Abstract. Black carbon (BC) in snow in the Himalayas has recently attracted considerable interest due to its impact on snow albedo, snow and glacier melting, regional climate and water resources. A single particle soot photometer (SP2) instrument was used to measure refractory BC (rBC) in a series of surface snow samples collected in the upper Khumbu Valley, Nepal between November 2009 and February 2012. The obtained time series indicates annual cycles with maximum rBC concentrations before the onset of the monsoon season and fast decreases during the monsoon period. Detected concentrations ranged from a few up to 70 ppb with rather large uncertainties due to the handling of the samples. Detailed modeling of the snowpack, including the detected range and an estimated upper limit of BC concentrations, was performed to study the role of BC in the seasonal snowpack. Simulations were performed for three winter seasons with the snowpack model Crocus, including a detailed description of the radiative transfer inside the snowpack. While the standard Crocus model strongly overestimates the height and the duration of the seasonal snowpack, a better calculation of the snow albedo with the new radiative transfer scheme enhanced the representation of the snow. However, the period with snow on the ground without BC in the snow was still overestimated between 37 and 66 days, which was further diminished by 8 to 15% and more than 40% in the presence of 100 or 300 ppb of BC. Compared to snow without BC, the albedo is reduced on average by 0.027 and 0.060 in the presence of 100 and 300 ppb BC. While the impact of increasing BC in the snow on the albedo is largest for clean snow, the impact on the local radiative forcing is the opposite. Here, increasing BC caused an even larger impact at higher BC concentrations. This effect is related to an accelerated melting of the snowpack caused by a more efficient metamorphism of the snow due to an increasing size of the snow grains with increasing BC concentrations. The melting of the winter snowpack was shifted by 3 to 10 and 17 to 27 days during the three winter seasons in the presence of 100 and 300 ppb BC compared to clean snow, while the simulated annual local radiative forcing corresponds to 3 to 4.5 and 10.5 to 13.0 W m−2. An increased sublimation or evaporation of the snow reduces the simulated radiative forcing, leading to a net forcing that is lower by 0.5 to 1.5 W m−2, while the addition of 10 ppm dust causes an increase of the radiative forcing between 2.5 and 3 W m−2. According to the simula-
1 Introduction

Black carbon (BC) constitutes the most important light-absorbing aerosol in the atmosphere, where it contributes to the warming of the atmosphere (Bond et al., 2013). It further affects cloud formation either as cloud nuclei or increasing the evaporation rates in cloudy layers. It is formed during incomplete combustion processes and mainly emitted due to natural and anthropogenic sources like biomass burning or fossil fuel and biofuel combustion (Bond et al., 2013). If BC is incorporated in snow, it can lead to further warming due to its impact on the albedo of snow and ice, causing an accelerated melting (e.g., Hansen and Nazarenko, 2004; Flanner et al., 2007; Ménégoz et al., 2014). BC is also a strong pollutant, dangerous for human health and the environment, and is considered an important short-lived climate forcer. Therefore, reductions in BC emissions can potentially lead to a fast climate response, in particular in regions where elevated BC concentrations are observed. The global annual climate forcing of BC in the atmosphere and in the snow remains uncertain with the most recent estimates ranging from +0.64 (±0.4) to +1.1 (~±1) W m\(^{-2}\) (Stocker et al., 2013; Bond et al., 2013).

Since regional warming due to BC can be much stronger than the global average, the Himalayas have become of great interest. The extended cryosphere in the high-altitude regions of the Himalayas including numerous glaciers (Kääb et al., 2012) and large snow-covered regions (Ménégoz et al., 2013a) is expected to be especially vulnerable because of high radiation intensities and the vicinity of large anthropogenic BC sources on the Indian subcontinent or in Southeast Asia. Xu et al. (2009) proposed that BC in snow contributes to the retreat of glaciers observed in parts of the Himalayas, while Ramanathan et al. (2007) suggested that BC transported to the Himalayas contributed to the melting of the snow. If BC has an impact on the glacier mass balance as well as on the timing of the run-off formation due to the snow melt in springtime, this would have implications on the hydrological cycle, water resources, hydropower generation, and agriculture in the downstream regions, possibly affecting the living conditions of a population of more than a billion people (e.g., Immerzeel et al., 2010). Changes in the cryosphere may further modify sensible and latent heat fluxes, affecting also the Asian monsoon (Lau and Kim, 2006; Qian et al., 2011).

