Abstract. Accurate assessment of anthropogenic carbon dioxide (CO₂) emissions and their redistribution among the atmosphere, ocean, and terrestrial biosphere is important to better understand the global carbon cycle, support the development of climate policies, and project future climate change. Here we describe data sets and a methodology to quantify all major components of the global carbon budget, including their uncertainties, based on the combination of a range of data, algorithms, statistics and model estimates and their interpretation by a broad scientific community. We discuss changes compared to previous estimates, consistency within and among components, alongside methodology and data limitations. CO₂ emissions from fossil-fuel combustion and cement production (E_{FF}) are based on energy statistics, while emissions from land-use change (E_{LUC}), mainly deforestation, are based on combined evidence from land-cover change data, fire activity associated with deforestation, and models. The global atmospheric CO₂ concentration is measured directly and its rate of growth (G_{ATM}) is computed from the annual changes in concentration. The mean ocean CO₂ sink (S_{OCEAN}) is based on observations from the 1990s, while the annual anomalies and trends are estimated with ocean models. The variability in S_{OCEAN} is evaluated for the first time in this budget with data products based on surveys of ocean CO₂ measurements. The global residual terrestrial CO₂ sink (S_{LAND}) is estimated by the difference of the other terms of the global carbon budget and compared to results of independent dynamic global vegetation models forced by observed climate, CO₂ and land cover change (some including nitrogen–carbon interactions). All uncertainties are reported as $\pm 1\sigma$, reflecting the current capacity to characterise the annual estimates of each component of the global carbon budget. For the last decade available (2003–2012), E_{FF} was $8.6 \pm 0.4 \text{ GtC yr}^{-1}$, E_{LUC} $0.9 \pm 0.5 \text{ GtC yr}^{-1}$, G_{ATM} $4.3 \pm 0.1 \text{ GtC yr}^{-1}$, S_{OCEAN} $2.5 \pm 0.5 \text{ GtC yr}^{-1}$, and S_{LAND} $2.8 \pm 0.8 \text{ GtC yr}^{-1}$. For year 2012 alone, E_{FF} grew to $9.7 \pm 0.5 \text{ GtC yr}^{-1}$, 2.2 % above 2011, reflecting a continued growing trend in these emissions, G_{ATM} was $5.1 \pm 0.2 \text{ GtC yr}^{-1}$, S_{OCEAN} was $2.9 \pm 0.5 \text{ GtC yr}^{-1}$, and assuming an E_{LUC} of $1.0 \pm 0.5 \text{ GtC yr}^{-1}$ (based on the 2001–2010 average), S_{LAND} was $2.7 \pm 0.9 \text{ GtC yr}^{-1}$. G_{ATM} was high in 2012 compared to the 2003–2012 average, almost entirely reflecting the high E_{FF} . The global atmospheric CO₂ concentration reached $392.52 \pm 0.10 \text{ ppm}$ averaged over 2012. We estimate that E_{FF} will increase by 2.1 % (1.1–3.1 %) to $9.9 \pm 0.5 \text{ GtC}$ in 2013, 61 % above emissions in 1990, based on projections of world gross domestic product and recent changes in the carbon intensity of the economy. With this projection, cumulative emissions of

CO₂ will reach about 535 ± 55 GtC for 1870–2013, about 70 % from E_{FF} (390 ± 20 GtC) and 30 % from E_{LUC} (145 ± 50 GtC).

This paper also documents any changes in the methods and data sets used in this new carbon budget from previous budgets (Le Quéré et al., 2013). All observations presented here can be downloaded from the Carbon Dioxide Information Analysis Center (doi:10.3334/CDIAC/GCP_2013_V2.3).

1 Introduction

The concentration of carbon dioxide (CO₂) in the atmosphere has increased from approximately 277 parts per million (ppm) in 1750 (Joos and Spahni, 2008), the beginning of the Industrial Era, to 392.52 in 2012 (Dlugokencky and Tans, 2013). Daily averages went above 400 ppm for the first time at Mauna Loa station in May 2013 (Scripps, 2013). This station holds the longest running record of direct measurements of atmospheric CO₂ concentration (Tans and Keeling, 2013). The atmospheric CO₂ increase above preindustrial levels was initially, primarily, caused by the release of carbon to the atmosphere from deforestation and other land-use change activities (Ciais et al., 2013). Emissions from fossil-fuel combustion started before the Industrial Era and became the dominant source of anthropogenic emissions to the atmosphere from around 1920 and continued to be the dominant source until present. Anthropogenic emissions occur on top of an active natural carbon cycle that circulates carbon between the atmosphere, ocean, and terrestrial biosphere reservoirs on timescales from days to millennia, while exchanges with geologic reservoirs have even longer timescales (Archer et al., 2009).

The global carbon budget presented here refers to the mean, variations, and trends in the perturbation of CO₂ in the atmosphere, referenced to the beginning of the Industrial Era. It quantifies the input of CO₂ to the atmosphere by emissions from human activities, the growth of CO₂ in the atmosphere, and the resulting changes in the storage of carbon in the land and ocean reservoirs in response to increasing atmospheric CO₂ levels, climate change and climate variability, and other anthropogenic and natural changes. An understanding of this perturbation budget over time and the underlying variability and trends of the natural carbon cycle are necessary to understand the response of natural sinks to changes in climate, CO₂ and land-use change drivers, and the permissible emissions for a given climate stabilisation target.

The components of the CO₂ budget that are reported in this paper include separate estimates for (1) the CO₂ emissions from fossil-fuel combustion and cement production (E_{FF}), (2) the CO₂ emissions resulting from deliberate human activities on land leading to land-use change (LUC; E_{LUC}), (3) the growth rate of CO₂ in the atmosphere (G_{ATM}), and the uptake of CO₂ by the “CO₂ sinks” in (4) the ocean (S_{OCEAN}) and (5) on land (S_{LAND}). The CO₂ sinks as defined here include the response of the land and ocean to elevated CO₂

and changes in climate and other environmental conditions. The global emissions and their partitioning among the atmosphere, ocean and land are in balance:

$$E_{\text{FF}} + E_{\text{LUC}} = G_{\text{ATM}} + S_{\text{OCEAN}} + S_{\text{LAND}}. \quad (1)$$

G_{ATM} is usually reported in ppm, which we convert to units of carbon mass using $1 \text{ ppm} = 2.120 \text{ GtC}$ (Prather et al., 2012; Table 1). We also include a quantification of E_{FF} by country, both computed with territorial and consumption-based accounting (see Methods).

Equation (1) partly omits two kinds of processes. The first is the net input of CO₂ to the atmosphere from the chemical oxidation of reactive carbon-containing gases from sources other than fossil fuels (e.g. landfills, industrial processes, etc.), primarily methane (CH₄), carbon monoxide (CO), and volatile organic compounds such as isoprene and terpene. The second is the anthropogenic perturbation to carbon cycling in terrestrial freshwaters, estuaries, and coastal areas, that modifies lateral fluxes from land ecosystems to the open ocean, the evasion CO₂ flux from rivers, lakes and estuaries to the atmosphere, and the net air–sea anthropogenic CO₂ flux of coastal areas (Regnier et al., 2013). These flows are omitted in the absence of annual information on the natural versus anthropogenic perturbation terms of these loops of the carbon cycle, and they are discussed in Sect. 2.6. The inclusion of these fluxes of anthropogenic CO₂ would affect the estimates of, and partitioning between, S_{LAND} and S_{OCEAN} in Eq. (1) in complementary ways, but would not affect the other terms in Eq. (1).

The CO₂ budget has been assessed by the Intergovernmental Panel on Climate Change (IPCC) in all assessment reports (Ciais et al., 2013; Denman et al., 2007; Prentice et al., 2001; Schimel et al., 1995; Watson et al., 1990), and by others (e.g. Ballantyne et al., 2012). These assessments included budget estimates for the decades of the 1980s, 1990s (Denman et al., 2007) and, most recently, the period 2002–2011 (Ciais et al., 2013). The IPCC methodology has been adapted and used by the Global Carbon Project (GCP, www.globalcarbonproject.org), which has coordinated a cooperative community effort for the annual publication of global carbon budgets up to year 2005 (Raupach et al., 2007; including fossil emissions only), year 2006 (Canadell et al., 2007), year 2007 (published online; GCP, 2007), year 2008 (Le Quéré et al., 2009), year 2009 (Friedlingstein et al., 2010), year 2010 (Peters et al., 2012b), and most recently, year 2011 (Le Quéré et al., 2013; Peters et al., 2013). Each of these papers updated previous

Table 1. Factors used to convert carbon in various units (by convention, Unit 1 = Unit 2· conversion).

Unit 1	Unit 2	Conversion	Source
GtC (gigatonnes of Carbon)	ppm (parts per million)	2.120	Prather et al. (2012)
GtC (gigatonnes of Carbon)	PgC (petagrammes of Carbon)	1	SI unit conversion
GtCO ₂ (gigatonnes of Carbon Dioxide)	GtC (gigatonnes of Carbon)	3.664	44/12 in mass equivalent
GtC (gigatonnes of Carbon)	MtC (megatonnes of Carbon)	1000	SI unit conversion

estimates with the latest available information for the entire time series. From 2008, these publications projected fossil-fuel emissions for 1 additional year using the projected world gross domestic product and estimated improvements in the carbon intensity of the economy.

We adopt a range of ± 1 standard deviation (σ) to report the uncertainties in our estimates, representing a likelihood of 68 % that the true value will be within the provided range if the errors have a Gaussian distribution. This choice reflects the difficulty of characterising the uncertainty in the CO₂ fluxes between the atmosphere and the ocean and land reservoirs individually, particularly on an annual basis, as well as the difficulty of updating the CO₂ emissions from LUC. A likelihood of 68 % provides an indication of our current capability to quantify each term and its uncertainty given the available information. For comparison, the Fifth Assessment Report of the IPCC (AR5) generally reported a likelihood of 90 % for large data sets whose uncertainty is well characterised, or for long time intervals less affected by year-to-year variability. Our 68 % uncertainty value is near the 66 % that the IPCC characterises as “likely” for values falling into the $\pm 1\sigma$ interval. The uncertainties reported here combine statistical analysis of the underlying data and expert judgement of the likelihood of results lying outside this range. The limitations of current information are discussed in the paper.

All units are presented in gigatonnes of carbon (GtC, 10^{15} gC), which is the same as petagrams of carbon (PgC; Table 1). Units of gigatonnes of CO₂ (or billion tonnes of CO₂) used in policy are equal to 3.664 multiplied by the value in units of GtC.

This paper provides a detailed description of the data sets and methodology used to compute the global carbon budget estimates for the preindustrial period (1750) to 2012 and in more detail for the period 1959 to 2012. We also provide decadal averages starting in 1960 including the last decade (2003–2012), results for the year 2012, and a projection of E_{FF} for year 2013. Finally we provide the total or cumulative emissions from fossil fuels and land-use change since the year 1750, the preindustrial period, and since the year 1870, the reference year for the cumulative carbon estimate used by the Fifth Assessment Report of the Intergovernmental Panel on Climate Change based on the availability of global temperature data (Stocker et al., 2013b). This paper will be updated every year using the format of “living data” in order to keep a record of budget versions and the changes

in new data, revision of data, and changes in methodology that lead to changes in estimates of the carbon budget. Additional materials associated with the release of each new version will be posted at the Global Carbon Project (GCP) website (<http://www.globalcarbonproject.org/carbonbudget>). Data associated with this release are also available through the Global Carbon Atlas (<http://www.globalcarbonatlas.org>). With this approach, we aim to provide the highest transparency and traceability in the reporting of a set of key indicators and drivers of climate change.

2 Methods

Multiple organisations and research groups around the world generated the original measurements and data used to complete the global carbon budget. The effort presented here is thus mainly one of synthesis, where results from individual groups are collated, analysed and evaluated for consistency. We facilitate access to original data with the understanding that primary data sets will be referenced in future work (see Table 2 for “How to cite” the data sets). Descriptions of the measurements, models, and methodologies follow below and in-depth descriptions of each component are described elsewhere (e.g. Andres et al., 2012; Houghton et al., 2012).

This is the second revised version of the “global carbon budget”. It is an update of Le Quéré et al. (2013), including data until year 2012 and a projection for fossil-fuel emissions for year 2013. The main changes from Le Quéré et al. (2013) are (1) we have introduced a new section (Sect. 2.6) that describes and quantifies the main missing processes; (2) we have introduced data products to assess the interannual variability in the ocean CO₂ sink; (3) we have introduced a qualitative assessment of confidence level to characterise the annual estimates from each term based on the type, amount, quality and consistency of the evidence as defined by the IPCC (Stocker et al., 2013b); and (4) we have also updated the cumulative CO₂ emissions. The main methodological differences between annual carbon budgets are summarised in Table 3.

Table 2. How to cite the individual components of the global carbon budget presented here.

Component	Primary reference
Territorial fossil-fuel and cement emissions (E_{FF}) global, by fuel type, and by country	Boden et al. (2013; CDIAC: http://cdiac.ornl.gov/trends/emis/meth_reg.html)
Consumption-based fossil-fuel and cement emissions (E_{FF}) by country (consumption)	Peters et al. (2011b) updated as described in Le Quéré et al. (this paper)
Land-use change emissions (E_{LUC})	Houghton et al. (2012)
Atmospheric CO ₂ growth rate	Dlugokencky and Tans (2013; NOAA/ESRL: www.esrl.noaa.gov/gmd/ccgg/trends/)
Ocean and land CO ₂ sinks (S_{OCEAN} and S_{LAND})	Le Quéré et al. (this paper) for S_{OCEAN} and S_{LAND} and references in Table 6 for individual models.

