eating very little of this item, whilst others eat more than 50%. In all cases gasteropods are much less eaten than bivalves, probably because they are harder to crack. Interestingly it is these same three families which consume the most echinoderms (Table 2), but this item accounts at best for 11% of the diet (Tetraodontidae). Echinoderms is in addition an irregular prey item within these families, except for Lethrinidae. Most echinoderms eaten by Lethrinidae are sand dwelling ones. Worms are consumed in significant amounts only by families which frequent soft bottoms (Table 2): Bothidae (28%), Nemipiteridae (23%) and Mullidae (10%). This item is however eaten only by specific species within these families (*Scolopsis taenioptera*, *Parupeneus heptacanthus*, *Upeneus australiae* and *Engiprosopon grandisquamma*). With the exception of Balistidae and Tetraodontidae, “others” is not an important food group for the carnivorous species investigated in our study.

### 3.3.2 Major families

Three families, Lethrinidae, Lutjanidae and Serranidae, make 61.3% of the observed occurrences. All three families eat mainly crustaceans, fish and molluscs. However, the relative importance of these items is different for these families, nekton being more important for Serranidae than for the two other families, crustaceans being of similar value for Serranidae and Lutjanidae. Lethrinidae tend to prefer less mobile prey as attested by the lower importance of nekton and crustaceans in their diet. To compensate, Lethrinidae eat more molluscs than Serranidae or Lutjanidae.

These differences between families may be in part attributed to the biotope; Lethrinidae ranging over both reefs and soft bottoms, whereas Lutjanidae and Serranidae are mainly reef feeders. There are also differences in foraging behaviours. Lutjanidae and Lethrinidae are schooling species. Two traits are associated to schooling in these families: 1- school size decreases with fish size; 2- larger fish have a larger home range. Schooling fish will tend to eat aggregated prey such as bivalve, sand urchin or small pelagic fish (sprat and anchovy are frequent prey for schooling Lutjanidae). Solitary fish within these families usually eat mobile prey, e.g. *Lethrinus olivaceus*, *Aprion virescens*, *Symphorus nematophorus*, large *Lutjanus sebae* or *Lethrinus nebulosus* will have a majority