Measurements at the Nepal Climate Observatory at Pyramid (NCO-P) carried out since 2006 at 5079 m a.s.l. have confirmed that aerosols including BC can effectively be transported from the sources to high-altitude regions of the Himalayas (Bonasoni et al., 2010; Marinoni et al., 2010). Ice cores and surface snow samples from different locations in the Himalayas (Ming et al., 2008; Kaspari et al., 2011; Ginot et al., 2014) and on the Tibetan Plateau (Ming et al., 2009; Xu et al., 2009) demonstrated that BC and other absorbing impurities like dust are efficiently incorporated into the snow. Based on ice core data, reductions in the snow albedo were estimated (Ginot et al., 2014), assuming that the profile of the ice core concentration directly corresponds to the evolution of the BC concentration in the surface snow layer. Furthermore, the transport of BC from the source regions and its deposition to the snow was calculated using different global transport and chemistry models (Flanner et al., 2007; Kopacz et al., 2011; Ménégoz et al., 2014). These studies resulted in an estimated annual radiative forcing due to BC in snow between 7 and 12 W m\(^{-2}\) close to the Mt. Everest (Kopacz et al., 2011) and between 1 and 4 W m\(^{-2}\) in the snow-covered areas of the Himalayas (Ménégoz et al., 2014), while peak values in the monthly radiative forcing exceeded 15 to 25 W m\(^{-2}\) for some parts of the Tibetan Plateau (Flanner et al., 2007; Kopacz et al., 2011; Qian et al., 2011). However, large uncertainties in the calculated radiative forcing remain because of the low spatial resolution of the global models used, preventing a precise representation of the high-altitude regions and the pronounced topography of the mountain range. These model limitations constrain a multitude of simulated processes including local-scale flow, transport of water vapor and aerosols, precipitation, and snow cover formation and melting (Ménégoz et al., 2013a), which are crucial in obtaining a correct radiative forcing for BC in snow. It has been demonstrated that these deficits can cause an overestimation of the snow cover on the Tibetan Plateau, producing also a likely positive bias in the estimated radiative forcing for BC in snow in this region (Ménégoz et al., 2013a, 2014). Moreover, some models generate significantly higher BC in snow concentrations compared to the few available observations in the Himalayas and on the Tibetan Plateau (Flanner et al., 2007; Ménégoz et al., 2014). However, the limited BC in snow measurements make it difficult to get a reliable idea of the spatial distribution, seasonal cycle, and interannual variability of BC in snow in this vast and complex region, greatly diminishing our capability to validate model results (Qian et al., 2011).

It is well known that BC is not the only absorbing impurity in the snow in the high-altitude region of Tibet and the Himalayas. High concentrations of dust have been observed in the atmosphere (e.g., Carrico et al., 2003; Duchí et al., 2014) and in ice cores (Thompson et al., 2000; Kaspari et al., 2011; Ginot et al., 2014). Duchí et al. (2014) reported the frequency of dust transport events at NCO-P with a maximum during the pre-monsoon period causing on average a 10-fold increase of PM\(_{10}\) in the atmosphere, compared to days without identified dust events. While the absorption of solar radiation due to dust is much less efficient compared to BC, this is at least partly compensated for by much higher concentrations. Ginot et al. (2014) found dust concentrations up to...
almost 70 ppm and an average concentration throughout all seasons around 10 ppm in an ice core from the Mera glacier, which is significantly higher than any observed concentration of BC or elemental carbon (EC) in snow in this region (Ming et al., 2008, 2009; Xu et al., 2006; Kaspari et al., 2011; Ginot et al., 2014).