2.1 CO₂ emissions from fossil-fuel combustion and cement production (E_{FF})

2.1.1 Fossil-fuel and cement emissions and their uncertainty

The calculation of global and national CO₂ emissions from fossil-fuel combustion, including gas flaring and cement production (E_{FF}), relies primarily on energy consumption data, specifically data on hydrocarbon fuels, collated and archived by several organisations (Andres et al., 2012). These include the Carbon Dioxide Information Analysis Center (CDIAC), the International Energy Agency (IEA), the United Nations (UN), the United States Department of Energy (DoE) Energy Information Administration (EIA), and more recently also the PBL Netherlands Environmental Assessment Agency. We use the emissions estimated by the CDIAC (Boden et al., 2013). The CDIAC emission estimates are the only ones that extend back in time to 1751 with consistent and well-documented emissions from fossil-fuel combustion, cement production, and gas flaring for all countries, including their uncertainty (Andres et al., 1999, 2012); this makes the data set a unique resource for research of the carbon cycle during the fossil-fuel era. During the period 1959–2010, the emissions are based primarily on energy data provided by the UN Statistics Division (Table 4; UN, 2013a, b). For the most recent 2 years (2011 and 2012) when the UN statistics are not yet available, CDIAC generated preliminary estimates based on the BP annual energy review for extrapolation of emissions in 2011 and 2012 (BP, 2013). BP's sources for energy statistics overlap with those of the UN data, but are compiled more rapidly using about 70 countries covering about 96 % of global emissions. We use the BP values only for the year-to-year rate of change, because the rates of change are less uncertain than the absolute values and to avoid discontinuities in the time series when linking the UN-based energy data (up to 2010) with the BP energy data (2011 and 2012). These preliminary estimates are replaced by the more complete CDIAC data based on UN statistics when they become

available. Past experience shows that projections based on the BP rate of change provide reliable estimates for the two most recent years (see Sect. 3.2 and the Supplement from Peters et al., 2013).

When necessary, fuel masses/volumes are converted to fuel energy content using coefficients provided by the UN and then to CO₂ emissions using conversion factors that take into account the relationship between carbon content and heat content of the different fuel types (coal, oil, gas, gas flaring) and the combustion efficiency (to account, for example, for soot left in the combustor or fuel otherwise lost or discharged without oxidation). Most data on energy consumption and fuel quality are available at the country level. In general, CO₂ emissions for equivalent primary energy consumption are about 30 % higher for coal compared to oil, and 70 % higher for coal compared to natural gas (Marland et al., 2007). All estimated fossil-fuel emissions are based on the mass flows of carbon and assume that the fossil carbon emitted as CO or CH₄ will soon be oxidised to CO₂ in the atmosphere and can be accounted with CO₂ emissions.

Emissions from cement production are based on cement data from the US Geological Survey (van Oss, 2013) up to year 2010, and from preliminary data for 2011 and 2012 where available (US Geological Survey, 2013). Some fraction of the CaO and MgO in cement is returned to the carbonate form during cement weathering but this is generally regarded to be small and is ignored here.

Emission estimates from gas flaring are calculated in a similar manner as those from solid, liquid, and gaseous fuels, and rely on the UN Energy Statistics to supply the amount of flared or vented fuel. For emission years 2011 and 2012, flaring is assumed constant from the emission year 2010 UN-based data. The basic data on gas flaring report atmospheric losses during petroleum production and processing that have large uncertainty and do not distinguish between gas that is flared as CO₂ or vented as CH₄. Fugitive emissions of CH₄ from the so-called upstream sector (e.g. coal mining and natural gas distribution) are not included in the accounts of CO₂

Table 3. Main methodological changes in the global carbon budget since first publication. Unless specified below, the methodology was identical to that described in the current paper. Furthermore, methodological changes introduced in one year are kept for the following years unless noted. Empty cells mean there were no methodological changes introduced that year.

Publication year ^a	Fossil-fuel emissions			LUC emissions	Reservoirs			Uncertainty and other changes
	Global	Country (territorial)	Country (consumption)		Atmosphere	Ocean	Land	
2006 Raupach et al. (2007)		Split in regions						
2007 Canadell et al. (2007)				E_{LUC} based on FAO-FRA 2005; constant E_{LUC} for 2006	1959–1979 data from Mauna Loa; data after 1980 from global average	Based on one ocean model tuned to reproduced observed 1990s sink		$\pm 1\sigma$ provided for all components
2008 (online release)				Constant E_{LUC} for 2007				
2009 Le Quéré et al. (2009)		Split between Annex B and non-Annex B	Results from an independent study discussed	Fire-based emission anomalies used for 2006–2008		Based on four ocean models normalised to observations with constant delta	First use of five DGVMs to compare with budget residual	
2010 Friedlingstein et al. (2010)	Projection for current year based on GDP	Emissions for top emitters		E_{LUC} updated with FAO-FRA 2010				
2011 Peters et al. (2012)			Split between Annex B and non-Annex B					
2012 Le Quéré et al. (2013), Peters et al. (2013)		129 countries from 1959	129 countries and regions from 1990–2010 based on GTAP8.0	E_{LUC} for 1997–2011 includes interannual anomalies from fire-based emissions	All years from global average	Based on five ocean models normalised to observations with ratio	Nine DGVMs available for S_{LAND} ; first use of four models to compare with E_{LUC}	
2013 (this study)		250 countries ^b	134 countries and regions 1990–2011 based on GTAP8.1	E_{LUC} for 2012 estimated from 2001–2010 average		Based on six models	Coordinated DGVM experiments for S_{LAND} and E_{LUC}	Confidence levels; cumulative emissions; budget from 1750

^a The naming convention of the budgets has changed. Up to and including 2010, the budget year (Carbon Budget 2010) represented the latest year of the data. From 2012, the budget year (Carbon Budget 2012) refers to the publication year.

^b The CDIAC database has about 250 countries, but we show data for about 216 countries since we aggregate and disaggregate some countries to be consistent with current country definitions (see Sect. 2.1.1 for more details).

emissions except to the extent that they are captured in the UN energy data and counted as gas “flared or lost”.

The published CDIAC data set has 250 countries and regions included. This expanded list includes countries that no longer exist, such as the USSR or East Pakistan. For the budget, we reduce the list to 219 countries by reallocating emissions to the currently defined territories. This involved both aggregation and disaggregation, and does not change global emissions. Examples of aggregation include merging East and West Germany to the currently defined Germany. Examples of disaggregation include reallocating the emissions from the former USSR to the resulting independent countries. For disaggregation, we use the emission shares when the current territory first appeared. For the 2 most recent years, 2011 and 2012, the BP statistics are more aggregated, but we retain the detail in CDIAC by applying the same growth rates to individual countries in CDIAC as in the aggregated regions in the BP data set.

Estimates of CO₂ emissions show that the global total of emissions is not equal to the sum of emissions from all countries. This is largely attributable to emissions that occur in international territory, in particular the combustion of fuels used in international shipping and aviation (bunker fuels), where the emissions are included in the global totals but are not attributed to individual countries. In practice, the emissions from international bunker fuels are calculated based on where the fuels were loaded, but they are not included with national emissions estimates. Smaller differences occur because globally the sum of imports in all countries is not equal to the sum of exports and because of differing treatment of oxidation of non-fuel uses of hydrocarbons (e.g. as solvents, lubricants, feedstocks, etc.), and changes in stock (Andres et al., 2012).

The uncertainty of the annual fossil-fuel and cement emissions for the globe has been estimated at $\pm 5\%$ (scaled down from the published $\pm 10\%$ at $\pm 2\sigma$ to the use of $\pm 1\sigma$ bounds reported here; Andres et al., 2012). This includes an

assessment of uncertainties in the amounts of fuel consumed, the carbon contents of fuels, and the combustion efficiency. While in the budget we consider a fixed uncertainty of $\pm 5\%$ for all years, in reality the uncertainty, as a percentage of the emissions, is growing with time because of the larger share of global emissions from non-Annex B countries (emerging economies and developing countries) with less precise statistical systems (Marland et al., 2009). For example, the uncertainty in Chinese emissions has been estimated at around $\pm 10\%$ (for $\pm 1\sigma$; Gregg et al., 2008). Generally, emissions from mature economies with good statistical bases have an uncertainty of only a few per cent (Marland, 2008). Further

research is needed before we can quantify the time evolution of the uncertainty, and their temporal error correlation structure. We note that even if they are presented as 1σ estimates, uncertainties of emissions are likely to be mainly country-specific systematic errors related to underlying biases of energy statistics and to the accounting method used by each country. We assign a medium confidence to the results presented here because they are based on indirect estimates of emissions using energy data (Durant et al., 2010). Thus there is only limited and indirect evidence for emissions, although there is a high agreement among the available estimates within the given uncertainty (Andres et al., 2012), and

the emission estimates are consistent with a range of other observations (Ciais et al., 2013).

2.1.2 Emissions embodied in goods and services

National emission inventories take a territorial (production) perspective and “include greenhouse gas emissions and removals taking place within national territory and offshore areas over which the country has jurisdiction” (Rypdal et al., 2006). That is, emissions are allocated to the country where and when the emissions actually occur. The territorial emission inventory of an individual country does not include the emissions from the production of goods and services produced in other countries (e.g. food and clothes) that are used for consumption. Consumption-based emission inventories for an individual country is another attribution point of view that allocates global emissions to products that are consumed within a country; these are conceptually calculated as the territorial emissions less the “embedded” territorial emissions to produce exported products plus the emissions in other countries to produce imported products (Consumption = Territorial – Exports + Imports). The difference between the territorial- and consumption-based emission inventories is the net transfer (exports minus imports) of emissions from the production of internationally traded products. Consumption-based emission attribution results (e.g. Davis and Caldeira, 2010) provide additional information to territorial inventories that can be used to understand emission drivers (Hertwich and Peters, 2009), quantify emission transfers by the trade of products between countries (Peters et al., 2011b) and potentially design more effective and efficient climate policy (Peters and Hertwich, 2008).

We estimate consumption-based emissions by enumerating the global supply chain using a global model of the economic relationships between sectors within and between every country (Andrew and Peters, 2013; Peters et al., 2011a). Due to the availability of the input data, detailed estimates are made for the years 1997, 2001, 2004, and 2007 (using the methodology of Peters et al., 2011b) using economic and trade data from the Global Trade and Analysis Project version 8.1 (GTAP; Narayanan et al., 2013). The results cover 57 sectors and 134 countries and regions. The results are extended into an annual time series from 1990 to the latest year of the fossil-fuel emissions or GDP data (2011 in this budget), using GDP data by expenditure in current USD (from the UN National Accounts main Aggregates database; UN, 2013c) and time series of trade data from GTAP (based on the methodology in Peters et al., 2011b).

The consumption-based emission inventories in this carbon budget incorporate several improvements over previous versions (Le Quéré et al., 2013; Peters et al., 2012b, 2011b). The detailed estimates for 2004 and 2007 and time series approximation from 1990–2011 are based on an updated version of the GTAP database (Narayanan et al., 2013). We estimate the sector level CO₂ emissions using our own calcula-

tions based on the GTAP data and methodology, include flaring and cement emissions from CDIAC, and then scale the national totals (excluding bunker fuels) to match the CDIAC estimates from the most recent carbon budget. We do not include international transportation in our estimates of national totals, but include them in the global total. The time series of trade data provided by GTAP covers the period 1995–2009 and our methodology uses the trade shares of this data set. For the period 1990–1994 we assume the trade shares of 1995, while in 2010 and 2011 we assume the trade shares of 2008, since 2009 was heavily affected by the global financial crisis. We identified errors in the trade shares of Taiwan in 2008 and 2009, so the trade shares for 2008–2010 are based on the 2007 trade shares.

We do not provide an uncertainty estimate for these emissions, but based on model comparisons and sensitivity analysis, they are unlikely to be larger than for the territorial emission estimates (Peters et al., 2012a). Uncertainty is expected to increase for more detailed results, and to decrease with aggregation (Peters et al., 2011b; e.g. the results for Annex B will be more accurate than the sector results for an individual country).

The consumption-based emissions attribution method considers the CO₂ emitted to the atmosphere in the production of products, but not the trade in fossil fuels (coal, oil, gas). It is also possible to account for the carbon trade in fossil fuels (Davis et al., 2011), but we do not present that data here. Peters et al. (2012a) additionally consider trade in biomass.

The consumption data do not modify the global average terms in Eq. (1), but are relevant to the anthropogenic carbon cycle, as they reflect the trade-driven movement of carbon across the earth’s surface in response to human activities (both physical for carbon trade in fossil fuels and economic for emissions embedded into products). Furthermore, if national and international climate policies continue to develop in an un-harmonised way, then the trends reflected in these data will need to be accommodated by those developing policies.