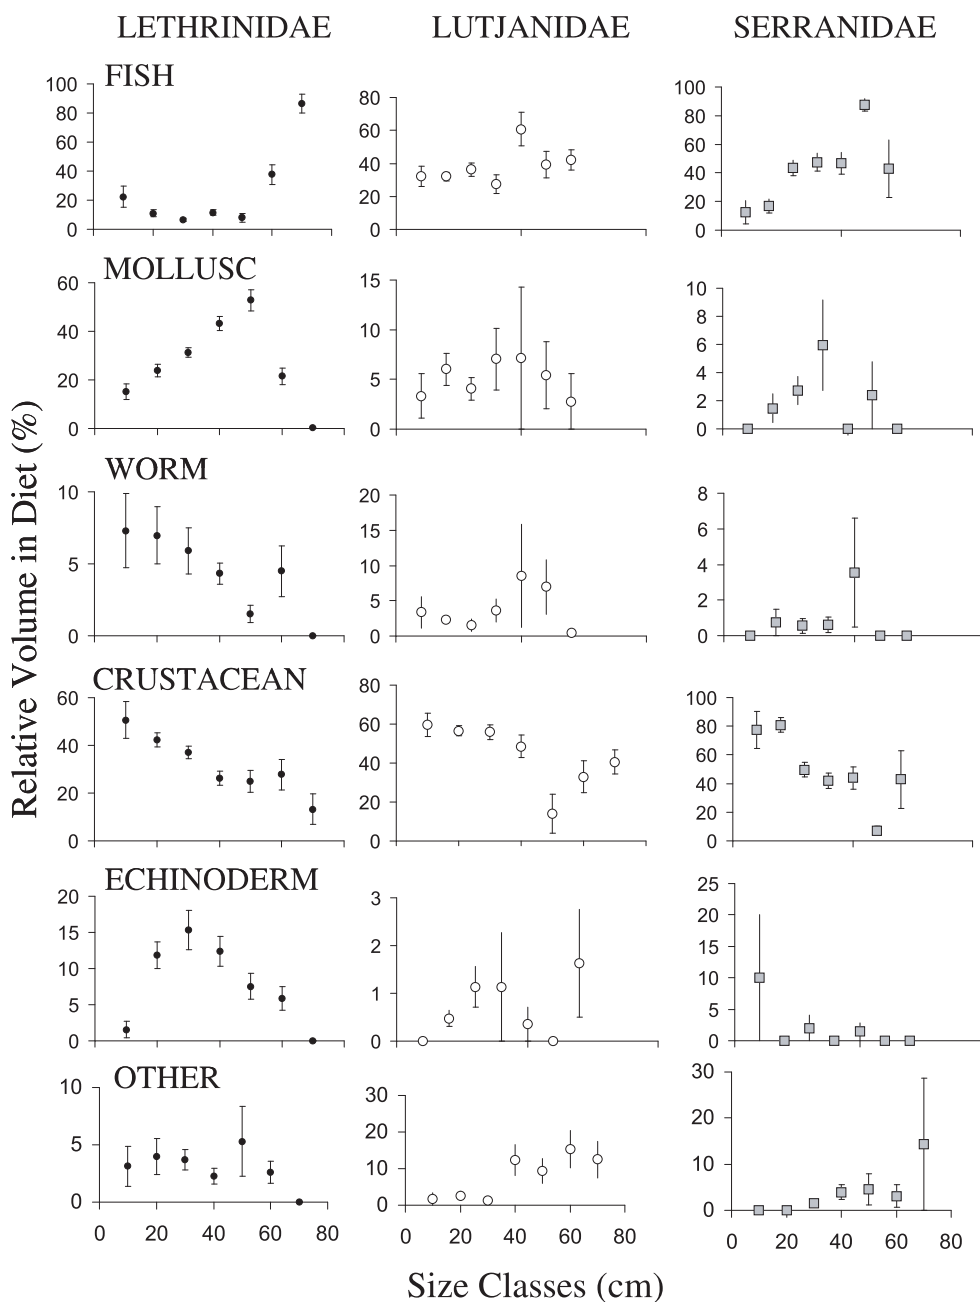

of fish in their diet. Serranidae (Epinephelinae) are all solitary species. They typically ambush their prey which are most of the time mobile (e.g. fish and crustaceans). These fish are not equipped to crush molluscs but they usually can manage to eat hard shelled crustaceans. The only time Serranidae are found in groups (not schools) is when they reproduce or when they feed on schools of small pelagic fish (Clupeidae and Atherinidae mainly).

A closer look at variations of diet with size within the three major families (Serranidae, Lutjanidae and Lethrinidae) shows that there are some convergences in their patterns. Fin-fish tended to increase in importance with predator size in all three families, whereas crustaceans tended to decrease for all three families as predator size increased (Fig. 4). There was no clear pattern for the other prey types with size within these families, except for the molluscs and echinoderms for Lethrinidae (Fig. 5). The importance of molluscs increased to nearly 55% of mean diet composition of Lethrinidae in the 40–50 cm size range and decreased rapidly afterwards. Echinoderms displayed a different pattern, their importance decreasing for Lethrinidae past 30 cm, this item never exceeding 20% for these fish.

### 3.3.3 Differences within a family

There are major differences in the diet of species within a family. To illustrate this, we chose to investigate three species of Lethrinidae. These three species, *Lethrinus atkinsoni*, *L. nebulosus* and *L. rubrioperculatus* have different life history traits. *L. atkinsoni* reaches a size of 43 cm and 2 kg, lives in small schools and is found in all lagoon biotopes except mangroves and estuaries. *L. nebulosus* reaches 70 cm and over 6 kg, lives in medium to large size schools, it is usually found on soft bottoms, algae and sea grass beds and near reefs, but is usually not seen on the reefs themselves. *L. rubrioperculatus* is a small species (35 cm for 1 kg), often found in large schools and restricted to hard bottoms, usually in areas under oceanic influence (passes and barrier reefs).