The presence of absorbers in the snow has multiple impacts on the properties of the snow, which finally contribute to the radiative forcing (Painter et al., 2007; Flanner et al., 2007). The first order impact is related to the direct reduction of the snow albedo due to the incorporation of the absorbers in the snow. A second order impact is linked to the fact that the reduction of the albedo leads to a stronger warming of the snowpack compared to the clean snow, causing a faster metamorphism (or snow aging) and, thus, a more efficient growing of the snow crystals. Since larger snow crystals cause a reduced albedo, this effect leads to a further reduction of the albedo of the snowpack. Nevertheless, the forcing related to changes in the albedo remains small compared to the positive radiative forcing induced by the earlier exposition of the underlying soil caused by an accelerated melting of the warmer snow containing BC. To study these multiple impacts of the absorbing impurities on the processes and properties of the snow in detail, a detailed physical snowpack model like Crocus with sufficient complexity is needed (Brun et al., 1989, 1992; Vionnet et al., 2012). Crocus is capable of calculating the internal energy budget of the snowpack, to resolve temperature gradients inside the snowpack, and to simulate the metamorphism of the snow. However, the standard model version does not allow considering absorbing impurities like BC or dust for the calculation of the albedo.

Here, we report multi-annual measurements of BC in surface snow sampled on the southern slopes of the Himalayas close to NCO-P. We compare the snow concentrations with simultaneous atmospheric measurements to investigate the role of wet and dry deposition. Moreover, we present the Crocus snowpack model with an upgraded radiative transfer scheme to study the impact of BC and dust in snow. Forced with 3 years of meteorological observations from the Pyramid International Laboratory (close to NCO-P) and with observed BC and dust concentrations, the model was used to study the impact of the two absorbing impurities on snow metamorphism, melting, and local radiative forcing. The model results including sensitivities of the melting and radiative forcing due to the presence of BC and/or dust in the snow are presented and compared to previous large-scale model studies.

2 Methods

2.1 Snow sampling

56 samples of surface snow were collected in Nepal during the period from 13 November 2009 to 29 February 2012 at three different locations in the Khumbu region south of the Mount Everest: At NCO-P (27.96° N, 86.81° E; 5079 m a.s.l.) and on the glaciers Changri Nup (27.98° N, 86.76° E; 5700 m a.s.l.) and Pokalde (27.93° N; 86.83° E; 5600 m a.s.l.; Fig. 1). In most cases, snow from the top layer (≤ 10 cm) was collected and transported to France. Using field notes, observed precipitation, and snow height at NCO-P, 51 of the available snow samples were classified into fresh snow (i.e., snowfall within 24 h before sampling) and old snow. Five samples remained unclassified.

2.2 Snow sample analysis and handling

The snow samples were analyzed using a Single Particle Soot Photometer (SP2, Droplet Measurement Technologies, US) to determine refractory BC (rBC) particles. Details of the analytical procedure are described in Lim et al. (2014). The SP2 applies a laser-induced incandescence technique to measure the mass of individual rBC particles (Schwarz et al., 2006), independent of particle morphology and light-scattering coating materials (Moteki and Kondo, 2007, 2010). Each rBC particle passes through the laser beam intracavity, where it absorbs light, reaches a vaporization temperature, at which it incandesces, and emits visible thermal radiation proportional to the mass of the individual particles. The SP2 is highly sensitive to rBC particles, but much less to other absorbing particles like dust. It was calibrated with fullerene soot (Alfa Aesar Inc., USA), a standard BC material of known single particle mass aggregating primary particles with graphitic structure. A new nebulizer (APEX-Q, Elemental Scientific Inc., Omaha, USA) was used to increase the efficiency of the transfer of the rBC particles in the snow into the gas phase. The rBC losses during aerosolization were determined using eight liquid Aquadag® standards, resulting in an average efficiency of 56 %, which was applied to all BC concentrations reported here.