2.1.3 Growth rate in emissions

We report the annual growth rate in emissions for adjacent years (in per cent per year) by calculating the difference between the 2 years and then comparing to the emissions in the first year: $\left[\frac{E_{FF(t_0+1)} - E_{FF(t_0)}}{E_{FF(t_0)}} \right] \% \text{ yr}^{-1}$. This is the simplest method to characterise a 1-year growth compared to the previous year and is widely used. We do not apply a leap-year adjustment, which could affect the growth rate by about 0.3 % yr⁻¹ (1/365.25).

The relative growth rate of E_{FF} over time periods of greater than 1 year can be rewritten using its logarithm equivalent as follows:

$$\frac{1}{E_{FF}} \frac{dE_{FF}}{dt} = \frac{d(\ln E_{FF})}{dt}. \quad (2)$$

Here we calculate relative growth rates in emissions for multi-year periods (e.g. a decade) by fitting a linear trend to $\ln(E_{\text{FF}})$ in Eq. (2), reported in per cent per year. We fit the logarithm of E_{FF} rather than E_{FF} directly because this method ensures that computed growth rates satisfy Eq. (6). This method differs from previous papers (Canadell et al., 2007; Le Quéré et al., 2009; Raupach et al., 2007) that computed the fit to E_{FF} and divided by average E_{FF} directly, but the difference is very small ($<0.05\%$) in the case of E_{FF} .

2.1.4 Emissions projections using GDP projections

Energy statistics are normally available around June for the previous year. We use the close relationship between the growth in world gross domestic product (GDP) and the growth in global emissions (Raupach et al., 2007) to project emissions for the current year. This is based on the so-called Kaya identity (also called IPAT identity for human impact (I) on the environment equaling the product of P = population, A = affluence, T = technology), whereby E_{FF} is decomposed by the product of GDP and the fossil-fuel carbon intensity of the economy (I_{FF}) as follows:

$$E_{\text{FF}} = \text{GDP} \times I_{\text{FF}}. \quad (3)$$

Such product-rule decomposition identities imply that the growth rates of the multiplied quantities are additive. Taking a time derivative of Eq. (3) gives:

$$\frac{dE_{\text{FF}}}{dt} = \frac{d(\text{GDP} \times I_{\text{FF}})}{dt} \quad (4)$$

and applying the rules of calculus:

$$\frac{dE_{\text{FF}}}{dt} = \frac{d\text{GDP}}{dt} \times I_{\text{FF}} + \text{GDP} \times \frac{dI_{\text{FF}}}{dt} \quad (5)$$

finally, dividing (5) by (3) gives :

$$\frac{1}{E_{\text{FF}}} \frac{dE_{\text{FF}}}{dt} = \frac{1}{\text{GDP}} \frac{d\text{GDP}}{dt} + \frac{1}{I_{\text{FF}}} \frac{dI_{\text{FF}}}{dt}, \quad (6)$$

where the left-hand term is the relative growth rate of E_{FF} , and the right-hand terms are the relative growth rates of GDP and I_{FF} , respectively, which can simply be added linearly to give overall growth rate. The growth rates are reported in per cent by multiplying each term by 100. As preliminary estimates of annual change in GDP are made well before the end of a calendar year, making assumptions on the growth rate of I_{FF} allows us to make projections of the annual change in CO_2 emissions well before the end of a calendar year.

2.2 CO_2 emissions from land use, land-use change and forestry (E_{LUC})

LUC emissions reported in the 2013 carbon budget (E_{LUC}) include CO_2 fluxes from deforestation, afforestation, logging (forest degradation and harvest activity), shifting cultivation (cycle of cutting forest for agriculture, then abandoning), and regrowth of forests following wood harvest or

abandonment of agriculture. Only some land management activities (Table 5) are included in our LUC emissions estimates (e.g. emissions or sinks related to management of established pasture and croplands are not included). Some of these activities lead to emissions of CO_2 to the atmosphere, while others lead to CO_2 sinks. E_{LUC} is the net sum of all anthropogenic activities considered. Our annual estimate for 1959–2010 is from a bookkeeping method (Sect. 2.2.1) primarily based on net forest area change and biomass data from the Forest Resource Assessment (FRA) of the Food and Agriculture Organization (FAO) which is only available at intervals of 5 years (Houghton et al., 2012). Interannual variability in emissions due to deforestation and degradation have been coarsely estimated from satellite-based fire activity in tropical forest areas (Sect. 2.2.2; Giglio et al., 2010; van der Werf et al., 2010). The bookkeeping method is used mainly to quantify the E_{LUC} over the time period of the available data, and the satellite-based deforestation fire information to reveal interannual variability due to tropical deforestation fires. The satellite-based deforestation and degradation fire emissions estimates are available for years 1997–2011. We calculate the global anomaly in deforestation and degradation fire emissions over tropical forest regions for each year, compared to the 1997–2010 period, and add this to the E_{LUC} estimated using the bookkeeping method which is available up to 2010 only. For 2011 we use the 2011 anomaly from the fire data, with the mean emission from the bookkeeping method over 1997 to 2010. We thus assume that all land management activities apart from deforestation and degradation do not vary significantly on a year-to-year basis. Other sources of interannual variability (e.g. the impact of climate variability on regrowth fluxes and shifting agriculture CO_2 fluxes) are accounted for in S_{LAND} . This is identical to the estimate presented in Le Quéré et al. (2013), except for a small update in the bookkeeping estimate from revisions in the data (Sect. 2.2.1). Fire emissions were not available for year 2012. E_{LUC} for 2012 is thus assigned the mean of 2001–2010 (last decade where the bookkeeping method is available) and a low confidence. In addition, we use results from nine dynamic global vegetation models (see Sect. 2.2.3 and Table 6) that calculate net LUC CO_2 emissions in response to observed land cover change prescribed to each model, to help quantify the uncertainty in E_{LUC} , and to explore the consistency of our understanding. The three methods are described below, and differences are discussed in Sect. 3.2.

2.2.1 Bookkeeping method

LUC CO_2 emissions are calculated by a bookkeeping model approach (Houghton, 2003) that keeps track of the carbon stored in vegetation and soils before deforestation or other land-use change, and the changes in forest age classes, or cohorts, of disturbed lands after land-use change. It tracks the CO_2 emitted to the atmosphere immediately during deforestation, and over time due to the follow-up decay of soil and

vegetation carbon in different pools, including wood products pools after logging and deforestation. It also tracks the regrowth of vegetation and associated build-up of soil carbon pools. It considers transitions between forests, pastures and cropland, shifting cultivation, degradation of forests where a fraction of the trees are removed, abandonment of agricultural land, and forest management such as wood harvest and, in the USA, fire management. In addition to tracking logging debris on the forest floor, the bookkeeping model tracks the fate of carbon contained in harvested wood products that is eventually emitted back to the atmosphere as CO₂, although a detailed treatment of the lifetime in each product pool is not performed (Earles et al., 2012). Harvested wood products are partitioned into three pools with different turnover times. All fuel-wood is assumed burnt in the year of harvest (1.0 yr⁻¹). Pulp and paper products are oxidised at a rate of 0.1 yr⁻¹, timber is assumed to be oxidised at a rate of 0.01 yr⁻¹, and elemental carbon decays at 0.001 yr⁻¹. The general assumptions about partitioning wood products among these pools are based on national harvest data (Houghton, 2003).

The primary land cover change and biomass data for the bookkeeping model analysis is the Forest Resource Assessment of the FAO which provides statistics on forest cover change and management at intervals of 5 years (FAO, 2010). The data are based on countries' self-reporting, some of which include satellite data in more recent assessments (Table 4). Changes in land cover other than forest are based on annual, national changes in cropland and pasture areas reported by the FAO Statistics Division (FAOSTAT, 2010). LUC country data are aggregated by regions. The carbon stocks on land (biomass and soils), and their response functions subsequent to LUC, are based on FAO data averages per land cover type, per biome and per region. Similar results were obtained using forest biomass carbon density based on satellite data (Baccini et al., 2012). The bookkeeping model does not include land ecosystems' transient response to changes in climate, atmospheric CO₂ and other environmental factors, but the growth/decay curves are based on contemporary data that will implicitly reflect the effects of CO₂ and climate at that time. Results from the bookkeeping method are available from 1850 to 2010.

2.2.2 Fire-based method

LUC-associated CO₂ emissions calculated from satellite-based fire activity in tropical forest areas (van der Werf et al., 2010) provide information on emissions due to tropical deforestation and degradation that are complementary to the bookkeeping approach. They do not provide a direct estimate of E_{LUC} as they do not include non-combustion processes such as respiration, wood harvest, wood products or forest regrowth. Legacy emissions such as decomposition from on-ground debris and soils are not included in this method either. However, fire estimates provide some insight on the year-to-year variations in the sub-component of the total E_{LUC} flux that result from immediate CO₂ emissions during deforestation caused by the interactions between climate and human activity (e.g. there is more burning and clearing of forests in dry years) that are not represented by other methods. The “deforestation fire emissions” assume an important role of fire in removing biomass in the deforestation process, and thus can be used to infer gross instantaneous CO₂ emissions from deforestation using satellite-derived data on fire activity in regions with active deforestation. The method requires information on the fraction of total area burned associated with deforestation versus other types of fires, and can be merged with information on biomass stocks and the fraction of the biomass lost in a deforestation fire to estimate CO₂ emissions. The satellite-based fire emissions are limited to the tropics, where fires result mainly from human activities. Tropical deforestation is the largest and most variable single contributor to E_{LUC} .

Burned area from Giglio et al. (2010) is merged with active fire retrievals to mimic more sophisticated assessments of deforestation rates in the pan-tropics (van der Werf et al., 2010). This information is used as input data in a modified version of the satellite-driven Carnegie Ames Stanford Approach (CASA) biogeochemical model to estimate carbon emissions, keeping track of what fraction was due to deforestation (van der Werf et al., 2010). The CASA model uses different assumptions to compute decay functions compared to the bookkeeping model, and does not include historical emissions or regrowth from land-use change prior to the

availability of satellite data. Comparing coincident CO emissions and their atmospheric fate with satellite-derived CO concentrations allows for some validation of this approach (e.g. van der Werf et al., 2008). Results from the fire-based method are available from 1997 to 2011 only. Our combination of LUC CO₂ emissions where the variability of instantaneous CO₂ deforestation emissions is diagnosed from fires assumes that year-to-year variability is dominated by variability in deforestation due to the large carbon losses involved.

2.2.3 Dynamic global vegetation models (DGVMs)

LUC CO₂ emissions have been estimated using an ensemble of nine DGVMs (from four in the 2012 carbon budget). New model experiments up to year 2012 have been coordinated by the project “Trends and drivers of the regional-scale sources and sinks of carbon dioxide” (TRENDY; <http://dgvn.ceh.ac.uk/node/9>). We use only models that have estimated LUC CO₂ emissions and the terrestrial residual sink following the TRENDY protocol (see Sect. 2.5.2), thus providing better consistency in the assessment of the causes of carbon fluxes on land. Models use their latest configurations, summarised in Tables 5 and 6.

The DGVMs were forced with historical changes in land cover distribution, climate, atmospheric CO₂ concentration, and N deposition. As further described below, each historical DGVM simulation was repeated with a time-invariant preindustrial land cover distribution, allowing to estimate, by difference with the first simulation, the dynamic evolution of biomass and soil carbon pools in response to prescribed land cover change. All DGVMs represent deforestation and (to some extent) regrowth, the most important components of E_{LUC} , but they do not represent all processes resulting directly from human activities on land (Table 5). DGVMs represent processes of vegetation establishment, growth, mortality and decomposition associated with natural cycles and include the vegetation and soil response to increasing atmospheric CO₂ levels, to climate variability and change, in addition to atmospheric N deposition in the presence of nitrogen limitation (in four models; Table 5). The DGVMs are independent from the other budget terms, except for their use of atmospheric CO₂ concentration to calculate the fertilisation effect of CO₂ on primary production.

The DGVMs used a consistent land-use change data set (Hurtt et al., 2011), which provided annual, half-degree, fractional data on cropland, pasture, primary vegetation and secondary vegetation, as well as all underlying transitions between land-use states, including wood harvest and shifting cultivation. This data set used the HYDE (Klein Goldewijk et al., 2011) spatially gridded maps of cropland, pasture, and ice/water fractions of each grid cell as an input. The HYDE data are based on annual FAO statistics of change in agricultural area (FAOSTAT, 2010). For the year 2012, the HYDE data set was extrapolated from 2011, based on the trend in

agricultural area over the previous 5 years. The HYDE data set is independent from the data set used in the bookkeeping method (Houghton, 2003 and updates), which is based primarily on forest area change statistics (FAO, 2010). Although the Hurtt land-use change data set indicates whether land-use changes occur on forested or non-forested land, typically only the changes in agricultural areas are used by the models and are implemented differently within each model (e.g. an increased cropland fraction in a grid cell can either be at the expense of grassland, or forest, the latter resulting in deforestation; land cover fractions of the non-agricultural land differ between models). Similarly, model-specific assumptions are also applied for the conversion of wood harvest mass or area and other product pools into carbon in some models (Table 5).