Both *L. nebulosus* and *L. atkinsoni* are compressed high bodied fish, whereas *L. rubrioperculatus* is elongated. For a similar size, *L. nebulosus* will tend to have a higher diversity of prey (except for fish <15 cm), whilst *L. atkinsoni* has a decreasing number of prey items with size and *L. rubrioperculatus* has a stable diversity of prey with size. These three species have different overall diet compositions (Fig. 5). *L. nebulosus* eats mainly molluscs, followed by crustaceans and echinoderms, whilst *L. atkinsoni* has a balanced diet with nekton, crustaceans, echinoderms and molluscs having nearly the same value, and *L. rubrioperculatus* has a diet dominated by crustaceans and fish, the former declining with size whilst the latter increases. The diet composition is the most variable with size for *L. rubrioperculatus*. *L. rubrioperculatus* eats mainly moving prey (crustaceans and nekton); it has an elongated body like most other Lethrinidae which eat these prey items mainly as well (*L. olivaceus*, *L. xanthocheilus*, *L. variegatus*). However, body shape within the family is not sufficient to predict prey type, as *L. miniatus*, which has an elevated body, is also essentially piscivorous, and *L. genivittatus* which is elongated has a very diversified diet with little moving prey.

**Fig. 4.** Relative volumetric contribution in Lethrinidae, Lutjanidae and Serranidae for the successive size classes (cm) (see Fig. 3 for details on calculation). Error bars indicate the standard deviation for each mean.

## Discussion

The present study on stomach contents encompasses more species of carnivorous fishes than any other to date (e.g. the most extensive studies published so far on the diets of Indo-Pacific coastal fishes are Hiatt and Strasburg 1960; Hobson 1974; Harmelin-Vivien 1979; Sano et al. 1984; Parrish 1987; Pinto 1987; Nakamura et al. 2003). However, this study looked mainly at large species, most small carnivorous species such as Apogonidae, small Labridae (e.g. genera *Halichoeres*, *Coris*, *Thalassoma*), Scorpaenidae, Callyonimidae, Leiognathidae or flatfishes are not covered by our study. The diets of such

species which are often amongst the most abundant species in tropical coastal waters of the Indo-Pacific are little known.

The number of prey types was low, but this is in great part due to the low number of types (6) retained for the analysis. Most species are opportunistic, eating what is available within a more or less restricted range of items. Changes in the number of prey types should reflect both this plasticity and the variability of prey in the biotopes where the fishes feed. This is reflected by our finding that the number of prey types increased with biotope complexity and with the home range of the species. An interesting point is that night active species tend to have a higher diversity of prey types probably because