All snow samples melted during transport from the field sites to France. They were stored at < 5 °C until analysis in April 2012. Before analysis, the samples were sonicated for 15 min to minimize rBC losses on the container wall. Five selected samples were reanalyzed almost 2 years later to evaluate the rBC particle loss during long-term storage of the samples in liquid form. The samples showed decreases in detected rBC concentrations between 0 and 80 %, which is probably related to particles’ attachment on the container wall and the agglomeration of particles. The loss during storage was not straightforward and seemed to be highly variable depending on storage time and rBC concentration. Therefore, all measured concentrations are presented here without any further correction for potential rBC losses during transport or storage and should be considered as minimum values.

2.3 Meteorological data and atmospheric BC

Meteorological parameters have been recorded at Pyramid International Laboratory close to NCO-P since 1994, and radiation and snow depth since 2002. Moreover, continuous measurements of atmospheric BC concentrations have been performed at NCO-P using a Multiangle Absorption Photometer since 2006. Further details of the instrument setup and the calculation of equivalent BC concentrations are described by Marinoni et al. (2010).

2.4 Modeling

Simulations were performed with the one-dimensional multilayer physical snowpack model Crocus (Brun et al., 1989, 1992; Vionnet et al., 2012), which explicitly solves the surface mass and energy budgets, taking into account heat diffusion, transfer of radiation, densification, sublimation, condensation, melting, and liquid water percolation in the snow. The model is forced using meteorological data like air temperature, wind speed, relative humidity, precipitation quantity and phase, incoming direct and diffuse solar radiation, incoming long-wave radiation, and cloud cover. The simulated snowpack consists of multiple homogeneous horizontal layers, which are established according to snowfall events undergoing transformation related to a metamorphism scheme. It calculates physical properties of each modeled snow layer including thickness, temperature, density, liquid water content, snow type, grain size, and age. The model further computes budgets of the snowpack like total height, run-off, latent and sensible heat fluxes, and fluxes of infrared and short-wave radiation.

In the Crocus standard version, the albedo is not prescribed, but parameterized using the snow grain size and age of only the uppermost layer of the snowpack (Vionnet et al., 2012). The albedo is subsequently applied to calculate the absorbed amount of incoming radiation, while the penetration of the absorbed radiation is simulated using absorption coefficients estimated from the density and grain size of each snowpack layer.