The DGVM model runs were forced by observed monthly temperature, precipitation, and cloud cover fields, provided on a 0.5° × 0.5° grid and updated to 2012 by the Climatic Research Unit (Harris et al., 2013). The forcing data include both gridded observations of climate change and change in global atmospheric CO₂ (Dlugokencky and Tans, 2013), and N deposition (as used in four models, Table 5; Lamarque et al., 2010). E_{LUC} is diagnosed in each model by the difference between a model simulation with prescribed historical land cover change and a simulation with constant, preindustrial land cover distribution. Both simulations were driven by changing atmospheric CO₂, climate, and in some models N deposition over the period 1860–2012. Using the difference between these two DGVM simulations to diagnose E_{LUC} is not consistent with the definition of E_{LUC} in the bookkeeping model (Gasser and Ciais, 2013; Pongratz et al., 2013). The DGVM approach to diagnose land-use change CO₂ emissions would be expected to produce systematically higher E_{LUC} emissions than the bookkeeping approach if all the parameters of the two approaches were the same (which is not the case). Here, given the different input data of DGVMs and the bookkeeping approach, this systematic difference cannot be quantified.

2.2.4 Uncertainty assessment for E_{LUC}

Differences between the bookkeeping, the addition of fire-based interannual variability to the bookkeeping, and DGVM methods originate from three main sources: the land cover change data set, different approaches in models, and in the different processes represented (Table 5). We examine the results from the nine DGVM models and of the bookkeeping method to assess the uncertainty in E_{LUC} .

The uncertainties in the annual E_{LUC} estimates are examined using the standard deviation across models, which ranged from 0.3 to 0.9 GtC yr⁻¹, with an average of 0.5 GtC yr⁻¹ from 1959 to 2012 (Table 7). The mean of the multi-model E_{LUC} estimates is higher than the bookkeeping estimate used in the budget with a mean absolute difference of 0.3 GtC for 1959 to 2010. The multi-model mean and

bookkeeping method differ by less than 0.5 GtC yr^{-1} over 85 % of the time. Based on this comparison, we assess that an uncertainty of $\pm 0.5 \text{ GtC yr}^{-1}$ provides a semi-quantitative measure of uncertainty for annual emissions, and reflects our best value judgment that there is at least a 68 % chance ($\pm 1\sigma$) that the true LUC emission lies within the given range for the range of processes considered here. This is consistent with the analysis of Houghton et al. (2012), which partly reflects improvements in data on forest area change using satellite data, and partly more complete understanding and representation of processes in models.

The uncertainties in the decadal mean estimates from the DGVM ensemble are likely correlated between decades, and thus we apply the annual uncertainty as a measure of the decadal uncertainty. The correlations between decades come from (1) common biases in system boundaries (e.g. not counting forest degradation in some models); (2) common definition for the calculation of E_{LUC} from the difference of simulations with and without LUC (a source of bias vs. the unknown truth); (3) common and uncertain land-cover change input data which also cause a bias, though if a different input data set is used each decade, decadal fluxes from DGVMs may be partly decorrelated; and (4) model structural errors (e.g. systematic errors in biomass stocks). In addition, errors arising from uncertain DGVM parameter values would be random but they are not accounted for in this study, since no DGVM provided an ensemble of runs with perturbed parameters.

Prior to 1959, the uncertainty in E_{LUC} is taken as $\pm 33\%$, which is the ratio of uncertainty to mean from the 1960s (Table 7), the first decade available. This ratio is consistent with the mean standard deviation of DGVMs LUC emissions over the period 1901–1958 (0.42 GtC) over the multi-model mean (1.3 GtC).

2.3 Atmospheric CO_2 growth rate (G_{ATM})

2.3.1 Global atmospheric CO_2 growth rate estimates

The atmospheric CO_2 growth rate is provided by the US National Oceanic and Atmospheric Administration Earth System Research Laboratory (NOAA/ESRL; Dlugokencky and Tans, 2013), which is updated from Ballantyne et al. (2012). For the 1959–1980 period, the global growth rate is based on measurements of atmospheric CO_2 concentration averaged from the Mauna Loa and South Pole stations, as observed by the CO_2 Program at Scripps Institution of Oceanography (Keeling et al., 1976). For the 1980–2012 time period, the global growth rate is based on the average of multiple-station selected from the marine boundary layer sites with well-mixed background air (Ballantyne et al., 2012), after fitting each station with a smoothed curve as a function of time, and averaging by latitude band (Masarie and Tans, 1995). The annual growth rate is estimated from atmospheric CO_2 concentration by taking the average of the most recent December–

January months corrected for the average seasonal cycle and subtracting this same average one year earlier. The growth rate in units of ppm yr^{-1} is converted to fluxes by multiplying by a factor of $2.120 \text{ GtC per ppm}$ (Prather et al., 2012) for comparison with the other components.

The uncertainty around the annual growth rate based on the multiple stations data set ranges between 0.11 and 0.72 GtC yr^{-1} , with a mean of 0.60 GtC yr^{-1} for 1959–1980 and 0.19 GtC yr^{-1} for 1980–2012, when a larger set of stations were available. It is based on the number of available stations, and thus takes into account both the measurement errors and data gaps at each station. This uncertainty is larger than the uncertainty of $\pm 0.1 \text{ GtC yr}^{-1}$ reported for decadal mean growth rate by the IPCC because errors in annual growth rate are strongly anti-correlated in consecutive years, leading to smaller errors for longer timescales. The decadal change is computed from the difference in concentration 10 years apart based on a measurement error of 0.35 ppm . This error is based on offsets between NOAA/ESRL measurements and those of the World Meteorological Organization World Data Center for Greenhouse Gases (NOAA/ESRL, 2013) for the start and end points (the decadal change uncertainty is the $\sqrt{2 * (0.35 \text{ ppm})^2}$ 10 years $^{-1}$ assuming that each yearly measurement error is independent). This uncertainty is also used in Table 8.

The contribution of anthropogenic CO and CH_4 is neglected from the global carbon budget (see Sect. 2.6.1). We assign a high confidence to the annual estimates of G_{ATM} because they are based on direct measurements from multiple and consistent instruments and stations distributed around the world (Ballantyne et al., 2012).

In order to estimate the total carbon accumulated in the atmosphere since 1750 or 1870, we use an atmospheric CO_2 concentration of $277 \pm 3 \text{ ppm}$ or $288 \pm 3 \text{ ppm}$, respectively, based on a cubic spline fit to ice core data (Joos and Spahni, 2008). The uncertainty of $\pm 3 \text{ ppm}$ (converted to $\pm 1\sigma$) is taken directly from the IPCC's assessment (Ciais et al., 2013). Typical uncertainties in the atmospheric growth rate from ice core data are $\pm 1\text{--}1.5 \text{ GtC per decade}$, as evaluated from the Law Dome data (Etheridge et al., 1996) for individual 20-year intervals over the period 1870–1960 (Bruno and Joos, 1997).

2.4 Ocean CO_2 sink

Estimates of the global ocean CO_2 sink are based on a combination of a mean CO_2 sink estimate for the 1990s from observations, and a trend and variability in the ocean CO_2 sink for 1959–2012 from six global ocean biogeochemistry models. Observation-based products that estimate the annual CO_2 sink are beginning to emerge. These are used here for the first time to provide a qualitative assessment of confidence in the reported results.

Table 7. Comparison of results from the bookkeeping model and budget residuals with results from the DGVMs for the periods 1960–1969, 1970–1979, 1980–1989, 1990–1999, 2000–2009 and the last decade-available. All values are in GtC yr^{-1} . The DGVM uncertainties represent $\pm 1\sigma$ of results from the nine individual models.

Ocean sink (S_{OCEAN}) ^b	1.2 ± 0.5	1.5 ± 0.5	1.9 ± 0.5	2.2 ± 0.4	2.4 ± 0.5	2.5 ± 0.5	2.9 ± 0.5
Residual terrestrial sink (S_{LAND})	1.7 ± 0.7	1.7 ± 0.8	1.6 ± 0.8	2.6 ± 0.7	2.4 ± 0.8	2.8 ± 0.8	2.7 ± 0.9

^a E_{LUC} for 2012 is assigned the mean of 2001–2010 as the estimate based on the bookkeeping method was not available for that year.

^b The uncertainty in S_{OCEAN} for the 1990s is directly based on observations, while that for other decades combines the uncertainty from observations with the model spread (Sect. 2.4.3).

2.4.1 Observation-based estimates

A mean ocean CO_2 sink of $2.2 \pm 0.4 \text{ GtC yr}^{-1}$ for the 1990s was estimated by the IPCC (Denman et al., 2007) based on indirect observations and their spread: ocean/land CO_2 sink partitioning from observed atmospheric O_2/N_2 concentration trends (Manning and Keeling, 2006), an oceanic inversion method constrained by ocean biogeochemistry data (Mikaloff Fletcher et al., 2006), and a method based on penetration timescale for CFCs (McNeil et al., 2003). This is comparable with the sink of $2.0 \pm 0.5 \text{ GtC yr}^{-1}$ estimated by Khatiwala et al. (2013) for the 1990s, and with the sink of 1.9 to 2.5 estimated from a range of methods for the period 1990–2009 (Wanninkhof et al., 2013), with uncertainties ranging from $\pm 0.3 \text{ GtC yr}^{-1}$ to $\pm 0.7 \text{ GtC yr}^{-1}$.

The interannual variability in the ocean CO_2 sink was estimated for 1990–2011 by Rödenbeck et al. (2014, version “oc_v1.2”) using an inversion method based on observed oceanic partial pressure of CO_2 ($p\text{CO}_2$) derived from the Surface Ocean CO_2 Atlas (SOCAT v2), a database of quality-controlled surface ocean fugacity of CO_2 ($p\text{CO}_2$ corrected for the non-ideal behaviour of the gas; Bakker et al., 2014;

Pfeil et al., 2013). Interannual variability in ocean CO_2 was also estimated with an update of Park et al. (2010) based on regional correlations between surface temperature and $p\text{CO}_2$, changes in surface temperature observed by satellite, and wind speed estimates also from satellite data for 1990–2009 (Atlas et al., 2011). This estimate provides a data-based assessment of the interannual variability combined with a model-based assessment of the trend and mean in S_{OCEAN} .

We use the data-based product of Khatiwala et al. (2009) updated by Khatiwala et al. (2013) to estimate the anthropogenic carbon accumulated in the ocean during the period 1765–1958 (60.2 GtC) and 1870–1958 (47.5 GtC), and assume an oceanic uptake of 0.4 GtC for 1750–1765 where no data are available based on the mean uptake during the period 1765–1770. The estimate of Khatiwala et al. (2009) is based on regional disequilibrium between surface $p\text{CO}_2$ and atmospheric CO_2 , and a Green’s function utilising transient ocean tracers like CFCs and ^{14}C to ascribe changes through time. It does not include changes associated with changes in ocean circulation, temperature and climate, but these are thought to be small over the time period considered here (Ciais et

al., 2013). The uncertainty in cumulative uptake of ± 20 GtC (converted to $\pm 1\sigma$) is taken directly from the IPCC's review of the literature (Rhein et al., 2013), or about $\pm 30\%$ for the annual values (Khatiwala et al., 2009).

2.4.2 Global ocean biogeochemistry models

The trend in the ocean CO₂ sink for 1959–2012 is computed using a combination of six global ocean biogeochemistry models (Table 6). The models represent the physical, chemical and biological processes that influence the surface ocean concentration of CO₂ and thus the air–sea CO₂ flux. The models are forced by meteorological reanalysis data and atmospheric CO₂ concentration available for the entire time period. Models do not include the effects of anthropogenic changes in nutrient supply. They compute the air–sea flux of CO₂ over grid boxes of 1 to 4° in latitude and longitude. The ocean CO₂ sink for each model is normalised to the observations, by dividing the annual model values by their observed average over 1990–1999, and multiplying this by the observation-based estimate of 2.2 GtC yr⁻¹. The ocean CO₂ sink for each year (t) is therefore

$$S_{\text{OCEAN}}(t) = \frac{1}{n} \sum_{m=1}^{m=n} \frac{S_{\text{OCEAN}}^m(t)}{S_{\text{OCEAN}}^m(1990-1999)} \times 2.2, \quad (7)$$

where n is the number of models. This normalisation ensures that the ocean CO₂ sink for the global carbon budget is based on observations, and that the trends and annual values in CO₂ sinks are consistent with model estimates. The normalisation based on a ratio assumes that if models over- or underestimate the sink in the 1990s, it is primarily due to the process of diffusion, which depends on the gradient of CO₂. Thus a ratio is more appropriate than an offset as it takes into account the time-dependence of CO₂ gradients in the ocean. We use the four models published in Le Quéré et al. (2009), including updates, of Aumont and Bopp (2006), Doney et al. (2009), Buitenhuis et al. (2010), and Galbraith et al. (2010) and further model estimates updated from Assman et al. (2010) and Ilyina et al. (2013); see Table 6. All models are available to 2012 except Galbraith et al. (2010), which is available to 2008. The mean uncorrected ocean CO₂ sink from the six models for 1990–1999 ranges between 1.5 and 2.6 GtC yr⁻¹, with a multi-model mean of 2.1 GtC yr⁻¹.