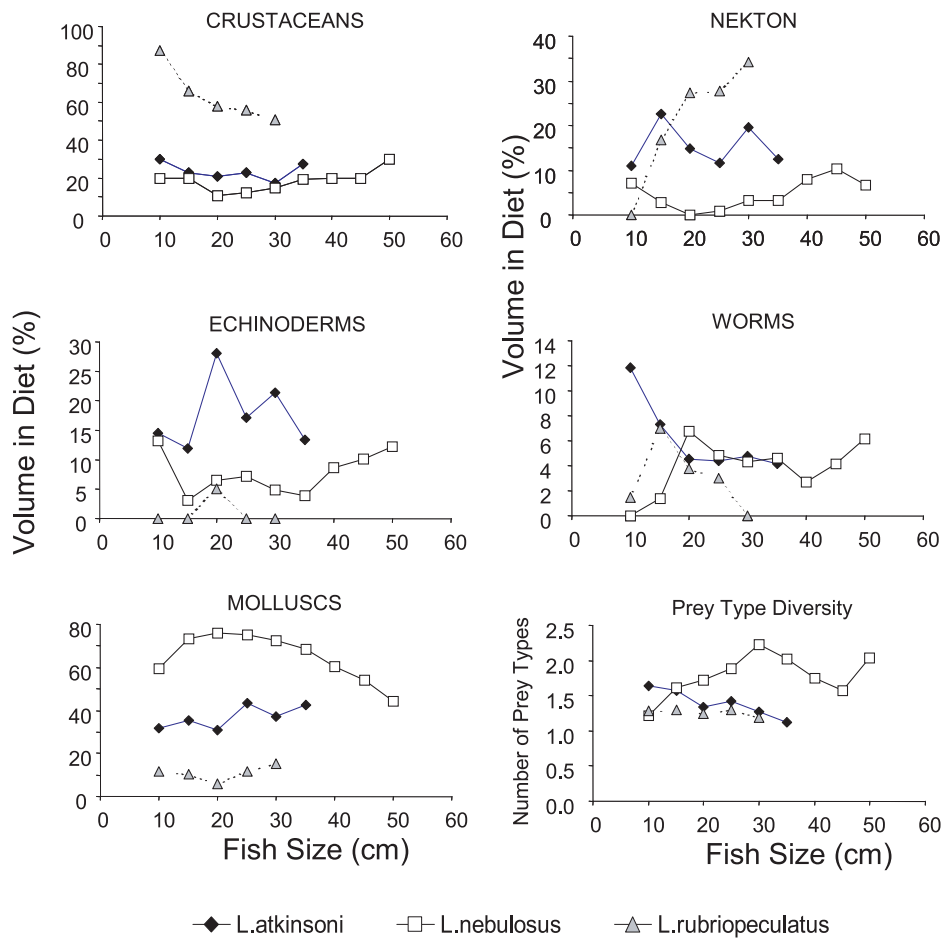

Fig. 5. Variations of prey items and prey diversity according to species and size within Lethrinidae.

most benthic invertebrates are only active at night trying to escape predation.

The most frequently eaten prey items (fish, crustaceans, molluscs, worms and echinoderms) are the same than in all other studies on the diet of tropical carnivorous coastal fishes. The frequency of these items is probably not necessarily proportional to their abundance in the environment. Our study does not investigate this relationship between prey abundance in the biotope and prey occurrence in the diet, however it indirectly points to this as the importance of prey in the diet were linked to biotope, home range and fish behaviour (Tables 3 and 4). There are few studies relating the diet of large carnivorous reef fish with food availability in the tropics (Harmelin-Vivien 1981; Parrish et al. 1985). Jones et al. (1991), about *Diagramma pictum* and *Lethrinus nebulosus* on the Great Barrier Reef, indicated that these fish fed on available molluscs but that the size range of their prey depended on the fish and not on prey abundance. Egretaud (1992) showed little correlation between the observed diet of 1400 *Lethrinus nebulosus*, and the food items found during a simultaneous benthos study (Clavier et al. 1992; Clavier and Garrigue 1993) on 64 stations on Ouvéa atoll (New Caledonia). In particular, many abundant benthic organisms were not found in the stomachs of *Lethrinus nebulosus* even though these invertebrates were part of the diet of this fish. On the opposite, some items in

their diet were not found or found in minute quantities during the benthos survey. This indicates that carnivorous fish choose their food items and do not necessarily feed on the most abundant items even if the latter are suitable. This is confirmed by Beukers-Stewart and Jones (2004) who showed that the feeding rate of two Serranidae was not linked to biotope despite differences in prey abundance.