The standard albedo parameterization does not offer the possibility to account for the presence of absorbing impurities. In order to study the impact of BC and dust on the snowpack with Crocus, we implemented a physically-based radiative transfer scheme without prescribed albedo values. We employed the theory of Wiscombe and Warren (1980) and Warren and Wiscombe (1980) based on a module previously used in the land surface scheme ORCHIDEE for simulations with the global model LMDZ (Krinner et al., 2006; Ménégoz et al., 2013b, 2014). Starting with a fixed soil albedo, the albedo for diffuse radiation is calculated at the top of the bottom snow layer using the snow water equivalent (SWE), grain size, and BC and dust concentrations of this layer. The same procedure is applied for the overlying snow layers until the surface layer is reached. For the surface layer, the albedo for direct radiation is calculated, taking into account the solar zenith angle. The albedo for diffuse and direct radiation is separately combined with the incoming direct and diffuse radiation to calculate the overall amount of absorbed radiation. Since the albedo calculation for the diffuse radiation delivers also absorption coefficients, these are used to calculate the amount of radiation energy absorbed in each snow layer, assuming that within the top snow layer all direct radiation was transformed into diffuse radiation. We used the same optical properties for ice like Krinner et al. (2006). For BC we assumed a log-normal size distribution with a median number radius of 11.8 nm, a density of 1 g cm$^{-3}$, and a refractive index of $m = 1.75 - 0.45 i$ (Ménégoz et al., 2013b); for dust a log-normal size distribution was used with a median mass diameter of 2 µm and a refractive index according to its hematite content (Krinner et al., 2006). Using these typical, but fixed properties for BC and dust may lead to an underestimation of the impact of the aerosols on the simulated albedo, mainly because the model only considers externally mixed aerosols (Flanner et al., 2012). Nevertheless, the derived BC mass absorption cross section of 7.6 m$^2$ g$^{-1}$ at 545 nm corresponds to previously published values (Bond and Bergstrom, 2006; Flanner et al., 2007). Since the standard version of Crocus considers three different wavelength ranges for the albedo and the absorption coefficient, the values derived from the radiative transfer module were also averaged for the same bands from 300 to 800 nm, 800 nm to 1.5 µm, and 1.5 to 2.8 µm.
For our simulations we used observations covering the period August 2004 to July 2007 obtained at an altitude of 5050 m a.s.l. at Pyramid Laboratory to construct the needed forcing data. Quality controlled 1 h averages were used for temperature, wind speed, humidity, and radiation without further correction. However, it is well known that the observed precipitation significantly underestimates solid precipitation (Bonasoni et al., 2010; Shrestha et al., 2012). Accordingly, the observed snow height shows for several instances strong increases, while no simultaneous precipitation was recorded as already described by Shrestha et al. (2012). As a result, preliminary simulations with the standard and upgraded Crocus model with the recorded precipitation did not lead to the build-up of a significant snowpack. Therefore, a corrected precipitation data set based on the observed snow height was constructed and employed for all further snowpack simulations. If the snow height showed an increase, while no precipitation was detected, the increase in snow height was transformed into accumulation using a density of fresh snow of 0.08 g cm$^{-3}$. Using such a density led to a good agreement of simulated and observed increases in the snowpack height during the 2004/2005 winter season. Since the detector of the snowpack height showed regular fluctuations around ±1 cm, only increases in height larger than 1 cm were considered (Shrestha et al., 2012). In addition, the snow height sensor recorded several peaks with strong increases in height and subsequent large decreases of several tens of cm within hours or days. These peaks were removed after visual inspection of the time series. Finally, the phase of the precipitation was estimated using observed air temperatures with only solid precipitation at $T_{\text{air}} < 0^\circ$C, only liquid precipitation at $T_{\text{air}} > +2^\circ$C, and mixed phase precipitation with 50 % solid precipitation in the remaining temperature range. A comparison of recorded and corrected time series of precipitation is shown in the Supplementary material (Figs. S1a, b, and c in the Supplement). After applying the corrections the estimated total annual precipitation corresponds to 491.7 mm (41 % solid precipitation), 423.8 mm (55 % solid precipitation), and 454.8 mm (51 % solid precipitation) for the years 2004/2005, 2005/2006, and 2006/2007, compared to the recorded total precipitation of only 360 (2004/2005), 231 (2005/2006), and 304 mm (2006/2007). The corrected annual values are in excellent agreement with an estimated multi-year average of the annual precipitation of ∼450 mm at NCO-P for the period 1994 to 2013 (Salerno et al., 2015). Due to the uncertainty in the estimated solid precipitation, the model sensitivity was tested using differing meteorological forcing data for the year 2004/2005. These data sets were generated with different thresholds for the solid, mixed phase, and liquid precipitation varying from 0 to 4 $^\circ$C. They are described in the Supplementary material and showed maximum and minimum values of solid precipitation ranging from 30 to 56 % of the total precipitation (Table S1 in the Supplement).