2.4.3 Uncertainty assessment for S_{OCEAN}

The uncertainty around the mean ocean sink of anthropogenic CO₂ was already quantified for the 1990s (see Sect. 2.4.1). To quantify the uncertainty around annual values, we examine the standard deviation of the normalised model ensemble. We use further information from the two data-based products to assess the confidence level. The standard deviation of the ocean model ensemble averages to 0.13 GtC yr⁻¹ during the period 1980–2010 (with

a maximum of 0.22), but it increases as the model ensemble goes back in time, with a standard deviation of 0.29 GtC yr⁻¹ across models in the 1960s. We estimate that the uncertainty in the annual ocean CO₂ sink is about ± 0.5 GtC yr⁻¹ from the quadratic sum of the data uncertainty of ± 0.4 GtC yr⁻¹ and standard deviation across models of up to ± 0.29 GtC yr⁻¹, reflecting both the uncertainty in the mean sink and in the interannual variability as assessed by models.

We examine the consistency between the variability of the model-based and the data-based products to assess confidence in S_{OCEAN} . The interannual variability of the ocean fluxes of the two data-based estimates for 1990–2009 (when they overlap) is ± 0.35 GtC yr⁻¹ (Rödenbeck et al., 2014) and ± 0.14 GtC yr⁻¹ (Park et al., 2010), compared to ± 0.20 GtC yr⁻¹ for the model mean. The phase is generally consistent between estimates, with a higher ocean CO₂ sink during El Niño events. The two data-based estimates correlate with the ocean CO₂ sink estimated here with the same correlation of $r = 0.59$ (simple linear regression), but with a mutual correlation between data-based estimates of 0.30 only. A comparison of variability in regional fluxes also shows generally consistent patterns in amplitude, although not everywhere in phase (not shown). We assess a medium confidence level to the annual ocean CO₂ sink and its uncertainty because they are based on multiple lines of evidence, and the results are consistent in that the interannual variability in the model and data-based estimates are both generally small and consistent in time, but nevertheless not in high agreement.

2.5 Terrestrial CO₂ sink

The difference between the fossil-fuel (E_{FF}) and LUC net emissions (E_{LUC}), the growth rate in atmospheric CO₂ concentration (G_{ATM}) and the ocean CO₂ sink (S_{OCEAN}) is attributable to the net sink of CO₂ in terrestrial vegetation and soils (S_{LAND}), within the given uncertainties. Thus, this sink can be estimated either as the residual of the other terms in the mass balance budget but also directly calculated using DGVMs. The residual land sink (S_{LAND}) is in part due to the fertilising effect of rising atmospheric CO₂ on plant growth, N deposition and climate change effects, such as the lengthening of the growing season in northern temperate and boreal areas. S_{LAND} does not include gross land sinks directly resulting from LUC (e.g. regrowth of vegetation) as these are estimated as part of the net land use flux (E_{LUC}). System boundaries make it difficult to attribute exact CO₂ fluxes on land between S_{LAND} and E_{LUC} (Erb et al., 2013), and by design most of the uncertainties in our method are allocated to S_{LAND} for those processes that are poorly known or represented in models.

2.5.1 Residual of the budget

For 1959–2012, the terrestrial carbon sink was estimated from the residual of the other budget terms by rearranging Eq. (1):

$$S_{\text{LAND}} = E_{\text{FF}} + E_{\text{LUC}} - (G_{\text{ATM}} + S_{\text{OCEAN}}). \quad (8)$$

The uncertainty in S_{LAND} is estimated annually from the quadratic sum of the uncertainty in the right-hand terms assuming the errors are not correlated. The uncertainty averages to $\pm 0.8 \text{ GtC yr}^{-1}$ over 1959–2012 (Table 7). S_{LAND} estimated from the residual of the budget includes, by definition, all the missing processes and potential biases in the other components of Eq. (8).

2.5.2 DGVMs

A comparison of the residual calculation of S_{LAND} in Eq. (8) with the same DGVMs used to estimate E_{LUC} in Sect. 2.2.3, but here excluding the effects of changes in land cover (using a constant preindustrial land cover distribution), provides an independent estimate of the consistency of S_{LAND} with our understanding of the functioning of the terrestrial vegetation in response to CO_2 and climate variability (Table 7). As described in Sect. 2.2.3, the DGVM runs that exclude the effects of changes in land cover include all climate variability and CO_2 effects over land, but do not include reductions in CO_2 sink capacity associated with human activity directly affecting changes in vegetation cover and management, which by design is allocated to E_{LUC} . This effect has been estimated to have led to a reduction in the terrestrial sink by 0.5 GtC yr^{-1} since 1750 (Gitz and Ciais, 2003). The models estimate the mean and variability of S_{LAND} based on atmospheric CO_2 and climate, and thus both terms can be compared to the budget residual.

The multi-model DGVM mean of $2.6 \pm 0.9 \text{ GtC yr}^{-1}$ for the period 2003–2012 agrees well with the value computed from the budget residual (Table 7). The standard deviation of the annual CO_2 sink across the nine DGVMs ranges from ± 0.3 to $\pm 1.2 \text{ GtC yr}^{-1}$, with a mean standard deviation of $\pm 0.8 \text{ GtC yr}^{-1}$ for the period 1959–2012. The model mean correlates with the budget residual with $r = 0.73$, compared to correlations of $r = 0.47$ to $r = 0.71$ (median of 0.65) by individual models. The standard deviation is similar to that of the five model ensembles presented in Le Quéré et al. (2009), but the correlation is improved compared to $r = 0.54$ obtained in the earlier study. The DGVM results confirm that the sum of our knowledge on annual CO_2 emissions and their partitioning is plausible (see Discussion), and they enable the attribution of the fluxes to the underlying processes and provide a breakdown of the regional contributions (not shown here). However as the standard deviation across the DGVMs (of $\pm 0.8 \text{ GtC yr}^{-1}$) is of the same magnitude as the combined uncertainty due to the other components (E_{FF} , E_{LUC} , G_{ATM} , S_{OCEAN} ; Table 7), the DGVMs do not provide further reduc-

tion of uncertainty on the terrestrial CO_2 sink compared to the residual of the budget (Eq. 8). Yet, DGVM results are largely independent from the residual of the budget, and it is worth noting that the residual method and DGVM results are consistent within their respective uncertainties. We assess a medium confidence level to the annual land CO_2 sink and its uncertainty because the estimates from the residual budget and DGVMs match well within the given uncertainty, and the estimates based on the residual budget are primarily dependent on E_{FF} and G_{ATM} , both of which are well constrained.

2.6 Processes not included in the global carbon budget

2.6.1 Contribution of anthropogenic CO and CH_4 to the global carbon budget

Anthropogenic emissions of CO and CH_4 to the atmosphere are eventually oxidised to CO_2 and thus are part of the global carbon budget. These contributions are omitted in Eq. (1), but an attempt is made in this section to estimate their magnitude, and identify the sources of uncertainty. Anthropogenic CO emissions are from incomplete fossil-fuel and biofuel burning and deforestation fires. The main anthropogenic emissions of fossil CH_4 that matter for the global carbon budget are the fugitive emissions of coal, oil and gas upstream sectors (see below). These emissions of CO and CH_4 contribute a net addition of fossil carbon to the atmosphere.

In our estimate of E_{FF} we assume that all the fuel burned is emitted as CO_2 , thus CO emissions and their atmospheric oxidation into CO_2 within a few months are already counted implicitly in E_{FF} and should not be counted twice (same for E_{LUC} and CO deforestation fires). Anthropogenic emissions of fossil CH_4 are not included in the fossil-fuel CO_2 emissions E_{FF} , because these mainly fugitive emissions are not included in fuel inventories, but they contribute to the carbon budget after CH_4 gets oxidised into CO_2 (lifetime 9.1 years; Masson-Delmotte et al., 2013). These anthropogenic fossil CH_4 emissions are estimated to be 0.07 GtC yr^{-1} [0.06–0.09] (after Kirschke et al., 2013). After 1 year, 89 % of these emissions thus remain in the atmosphere as CH_4 and contribute to the observed CH_4 global growth rate but not to the CO_2 growth rate, whereas the rest (11 %) gets oxidised into CO_2 , and contributes to the CO_2 growth rate. Given that anthropogenic fossil-fuel CH_4 emissions represent a fraction of 15 % of the total global CH_4 source (Kirschke et al., 2013) we assumed that a fraction of 0.15×0.92 of the observed global growth rate of CH_4 of 6 TgC yr^{-1} during the period 2000–2009 is due to fossil CH_4 sources. Therefore, annual fossil-fuel CH_4 emissions contribute 0.8 TgC yr^{-1} to the CH_4 growth rate and 0.8 TgC yr^{-1} (units of C in CO_2 form) to the CO_2 growth rate. Summing up the effect of fossil-fuel CH_4 emissions from each previous year during the past 10 years, a fraction of which is oxidised into CO_2 in the current year, this defines a contribution of 5 TgC yr^{-1} to the CO_2 growth rate, or about 0.1 %. Thus the effect of

anthropogenic fossil CH_4 emissions and their oxidation to CO_2 in the atmosphere can be assessed to have a negligible effect on the observed CO_2 growth rate, although they do contribute significantly to the global CH_4 growth rate.

Other anthropogenic biogenic sources of CO and CH_4 from wildfires, biomass, wetlands or permafrost changes are similarly assumed to have a small effect on the CO_2 growth rate.

2.6.2 Anthropogenic carbon fluxes in the land to ocean continuum

The approach used to determine the global carbon budget considers only anthropogenic CO_2 emissions and their partitioning among the atmosphere, ocean and land. In analysis, the land and ocean reservoirs that take up anthropogenic CO_2 from the atmosphere are conceived as independent carbon storage repositories. This approach thus omits that carbon is continuously displaced along the land–ocean aquatic continuum (LOAC) comprising freshwaters, estuaries and coastal areas. Carbon is transferred both in inorganic (bicarbonates and dissolved CO_2), and organic (dissolved and particulate organic carbon) forms along this continuum. During its journey from upland terrestrial ecosystems to the oceans, carbon is not only transferred laterally, but is also sequestered in, for example, freshwater and coastal sediments (Krumins et al., 2013; Tranvik et al., 2009) or released back to the atmosphere, mainly as respired CO_2 (Aufdenkampe et al., 2011; Battin et al., 2009; Cole et al., 2007; Laruelle et al., 2010; Regnier et al., 2013), and to a much lesser extent, as CH_4 (Bastviken et al., 2011; Borges and Abril, 2011). A significant fraction of this lateral carbon flux is entirely “natural” and is thus a steady-state component of the preindustrial carbon cycle that can be ignored in the current analysis. The remaining fraction is anthropogenic carbon entrained into the lateral transport loop of the LOAC, a perturbation that is relevant for the global carbon budget presented here.

The recent synthesis by Regnier et al. (2013) is the first attempt to estimate the anthropogenic component of LOAC carbon fluxes and their significance for the global carbon budget. The results of their analysis can be summarised in three points of relevance to the budget. First, only a portion of the anthropogenic CO_2 taken up by land ecosystems is sequestered in soil and biomass pools, as $1 \pm 0.5 \text{ GtC yr}^{-1}$ is exported to the LOAC. This flux is comparable to the C released into the atmosphere by LUC (Table 8). Second, the exported anthropogenic carbon is both stored ($0.55 \pm 0.3 \text{ GtC yr}^{-1}$) and released back into the atmosphere as CO_2 ($0.35 \pm 0.2 \text{ GtC yr}^{-1}$), the magnitude of these fluxes resulting from the combined effects of freshwaters, estuaries and coastal seas. Third, a small fraction of anthropogenic carbon displaced by the LOAC accumulates in the open ocean ($0.1 \pm 0.05 \text{ GtC yr}^{-1}$). The anthropogenic perturbation of the carbon fluxes from land to ocean does not contradict the method used in Sect. 2.5 to define the ocean

Figure 1. Schematic representation of the overall perturbation of the global carbon cycle caused by anthropogenic activities, averaged globally for the decade 2003–2012. The arrows represent emission from fossil-fuel burning and cement production (E_{FF}); emissions from deforestation and other land-use change (E_{LUC}); the growth of carbon in the atmosphere (G_{ATM}) and the uptake of carbon by the “sinks” in the ocean (S_{OCEAN}) and land (S_{LAND}) reservoirs. All fluxes are in units of GtC yr^{-1} , with uncertainties reported as $\pm 1\sigma$ (68 % confidence that the real value lies within the given interval) as described in the text. This figure is an update of one prepared by the International Geosphere Biosphere Programme for the GCP, first presented in Le Quéré (2009).

sink and residual land sink. However, it does point to the need to account for the fate of anthropogenic carbon once it is removed from the atmosphere by land ecosystems (summarised in Fig. 1). In theory, direct estimates of changes of the ocean inorganic carbon inventory over time would see the land flux of anthropogenic carbon and would thus have a bias relative to air–sea flux estimates and tracer based reconstructions. However, currently the value is small enough to be not noticeable relative to the errors in the individual techniques.

Of greater importance is the finding that the residual land sink calculated in a budget which accounts for the LOAC ($3.15 \pm 0.9 \text{ GtC yr}^{-1}$) is larger than the value of $2.8 \pm 0.8 \text{ GtC yr}^{-1}$ reported in Table 7, because this flux is partially offset by the net source of CO_2 to the atmosphere of $0.35 \pm 0.3 \text{ GtC yr}^{-1}$ from rivers, estuaries and coastal seas. In addition, because anthropogenic CO_2 taken up by land ecosystems is exported to the LOAC, the annual land carbon storage change (1.25 GtC yr^{-1}) is notably smaller than the net CO_2 uptake by land ecosystems calculated in the GCP budget (1.9 GtC yr^{-1}), a significant fraction of the displaced carbon (0.65 GtC yr^{-1}) being stored in freshwater and

coastal sediments (0.55 GtC yr^{-1}), and to a lesser extent, in the open ocean (0.1 GtC yr^{-1}).