Predation is thought to be a major determinant in structuring reef fish assemblages (e.g. Hixon 1991; Planes and Lecaillon 2001; Stewart and Jones 2001) and our data indicate that fish was the major food item for large carnivorous fishes in New Caledonia. Piscivory by small fish is certainly also high, fishes such as the labrids *Halichoeres* and *Thalassoma* or some Apogonidae (e.g. *Cheilodipterus* spp.) being often abundant on reefs. Night feeding and cryptic species such as the Holocentridae and most anguilliform fishes (Muraenidae, Congridae, Ophichtidae, Scorpaenidae) are probably more abundant than usually indicated by visual reef fish surveys (Kulbicki 1990) and consequently may represent a major but unsuspected source of piscivory.

Our data show that biotope does not play the same role on the volume of the various prey types eaten by large carnivorous fishes. There is a gradient in the complexity of the biotopes we considered, reefs being the most complex and pelagic the least, nearshore and soft bottoms being intermediate. There seems to

be a relationship between the type of protection displayed by prey and this complexity, prey speed being linked to poor complexity, physical defenses (e.g. shell thickness or cover, spines) increasing as biotope complexity decreases. There is little or no information in the literature on the links between prey characteristics and biotope complexity. However, there is a strong link between biotope complexity and the abundance and diversity of reef fish assemblages (e.g. Friedlander and Parrish 1998; Parrish and Bolland 2004) and consequently on the diversity of feeding modes.

Home range of fish is a significant factor in the level of several prey types in our study (Tables 3 and 4). The trends we observe seem at first opposite to logic. Species with a large home range are usually large species and therefore nekton should represent a larger part of their diet than for species with small home range. The opposite is observed. Similarly molluscs, and worms which may be eaten by small species are found in much higher volumes in species with a large home range. One possible explanation could be found in the nutritional values of these items. Nekton is most of the time of higher nutritional value than worms or molluscs and therefore lesser quantities are needed and may be obtained from a more restricted area.

Most herbivorous and plankton feeding species tend to form schools, but the causes and consequences of this behaviour are not well known (e.g. for herbivores, see Wolf 1987; Choat and Clements 1998; Choat et al. 2004 or Floeter et al., in press). Consequences of schooling on the diet of carnivorous fishes is not well documented, most studies considering the benefits of schooling for the prey not for the predator (e.g. Krause et al. 1998; Hemelrijk and Hanspeter 2005). Our study shows that even though prey volume is not affected by this factor, it does influence the choice of prey to some extent. For instance, nekton is eaten either by solitary species (mainly species ambushing their prey) or by species forming large schools (which may be more efficient in pursuing nekton). Several of our findings are however difficult to explain, e.g. why don't pairing carnivorous species eat molluscs, or why worms are mainly eaten by species forming small schools?

Nycthemeral activity is a very significant factor for the volume of prey. There are strong relationships between predator and prey behaviours (e.g. Temming et al. 2004; Stoner 2004) which are reflected in the choice of prey and feeding time. In our case several prey groups tend to be nocturnal: echinoderms, crustaceans and gasteropods. Therefore they are more vulnerable during that time and consequently are less targeted by day active species. Nekton may also be more vulnerable at night as many small reef fish species, which may be predated by piscivores, are active only during the day and rest motionless during the night. Day active fish eat more worms than other species. Worms tend to stay hidden at all times and therefore night feeding should present no specific advantage for this food type.

Crypticity is an important factor for some diet items in our study. Cryptic species eat no echinoderm, which indicates that this behaviour has no use for such prey types. On the opposite such species have the highest level of nekton in their diet, thus indicating that ambushing fish is probably more successful than chasing them, at least in terms of energy. Interestingly, the most cryptic species are those which specialise on crustaceans.

Most crustaceans are night active. Being prey of very cryptic fish, when light conditions are at the lowest, suggests that these prey are able to detect, most likely by sight, less cryptic predators. On the opposite, the non cryptic species are those which consume essentially prey with little or no sighting abilities (worms, echinoderms and molluscs).