All estimates of LOAC are given with low confidence, because they originate from a single source. The carbon budget presented here implicitly incorporates the fluxes from the LOAC with S_{LAND} . We do not attempt to separate these fluxes because the uncertainties in either estimate are too large, and there is insufficient information available to estimate the LOAC fluxes on an annual basis.

3 Results

3.1 Global carbon budget averaged over decades and its variability

The global carbon budget averaged over the last decade (2003–2012) is shown in Fig. 1. For this time period, 90 % of the total emissions ($E_{\text{FF}} + E_{\text{LUC}}$) were caused by fossil-fuel combustion and cement production, and 10 % by land-use change. The total emissions were partitioned among the atmosphere (45 %), ocean (26 %) and land (29 %). All components except land-use change emissions have grown since 1959 (Figs. 2 and 3), with important interannual variability in the atmospheric growth rate and in the land CO_2 sink (Fig. 3), and some decadal variability in all terms (Table 8).

Global CO_2 emissions from fossil-fuel combustion and cement production have increased every decade from an average of $3.1 \pm 0.2 \text{ GtC yr}^{-1}$ in the 1960s to an average of $8.6 \pm 0.4 \text{ GtC yr}^{-1}$ during the period 2003–2012 (Table 8 and Fig. 4). The growth rate in these emissions decreased between the 1960s and the 1990s, from $4.5 \% \text{ yr}^{-1}$ in the 1960s, $2.7 \% \text{ yr}^{-1}$ in the 1970s, $2.0 \% \text{ yr}^{-1}$ in the 1980s, $1.1 \% \text{ yr}^{-1}$ in the 1990s, and began increasing again in the 2000s at an average growth rate of $3.1 \% \text{ yr}^{-1}$, decreasing slightly, to $2.7 \% \text{ yr}^{-1}$ for the last decade (2003–2012). In contrast, CO_2 emissions from LUC have remained constant at around $1.5 \pm 0.5 \text{ GtC yr}^{-1}$ between 1960 and 1999, and decreased to $1.0 \pm 0.5 \text{ GtC yr}^{-1}$ between 2003 and 2012. The E_{LUC} estimates from the bookkeeping method and the DGVM models are consistent within their respective uncertainties (Table 7 and Fig. 5). The decrease in emissions from LUC since 2000 is reproduced by the DGVMs (Fig. 5).

The growth rate in atmospheric CO_2 increased from $1.7 \pm 0.1 \text{ GtC yr}^{-1}$ in the 1960s to $4.3 \pm 0.1 \text{ GtC yr}^{-1}$ during the period 2003–2012 with important decadal variations (Table 8). The ocean CO_2 sink increased from $1.2 \pm 0.5 \text{ GtC yr}^{-1}$ in the 1960s to $2.5 \pm 0.5 \text{ GtC yr}^{-1}$ during the period 2003–2012, with interannual variations of the order of a few tenths of GtC yr^{-1} . The low uptake anomaly around year 2000 originates from multiple regions in all models (western equatorial Pacific, Southern Ocean and North Atlantic), and is caused by climate variability. The land CO_2 sink increased from $1.7 \pm 0.7 \text{ GtC yr}^{-1}$ in the 1960s to $2.8 \pm 0.8 \text{ GtC yr}^{-1}$ during the period 2003–2012, with important interannual variations of up to 2 GtC yr^{-1} .

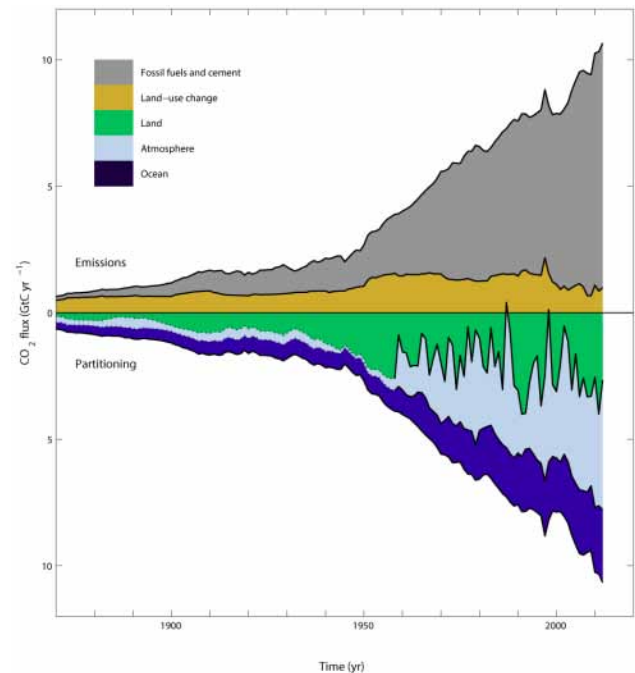

Figure 2. Combined components of the global carbon budget illustrated in Fig. 1 as a function of time, for (top) emissions from fossil-fuel combustion and cement production (E_{FF} ; grey) and emissions from land-use change (E_{LUC} ; brown), and (bottom) their partitioning among the atmosphere (G_{ATM} ; light blue), land (S_{LAND} ; green) and oceans (S_{OCEAN} ; dark blue). All time series are in GtC yr^{-1} . G_{ATM} and S_{OCEAN} (and by construction also S_{LAND}) prior to 1959 are based on different methods and shown as a dashed line. The primary data sources are for fossil-fuel and cement emissions from Boden et al. (2013), with uncertainty of about $\pm 5 \% (\pm 1\sigma)$; land-use change emissions from Houghton et al. (2012) with uncertainties of about $\pm 30 \%$; atmospheric growth rate prior to 1959 is from Joos and Spahni (2008) with uncertainties of about $\pm 1\text{--}1.5 \text{ GtC decade}^{-1}$ or $\pm 0.1\text{--}0.15 \text{ GtC yr}^{-1}$ (Bruno and Joos, 1997), and from Dlugokencky and Tans (2013) from 1959 with uncertainties of about $\pm 0.2 \text{ GtC yr}^{-1}$; ocean sink prior to 1959 is from Khatiwala et al. (2013) with uncertainty of about $\pm 30 \%$, and from this study from 1959 with uncertainties of about $\pm 0.5 \text{ GtC yr}^{-1}$; residual land sink is obtained by difference (Eq. 8), resulting in uncertainties of about $\pm 50 \%$ prior to 1959 and $\pm 0.8 \text{ GtC yr}^{-1}$ after that. See the text for more details of each component and their uncertainties.

The high uptake anomaly around year 1991 is thought to be caused by the effect of the volcanic eruption of Mount Pinatubo on climate and is not generally reproduced by the DGVMs (Fig. 5). The larger land CO_2 sink during the period 2003–2012 is reproduced by the DGVMs in response to combined atmospheric CO_2 increase and climate change and variability, fully consistent with the budget residual (Table 7). Both ocean and land CO_2 sinks increased roughly in line with the atmospheric increase, but with significant decadal variability on land (Table 8).

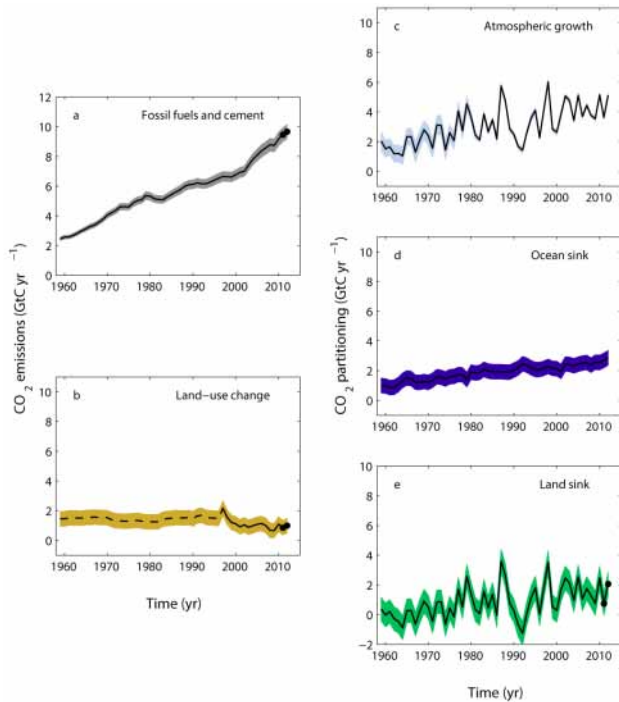

Figure 3. Components of the global carbon budget and their uncertainties as a function of time, presented individually for (a) emissions from fossil-fuel combustion and cement production (E_{FF}), (b) emissions from land-use change (E_{LUC}), (c) atmospheric CO_2 growth rate (G_{ATM}), (d) the ocean CO_2 sink (S_{OCEAN} , positive indicates a flux from the atmosphere to the ocean), and (e) the land CO_2 sink (S_{LAND} , positive indicates a flux from the atmosphere to the land). All time series are in GtC yr^{-1} with the uncertainty bounds representing $\pm 1\sigma$ in shaded colour. Data sources are as in Fig. 2. The black dots in (a), (b) and (e) show values for 2011 and 2012 that originate from a different data set to the remainder of the data, as explained in the text.

3.2 Global carbon budget for year 2012 and emissions projection for 2013

Global CO_2 emissions from fossil-fuel combustion and cement production reached $9.7 \pm 0.5 \text{ GtC}$ in 2012 (Fig. 4), 2.2 % higher than the emissions in 2011. This compares to our estimate of 2.6 % yr^{-1} made last year (Peters et al., 2013), based on an estimated GDP growth of 3.3 % yr^{-1} and improvement in I_{FF} of -0.7 % yr^{-1} (Table 9). The latest estimate of GDP growth for 2012 was 3.2 % yr^{-1} (IMF, 2013) and hence I_{FF} improved -1.0 % yr^{-1} , slightly better than our prediction. The 2012 emissions were distributed among coal (43 %), oil (33 %), gas (18 %), cement (5.3 %) and gas flaring (0.6 %). These first four categories increased by 2.8 %, 1.2 %, 2.5 % and 2.5 %, respectively, over the previous year. Due to lack of data gas flaring in 2012 is assumed equal to 2011.

Using Eq. (6), we estimate that global fossil-fuel CO_2 emissions in 2013 will reach $9.9 \pm 0.5 \text{ GtC}$, or 2.1 % above

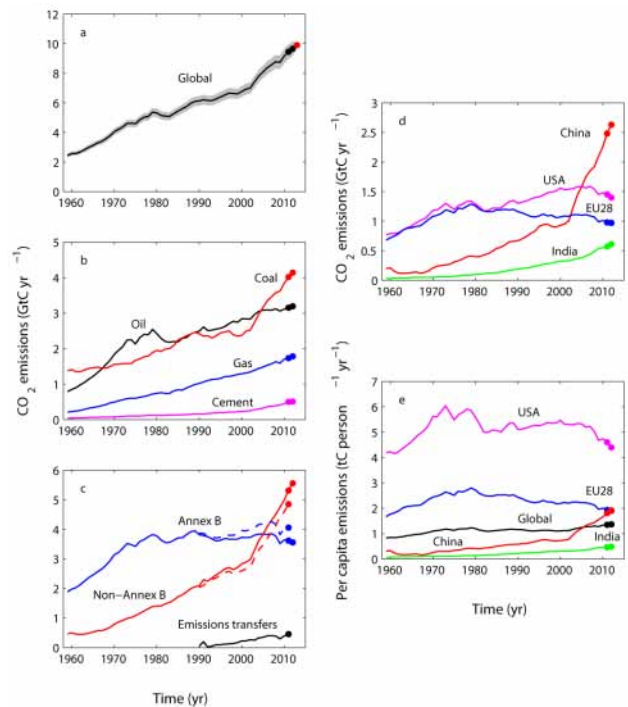

Figure 4. CO_2 emissions from fossil-fuel combustion and cement production for (a) the globe, including an uncertainty of $\pm 5 \%$ (grey shading), the emissions extrapolated using BP energy statistics (black dots) and the emissions projection for year 2012 based on GDP projection (red dot), (b) global emissions by fuel type, including coal (red), oil (black), gas (blue), and cement (purple), and excluding gas flaring which is small (0.7 % in 2011), (c) territorial (full line) and consumption (dashed line) emissions for the countries listed in the Annex B of the Kyoto Protocol (blue lines; mostly advanced economies with emissions limitations) versus non-Annex B countries (red lines); also shown are the emissions transfer from non-Annex B to Annex B countries (black line), (d) territorial CO_2 emissions for the top three country emitters (USA – purple; China – red; India – green) and for the European Union (EU; blue for the 28 member states of the EU in 2012), and (e) per-capita emissions for the top three country emitters and the EU (all colours as in d) and the world (black). In (b–e), the dots show the data that were extrapolated from BP energy statistics for 2011 and 2012. All time series are in GtC yr^{-1} except the per-capita emissions (e), which are in tonnes of carbon per person per year ($\text{tC person}^{-1} \text{ yr}^{-1}$). All territorial emissions are primarily from Boden et al. (2013) as detailed in the text; consumption-based emissions are updated from Peters et al. (2011a).

2012 levels (likely range of 1.1–3.1 %), and that emissions in 2013 will be 61 % above emissions in 1990. The expected value is computed using the world GDP projection of 2.9 % made by the IMF (2013) and a growth rate for I_{FF} of -0.8 % yr^{-1} which is the average from the previous 10 years. The I_{FF} is based on GDP in constant PPP (purchasing power parity) from the IEA (2012) up to 2010 (IEA/OECD, 2012) and extended using the IMF growth rates of 3.9 % in 2011 and 3.2 % in 2012. The uncertainty range is based on an

Table 9. Actual CO₂ emissions from fossil-fuel combustion and cement production (E_{FF}) compared to projections made the previous year based on world GDP (IMF October 2013), and the fossil-fuel intensity of GDP (I_{FF}) based on subtracting the CO₂ and GDP growth rates. The “Actual” values are the latest estimates available and the “Projected” values for 2013 refers to those presented in this paper.

Component	2009 ^a		2010 ^b		2011 ^c		2012 ^d		2013
	Projected	Actual	Projected	Actual	Projected	Actual	Projected	Actual	Projected
E_{FF}	−2.8 %	−0.5 %	> 3 %	4.9 %	3.1 ± 1.5 %	3.2 %	2.6 (1.9–3.5) %	2.2 %	2.1 %
GDP	−1.1 %	−0.4 %	4.8 %	5.2 %	4.0 %	3.9 %	3.3 %	3.2 %	2.9 %
I_{FF}	−1.7 %	−0.9 %	> −1.7 %	−0.3 %	−0.9 ± 1.5 %	−0.7 %	−0.7 %	−1.0 %	−0.8 %

^a Le Quéré et al. (2009); ^b Friedlingstein et al. (2010); ^c Peters et al. (2013); ^d Le Quéré et al. (2013).

uncertainty of 0.6 % for GDP growth (the range in IMF estimates of 2013 GDP growth published in January, April, July, and October 2013 was 3.5 %, 3.3 %, 3.1 % and 2.9 %, respectively) and the range in I_{FF} due to short-term trends of -0.4 yr^{-1} (2008–2012) and medium-term trends of -1.2 yr^{-1} (1990–2012). The combined uncertainty range is therefore 1.1 % (2.9–0.6–1.2; low GDP growth, large I_{FF} improvements) and 3.1 % (2.9 + 0.6–0.4; high GDP growth, small I_{FF} improvements). Projections made in the previous global carbon budgets compared well to the actual CO₂ emissions for that year (Table 9 and Fig. 6) and were useful to capture the current state of the fossil-fuel emissions (see also Peters et al., 2013).

In 2012, global CO₂ emissions were dominated by emissions from China (27 %), the USA (14 %), the EU (28 member states; 10 %), and India (6 %) compared to the global total including bunker fuels. These five regions account for 63 % of global emissions. Growth rates for these countries from 2011 to 2012 were 5.9 % (China), -3.7 % (USA), -1.3 % (EU28), and 7.7 % (India). The countries contributing most to the 2012 change in emissions were China (71 % increase), USA (26 % decrease), India (21 % increase), and Japan (11 % increase). The per-capita CO₂ emissions in 2012 were $1.4 \text{ tC person}^{-1} \text{ yr}^{-1}$ for the globe, and were 4.4 (USA), 1.9 (China), 1.9 (EU) and 0.5 (India) $\text{tC person}^{-1} \text{ yr}^{-1}$ (Fig. 4e).

Territorial-based emissions in Annex B countries remained stable from 1990 to 2011, while consumption-based emissions grew at 0.5 % yr^{-1} (Fig. 4c). In non-Annex B countries, territorial-based emissions have grown at 4.3 % yr^{-1} , while consumption-based emissions have grown at 4.0 % yr^{-1} . In 1990, 62 % of global territorial-based emissions were emitted in Annex B countries (34 % in non-Annex B, and 4 % in bunker fuels used for international shipping and aviation), while in 2011 this had reduced to 38 % (56 % in non-Annex B, and 6 % in bunkers). In terms of consumption-based emissions, this split was 63 % in 1990 and 43 % in 2011 (33 % to 51 % in non-Annex B). The difference between territorial-based and consumption-based emissions (the net emission transfer via international trade) from non-Annex B to Annex B countries has increased from 0.05 GtC yr^{-1} in 1990 to 0.46 GtC in 2011 (Fig. 4), with

an average annual growth rate of 12 % yr^{-1} . The increase in net emission transfers of 0.41 GtC from 1990 to 2011 compares with the emission reduction of 0.21 GtC in Annex B countries. These results clearly show a growing net emission transfer via international trade from non-Annex B to Annex B countries. In 2011, the biggest emitters from a consumption-based perspective were China (22 % of the global total), USA (17 %), EU28 (14 %), and India (5 %).

Based on DGVMs only, the global CO₂ emissions from land-use change activities are estimated as $0.6 \pm 0.7 \text{ GtC}$ in 2012, lower than the 2003–2012 average of $1.1 \pm 0.5 \text{ GtC yr}^{-1}$. However, although the decadal mean generally agreed, the estimated annual variability was not consistent between the bookkeeping method and the DGVMs (Fig. 5a). This could be partly due to the design of the DGVM experiments, which use flux differences between simulations with and without land cover change, and thus may overestimate variability, for example, due to fires in forest regions where the contemporary forest cover is smaller than preindustrial cover used in the without land cover change runs. For this reason we assign a mean value to E_{LUC} for year 2012 based on the 2001–2010 average from the bookkeeping method.

The atmospheric CO₂ growth rate was $5.1 \pm 0.2 \text{ GtC}$ in 2012 ($2.41 \pm 0.09 \text{ ppm}$; Fig. 3; Dlugokencky and Tans, 2013). This is significantly above the 2003–2012 average of $4.3 \pm 0.1 \text{ GtC yr}^{-1}$, though the interannual variability in atmospheric growth rate is large.

The ocean CO₂ sink was $2.9 \pm 0.5 \text{ GtC yr}^{-1}$ in 2012, an increase of 0.2 GtC yr^{-1} over 2011. This is larger than the 2003–2012 average of $2.5 \pm 0.5 \text{ GtC yr}^{-1}$. All models produce an increase in the ocean CO₂ sink in 2012 compared to 2011 except for MICOM-HAMOCC, which shows a very small decrease in the sink.

The terrestrial CO₂ sink calculated as the residual from the carbon budget was $2.7 \pm 0.9 \text{ GtC}$ in 2012, well below the $4.0 \pm 0.9 \text{ GtC}$ in 2011, which was a La Niña year, but near the 2003–2012 average of $2.8 \pm 0.8 \text{ GtC yr}^{-1}$ (Fig. 3). The DGVMs model mean suggests a lower terrestrial CO₂ sink in 2012 of $1.8 \pm 1.1 \text{ GtC}$ (Table 7), possibly from weak El Niño conditions in the Northern Hemisphere spring of year 2012.

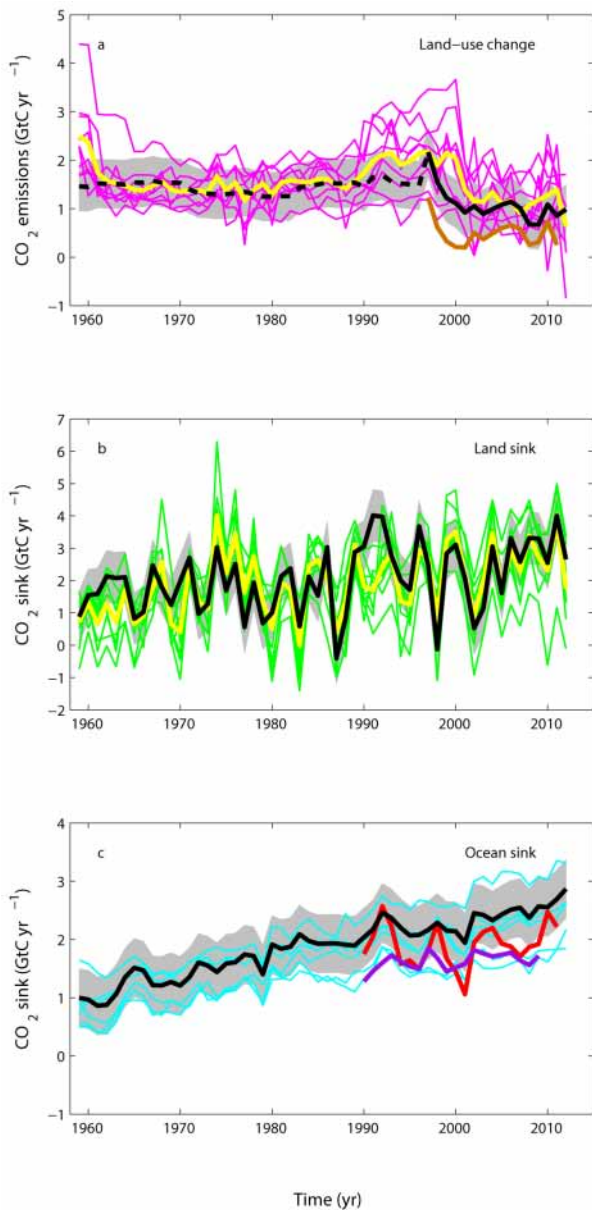

Figure 5. Comparison between the CO₂ budget values estimated here (black line), and other methods and models (Table 6; coloured lines) for (a) CO₂ emissions from land-use change showing individual DGVM model results (magenta) and the multi model mean (yellow line), and fire-based results (orange), LUC data prior to 1997 (dashed black line) highlights the start of satellite data from that year (b) land CO₂ sink (S_{LAND}) showing individual DGVM model results (green) and multi model mean (yellow line), and (c) ocean CO₂ sink (S_{OCEAN}) showing individual models before normalisation (blue lines), and the two data-based products (red line for Rödenbeck et al. (2014) and purple line for Park et al., 2010). Both data-based products were corrected for the preindustrial source of CO₂ from riverine input to the ocean, which is not present in the models, by adding a sink of 0.45 GtC yr⁻¹ (Jacobson et al., 2007), to make them comparable to SOCEAN.

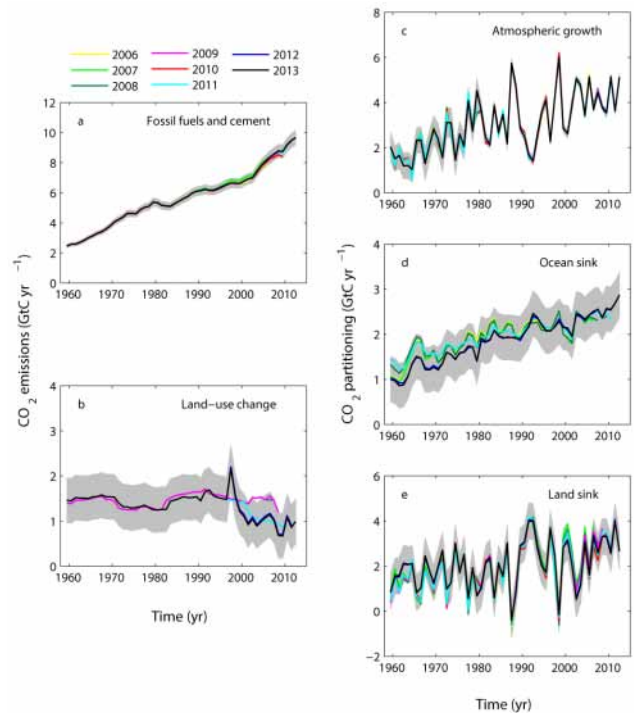

Figure 6. Comparison of global carbon budget components released annually by GCP since 2005. CO₂ emissions from both (a) fossil-fuel combustion and cement production (E_{FF}), and (b) land-use change (E_{LUC}), and their partitioning among (c) the atmosphere (G_{ATM}), (d) the ocean (S_{OCEAN}), and (e) the land (S_{LAND}). See legend for the corresponding years, with the 2006 carbon budget from Raupach et al. (2007); 2007 from Canadell et al. (2007); to 2008 published online only; 2009 from Le Quéré et al. (2009); 2010 from Friedlingstein et al. (2010); 2011 from Peters et al. (2012b); 2012 from Le Quéré et al. (2013); and this year's budget (2013). The budget year generally corresponds to the year when the budget was first released. All values are in GtC yr⁻¹.

The DGVMs thus estimate internally consistent land fluxes over 2012, with both E_{LUC} and S_{LAND} being weaker than those of the carbon budget. Internal consistency is an emerging property of the models, not an a priori constraint as is the residual calculation of S_{LAND} . These results thus suggest that constraints from DGVMs may provide sufficient information to be directly incorporated in the budget calculations in the future.

3.3 Cumulative emissions

Cumulative emissions for 1870–2012 were 380 ± 20 GtC for E_{FF} , and 145 ± 55 GtC for E_{LUC} based on the bookkeeping method of Houghton et al. (2012) for 1870–2010, with an extension to 2012 based on methods described in Sect. 2.2 (Table 10). The cumulative emissions are rounded to the nearest 5 GtC. The total cumulative emissions for 1870–2012 are 525 ± 55 GtC. These emissions were partitioned among the atmosphere (220 ± 5 GtC) based on atmospheric

measurements in ice cores of 288 ppm (Sect. 2.3.1; Joos and Spahni, 2008) and recent direct measurements of 392.52 ppm (Dlugokencky and Tans, 2013), ocean (150 ± 20 GtC using Khatiwala et al. (2013) prior to 1959 and Table 8 otherwise), and the land (155 ± 55 GtC by difference).