Fish diet is highly linked to fish size as demonstrated by numerous studies which show that it acts on prey preference, prey diversity, feeding behaviour or feeding rate. Our study confirms the relationship between fish size and number of prey items (prey types in our case). Several authors found that this relationship was not linear but first increased, then as the fish got to their maximum size, the diversity of their prey tended to decrease, thus showing a specialisation with size or age (e.g. Harmelin-Vivien 1981, 1989; Lundvall et al. 1999; St John 1999). This parabolic trend was also detected in our data for 22 species, but a linear fit was usually better (25 species); thus, such a trend is not necessarily general. This relationship depended on the biotope and home range, being more important for reefs and for species with large home range (Table 5). This is probably linked to prey availability, the diversity of prey being much higher on reefs and species with a larger home range being able to access more prey types.

The present study, as many others (e.g. McCormick 1998; Piet 1998; Jennings et al. 2001; Hanson and Chouinard 2002; Nakamura et al. 2003) indicates that there may be important changes of diet with size, many species switching from smaller, easier to access prey, to larger prey or to prey more difficult to catch or extract but of higher nutritive value. It is difficult to assess the consequence of such shifts in terms of energy flow as well as in terms of impact on the environment (Jones et al. 1991). These changes in diet with size go often together with a change in biotope. For instance, Egretaud (1992) found that the smaller *Lethrinus nebulosus* were found in the shallowest parts of the Ouvea lagoon where they fed on relatively small sand dwelling prey, whereas the larger specimen were found in the deeper parts of the lagoon and fed on larger mobile prey. More interestingly, the feeding schedule of these fish suggested that adult fish would travel great distances to feed whereas the smaller fish tended to stay within the same area. In other words, larger fish can cover wider feeding grounds and choose amongst a wider category of prey, the smaller fish being limited by factors such as their swimming abilities or predation by larger fish.

Nekton was an increasingly important diet item as fish size increased, with more species eating this item as size increased. Nekton probably offers the best nutritional input for carnivorous fish and is therefore favored when possible. Access to nekton depends in great part on predator swimming speed (see review by Domenci and Blake 1997), as attested by the fact that the largest fish sizes (>80 cm) eat a far larger proportion of nekton than the smaller size classes (Table 5), this being true for all behaviour types (schooling, crypticity, diel activity) and all biotopes. Swimming speed is not the only factor in play, as one notices that cryptic species eat more nekton than other species for all size classes. This suggests that either cryptic species are more efficient in getting nekton, or that they are more specialized. As these fish ambush their prey, it is their initial speed

more than their sustained speed which is important (Domenci and Blake 1997).

Crustaceans decrease in importance in the diet of most fishes as size increases. This has been observed in other ecosystems, carnivorous fishes switching from crustacean to nekton as they grow (e.g. Cardinale 2000; Hanson and Chouinard 2002). This prey type seems specifically important for small reef species with a short home range. Prey abundance in the various biotopes is not available, but shrimps and crabs may be observed in large numbers on reefs at night, whereas they are seldom seen in the other biotopes, except nearshore (seagrass and algae beds, mangroves and estuaries) where this prey item is also important but for larger size species than on reefs.

Predation of urchins on reefs has received special attention as urchins compete with herbivorous fishes for turf algae (Hay and Taylor 1985; Carpenter 1988; McClanahan 1994, 1999). The increase of urchins by the removal of their fish predators through fishing may affect the growth of turf algae which in turn will affect herbivorous fish and even the entire ecosystem by cascade effect (Hughes 1994). The present study indicates that reef urchins were not a preferred food and it was a prey item only for the largest Lethrinidae. Our data did not cover well other potential urchin predators such as large Labridae, Tetraodontidae and Balistidae, but these fish are usually not abundant on reefs in New Caledonia (Kulbicki 1997; Letourneur et al. 2000) and are not targeted by fishermen in general. Therefore, the control of urchin by fish may not occur on large urchins, but rather on their very initial stages. These are probably preyed upon by small species (e.g. small Labridae, Monacanthidae, Balistidae) or accidentally destroyed by grazers (Scaridae, Acanthuridae). This might explain the lack of a direct link between the abundance and sizes of large predatory fish and the abundance of reef urchins in the south west Pacific (Mitchell 2004) opposite to the results in the Western Indian Ocean (McClanahan 1994). In our study, no pattern could be detected between the importance of urchin as prey and fish size, but this prey item was mainly eaten by large fish.

Worms never represented a high volume in the diet of the fish examined, probably due to the fact that this prey type is small, difficult to find and maybe of low nutritional value compared to other prey types. This prey type significantly decreased with fish size, especially on soft bottoms (where this prey is the most important), for non cryptic, daytime active species and species with a large home range and small to medium size schools (Table 5). It is likely that worms are not found in sufficient quantities to feed large fish and that these prey are probably found in aggregates which would favor schooling fish (schooling is known to favor the finding of prey with patchy distributions – e.g. Ward et al. 2000).

The importance of molluscs in the diet of carnivorous fishes from New Caledonia displays a dome shaped curve as size increases. It is general to most behaviours and most marked for reefs and soft bottoms (Table 5). Eating molluscs requires powerful jaws and this may not be reached before a given size; thus explaining the low contribution of this prey type to the diet of small fishes. The absence of molluscs in the largest fishes could be due to a low nutritional value compared

to the energy needed to consume large enough quantities. Large molluscs are not very abundant in the coastal waters of New Caledonia (Clavier et al. 1992) and the few species which are available are usually gasteropods with very thick shells which can be crunched only by very well adapted fish species (i.e. Balistidae, Tetraodontidae, some of the largest Labridae and Lethrinidae).

All the factors analysed so far in this article are not sufficient to explain all the observed variations in fish diet. There are major and significant differences due to taxonomy (Table 3), each family and each species within a family having specific requirements. The differences between families are intrinsic. For instance, Nemipteridae and Mullidae share many characteristics in common (size, behaviour, biotopes), the former preferring worms and the latter shrimps. On the opposite differences between the three major families (Serranidae, Lutjanidae, Lethrinidae) may be in great part explained by differences in behaviour and biotopes. This allows for a better allocation of resources amongst species within the fish assemblage. It shows in particular that creating large trophic categories based on major prey types, as is usually done for reef fishes (see review Kulbicki 1991), may hide important differences in targeted prey.

Differences within a family may also be important as indicated by the studied example of the Lethrinidae. In this case, some of the differences may be explained by the general factors considered earlier (biotope, size, behaviour), but there remain differences which are intrinsic to the species. For instance *L. rubrioperculatus*, despite its smaller size, eats more fish than the two other species. Its elongate shape is an advantage to eat fish, but not a sufficient explanation, as some high bodied Lethrinidae are also mainly piscivores.

The present study brings information on the diet of large carnivorous fish, but we still need much more information on the diet of fish if we wish to achieve adequate trophic models. Amongst carnivorous species, the main needs are towards the smaller species (Apogonidae, Labridae, Nemipteridae, Gobiidae, etc.) which often make the bulk of the abundance in lagoons, even though their contribution to biomass is often low.

*Acknowledgements.* We wish to thank the many persons who assisted in the collection and the dissection of the fish analyzed in this study, especially the crews of the RV *Alis*, *Dawa* and *Dar Mad*, Nicolas Audran and Pierre Boblin.

(1) Benthic algae, (2) planktonic crustaceans, (3) corals, (4) sponges, (5) octopi.

**Appendix II.** Summary of the stomach content analysis by number of species (A) and by % volume (B), according to fish size. Data by volume are averaged per species, not per individual. "Total" indicates the number of species involved.

**A) By species: number of species per size class (5 cm) which had the item in their stomach.**

SIZE CLASS (cm)	5-	10-	15-	20-	25-	30-	35-	40-	45-	50-	60-	70-	80-	90-	>100	Total