Cumulative emissions for the early period 1750–1869 were 3 GtC for E_{FF} , and about 45 GtC for E_{LUC} , of which 15 GtC were emitted in the period 1850–1870 (Houghton et al., 2012) and 30 GtC were emitted in the period 1750–1850 based on the average of four publications (22 GtC by Pongratz et al. (2009); 15 GtC by van Minnen et al. (2009); 64 GtC by Shevliakova et al. (2009) and 24 GtC by Zaehle et al., 2011). The growth in atmospheric CO_2 during that time was about 25 GtC, and the ocean uptake about 15 GtC, implying a land uptake of 10 GtC. These numbers have large relative uncertainties but balance within the limits of our understanding.

Cumulative emissions for 1750–2012 based on the sum of the two periods above were 385 ± 20 GtC for E_{FF} , and 185 ± 65 GtC for E_{LUC} , for a total of 570 ± 70 GtC, partitioned among the atmosphere (245 ± 5 GtC), ocean (165 ± 20 GtC), and the land (160 ± 70 GtC).

Cumulative emissions through to year 2013 can be estimated based on the 2013 projections of E_{FF} (Sect. 3.2), the largest contributor, and assuming a constant E_{LUC} . For 1870–2013, these are 535 ± 55 GtC for total emissions, with about 70 % contribution from E_{FF} (390 ± 20 GtC) and about 30 % contribution from E_{LUC} (145 ± 50 GtC). Cumulative emissions since year 1870 are higher than the emissions of 515 [445 to 585] GtC reported in the IPCC (Stocker et al., 2013b) because they include an additional 21 GtC from emissions in 2012 and 2013 (mostly from E_{FF}). The uncertainty presented here ($\pm 1\sigma$) is smaller than the range of 90 % used by IPCC, but both estimates overlap within their uncertainty ranges.

4 Discussion

Each year when the global carbon budget is published, each component for all previous years is updated to take into account corrections that are due to further scrutiny and verification of the underlying data in the primary input data sets. The updates have generally been relatively small and focused on the most recent years, except for LUC, where they are more significant but still generally within the provided uncertainty range (Fig. 6). The difficulty in accessing land cover change data to estimate E_{LUC} is the key problem to providing continuous records of emissions in this sector. Revisions in E_{LUC} for the 2008/2009 budget were the result of the release of FAO 2010, which contained a major update to forest cover change for the period 2000–2005 and provided the data for the following 5 years to 2010 (Fig. 6b). The differences this year could be attributable to both the different data and the different methods. Updates were at most 0.24 GtC yr⁻¹ for

the fossil fuel and cement emissions, 0.19 GtC yr⁻¹ for the atmospheric growth rate, 0.20 GtC yr⁻¹ for the ocean CO_2 sink, all within the reported uncertainty. The update for the residual land CO_2 sink was also large (Fig. 6e), with a maximum value of 0.71 GtC yr⁻¹, directly reflecting revisions in other terms of the budget, but still within the reported uncertainty.

Our capacity to separate the carbon budget components can be evaluated by comparing the land CO_2 sink estimated with the budget residual (S_{LAND}), which includes errors and biases from all components, with the land CO_2 sink estimated by the DGVM ensemble, which are based on our understanding of processes of how the land responds to increasing CO_2 , climate change and variability. The two estimates are generally close (Fig. 5), both for the mean and for the interannual variability. The DGVM mean correlates with the budget residual with $r = 0.71$ (Sect. 2.5.2; Fig. 5). The DGVMs produce a decadal mean and standard deviation across nine models of 2.5 ± 0.8 GtC yr⁻¹ for the period 2000–2009, nearly the same as the estimate produced with the budget residual (Table 7). Finally the fact that the DGVMs provide an internally consistent split between E_{LUC} and S_{LAND} for year 2012 suggests that they could inform the annual budget analysis more extensively as the effort evolves. Analysis of regional carbon budgets would provide further information to quantify and improve our estimates, as has been undertaken by the Regional Carbon Cycle Assessment and Processes (Canadell et al., 2012–2013).

Annual estimates of each component of the global carbon budgets have their limitations, some of which could be improved with better data and/or better understanding of carbon dynamics. The primary limitations involve resolving fluxes on annual timescales and providing updated estimates for recent years for which data-based estimates are not yet available or only beginning to emerge. Of the various terms in the global budget, only the fossil-fuel burning and atmospheric growth rate terms are based primarily on empirical inputs supporting annual estimates in this carbon budget. The data on fossil-fuel consumption and cement production are based on survey data in all countries. The other terms can be provided on an annual basis only through the use of models. While these models represent the current state of the art, they provide only estimates of actual changes. For example, the decadal trends in ocean uptake and the interannual variations associated with El Niño/La Niña (ENSO) are not directly constrained by observations, although many of the processes controlling these trends are sufficiently well known that the model-based trends still have value as benchmarks for further validation. Data-based products for the ocean CO_2 sink provide new ways to evaluate the model results, and could be used directly as data become more rapidly available and methods for creating such products improve. Estimates of land-use emissions and their year-to-year variability have even larger uncertainty, and much of the underlying data are not available as an annual update. Efforts are underway to

Table 10. Cumulative CO₂ emissions for the periods 1750–2012, 1870–2012 and 1870–2013 in GtC. All uncertainties are reported as $\pm 1\sigma$. All values are rounded to nearest 5 GtC as in Stocker et al. (2013b), reflecting the limits of our capacity to constrain cumulative estimates.

	1750–2012 (GtC)	1870–2012 (GtC)	1870–2013 (GtC)
Emissions			
Fossil-fuel combustion and cement production (E_{FF})	385 \pm 20	380 \pm 20	390 \pm 20*
Land-use change emissions (E_{LUC})	185 \pm 65	145 \pm 55	145 \pm 50*
Total emissions	570 \pm 70	525 \pm 55	535 \pm 55*
Partitioning			
Atmospheric growth rate (G_{ATM})	245 \pm 5	220 \pm 5	
Ocean sink (S_{OCEAN})	165 \pm 20	150 \pm 20	
Residual terrestrial sink (S_{LAND})	160 \pm 70	155 \pm 55	

* The extension to year 2013 uses the emissions projections for 2013 of 9.9 GtC (Sect. 3.2) and assumes a constant E_{LUC} flux as in 2012 (Sect. 2.2).

work with annually available satellite area change data or FAO reported data in combination with fire data and modelling to provide annual updates for future budgets. The best-resolved changes are in atmospheric growth (G_{ATM}), fossil-fuel emissions (E_{FF}), and by difference, the change in the sum of the remaining terms ($S_{OCEAN} + S_{LAND} - E_{LUC}$). The variations from year-to-year in these remaining terms are largely model-based at this time. Further efforts to increase the availability and use of annual data for estimating the remaining terms with annual to decadal resolution are especially needed.

Our approach also depends on the reliability of the energy and land-cover change statistics provided at the country level, and are thus potentially subject to biases. Thus it is critical to develop multiple ways to estimate the carbon balance at the global and regional level, including estimates from the inversion of atmospheric CO₂ concentration, the use of other oceanic and atmospheric tracers, and the compilation of emissions using alternative statistics (e.g. sectors). Multiple approaches ranging from global to regional scale would greatly help increase confidence and reduce uncertainty in CO₂ emissions and their fate.

5 Conclusions

The estimation of global CO₂ emissions and sinks is a major effort by the carbon cycle research community that requires a combination of measurements and compilation of statistical estimates and results from models. The delivery of an annual carbon budget serves two purposes. First, there is a large demand for up-to-date information on the state of the anthropogenic perturbation of the climate system and its underpinning causes. A broad stakeholder community relies on the data sets associated with the annual carbon budget including scientists, policy makers, businesses, journalists, and the broader society increasingly engaged in adapting to and mit-

igating human-driven climate change. Second, over the last decade we have seen unprecedented changes in the human and biophysical environments (e.g. increase in the growth of fossil-fuel emissions, ocean temperatures, and strength of the land sink), which call for more frequent assessments of the state of the planet, and by implications a better understanding of the future evolution of the carbon cycle, and the requirements for climate change mitigation and adaptation. Both the ocean and the land surface presently remove a large fraction of anthropogenic emissions. Any significant change in the function of carbon sinks is of great importance to climate policymaking, as they affect the excess carbon dioxide remaining in the atmosphere and therefore the compatible emissions for any climate stabilisation target. Better constraints of carbon cycle models against contemporary data sets raises the capacity for the models to become more accurate at future projections.

This all requires more frequent, robust, and transparent data sets and methods that can be scrutinised and replicated. After eight annual releases from the GCP, the effort is growing and the traceability of the methods has become increasingly complex. Here, we have documented in detail the data sets and methods used to compile the annual updates of the global carbon budget, explained the rationale for the choices made, the limitations of the information, and finally highlighted the need for additional information where gaps exist.

This paper, via “living data”, will help to keep track of new budget updates. The evolution over time of the carbon budget is now a key indicator of the anthropogenic perturbation of the climate system, and its annual delivery joins a set of other climate indicators to monitor the evolution of human-induced climate change, such as the annual updates on the global surface temperature, sea level rise, minimum Arctic sea ice extent and others.

6 Data access

The data presented here is made available in the belief that their wide dissemination will lead to greater understanding and new scientific insights of how the carbon cycle works, how humans are altering it, and how we can mitigate the resulting human-driven climate change. The free availability of these data does not constitute permission for publication of the data. For research projects, if the data are essential to the work, or if an important result or conclusion depends on the data, co-authorship may need to be considered. Full contact details and information on how to cite the data are given at the top of each page in the accompanying database, and summarised in Table 2.

The accompanying database includes an Excel file organised in the following spreadsheets (accessible with the free viewer <http://www.microsoft.com/en-us/download/details.aspx?id=10>):

1. summary
2. the global carbon budget (1959–2012)
3. global CO₂ emissions from fossil-fuel combustion and cement production by fuel type, and the per-capita emissions (1959–2012)
4. territorial-based (e.g. as reported to the UN Framework Convention on Climate Change) country CO₂ emissions from fossil-fuel combustion and cement production (1959–2012)
5. consumption-based country CO₂ emissions from fossil-fuel combustion and cement production and emissions transfer from the international trade of goods and services (1990–2011)
6. emissions transfers (consumption minus territorial emissions; 1990–2011)
7. CO₂ emissions from land-use change from the individual methods and models (1959–2012)
8. ocean CO₂ sink from the individual ocean models (1959–2012)
9. terrestrial residual CO₂ sink from the DGVMs (1959–2012)
10. additional information on the carbon balance prior to 1959 (1750–2012)
11. country definitions.

Acknowledgements. We thank all people and institutions that provided data used in this carbon budget, P. Cadule, C. Enright, J. Ghattas, and G. Hurtt for support to the model simulations,

F. Joos and S. Khatiwala for providing historical data, M. Heimann and G. McKinley for their comments and suggestions. The observations and modelling analysis were possible thanks to the generous support from the author's institutions and funding from multiple agencies around the world. We thank the many researchers and funding agencies responsible for the collection and quality control of the data included in SOCAT, and the support of the International Ocean Carbon Coordination Project (IOCCP), the Surface Ocean Lower Atmosphere Study (SOLAS), and the Integrated Marine Biogeochemistry and Ecosystem Research program (IMBER). The UK Natural Environment Research Council (NERC) provided funding to C. Le Quéré, R. Moriarty and the GCP through their International Opportunities Fund specifically to support this publication (project NE/103002X/1). R. J. Andres and T. A. Boden were supported by the US Department of Energy, Office of Science, Biological and Environmental Research (BER) programs under US Department of Energy contract DE-AC05-00OR22725. G. P. Peters and R. M. Andrews were supported by the Norwegian Research Council (221355). A. Arneeth, A. Omar, C. Le Quéré, J. Schwinger, P. Ciais, P. Friedlingstein, P. Regnier, J. Segschneider, S. Sitch and S. Zaehle were supported by the EU FP7 for funding through projects GEOCarbon (283080), COMBINE (226520), CARBOCHANGE (264879), EMBRACE (GA282672), and LUC4C (GA603542). A. Harper was supported by the NERC Joint Weather and Climate Research Programme. A. K. Jain was supported by the US National Science Foundation (NSF AGS 12-43071) the US Department of Energy, Office of Science and BER programs (DOE DE-SC0006706) and NASA LCLUC program (NASA NNX14AD94G). B. D. Stocker was supported by the Swiss National Science Foundation. A. Wiltshire was supported by the Joint UK DECC/Defra Met Office Hadley Centre Climate Programme (GA01101). E. Kato was supported by the Environment Research and Technology Development Fund (S-10) of the Ministry of Environment of Japan. J. G. Canadell and M. R. Raupach were supported by the Australian Climate Change Science Program. J. I. House was supported by a Leverhulme Research Fellowship. S. C. Doney was supported by the US National Science Foundation (NSF AGS-1048827).