In the Crocus simulations, the fraction of cloud cover is used to determine the contributions of direct and diffuse radiation to the total incoming radiation. For the simulations, the cloud cover fraction was set to 0 (denoting clear sky) if the ratio between observed and theoretical incoming solar radiation was larger than 0.8, to 0.5 (denoting cloudy) if the ratio was between 0.2 and 0.8, and to 1 (denoting overcast) if the ratio was below 0.2. Based on these derived cloud fractions, the observed incoming shortwave radiation was divided into direct and diffuse radiation using the same parameterizations as in the Crocus model. As a result the total incoming radiation for the forcing of the model corresponds exactly to the measured values. The estimated cloud cover only affects the distribution between direct and diffuse radiation, which has a slight impact on the calculation of the albedo as described above.

3 Results and discussion

3.1 BC concentrations in surface snow

Observed rBC concentrations are highly variable ranging from less than 0.1 to more than 70 ppb (Fig. 2). Calculated average and median concentrations of all samples correspond to 10 and 1.5 ppb. As described in the Methods section, the reported concentrations are potentially underestimating the real BC concentrations. Nevertheless, the increases in the concentrations during the dry seasons 2009/2010 and 2010/2011 are well beyond the uncertainty of the measurements, which can be as high as a factor of 5. Despite this uncertainty and the high variability, we conclude that the concentrations follow a seasonal cycle with low values in the post-monsoon and winter season and higher concentrations in the pre-monsoon, culminating at maximum concentrations before the onset of the monsoon.

Regarding snow types, we obtained somewhat higher concentrations in the old snow samples (average 15 ppb, median 3 ppb) compared to the fresh snow samples, with average and median concentrations of 5 and 1.3 ppb. However, these differences as well as differences between the sampling sites remain questionable because they are small compared to the uncertainty of the rBC concentrations.

Lower rBC concentrations were measured by Kaspari et al. (2011) in an ice core from the East Rongbuk Glacier at 6500 m a.s.l. close to Mt. Everest using the same analytical method. They found average concentrations of (0.7 ± 0.1) ppb for the period 1975 to 2000 and a maximum of 32 ppb. However, the same uncertainty in the measured rBC concentrations as for our samples due to the sample handling applies to the data reported by Kaspari et al. (2011).

Finally, the concentrations reported here are lower compared to the results for EC obtained with the thermo-optical method for snow and ice core samples from the high-altitude region of the Himalayas and the Tibetan Plateau. For ex-
It seems that wet deposition due to the accumulation of fresh snow leads to relatively small concentrations of rBC around 1 ppb. However, in the case of snowfall during the pre-monsoon season, when atmospheric BC concentrations are high, rBC concentrations in fresh snow can increase to more than 10 ppb. Additional dry deposition of BC seems to have a relatively small impact during the winter period and old snow exposed at the surface contains relatively low BC amounts. Maximum BC concentrations are reached again in the pre-monsoon season potentially combining large inputs due to wet and dry deposition. Yasunari et al. (2013) estimated BC concentrations in surface snow using deposition velocities calculated with meteorological measurements at NCO-P and atmospheric measurements of equivalent BC. Considering only dry deposition they obtained concentrations between 90 and 130 ppb in old snow for a continuous snowpack until end of May. The observed rBC maxima are somewhat lower than these values, possibly because the seasonal snowpack at NCO-P melts earlier and some of the BC may be lost due to the handling of the samples.

### 3.2 Snowpack modeling: standard vs. upgraded model

Although the Crocus model has so far been used in different alpine and polar regions (e.g., Jacobi et al., 2010; Brun et al., 2011; Vionnet et al., 2012), it has to our knowledge never been applied to simulate the seasonal snowpack in the Himalayas. Recently, a modified version of the model was employed to simulate the snow on top of a debris-covered glacier in the Khumbu Valley (Lejeune et al., 2013). To examine the performance of the two model versions, we first compared the results of the standard Crocus model and the upgraded version including the radiative transfer for the seasons 2004/2005, 2005/2006, and 2006/2007, applying the forcing data based on the observations at the Pyramid site. The simulated snowpack heights for the season 2004/2005 are shown in Fig. 3 (for the seasons 2005/2006 and 2006/2007 in the Supplement, Figs. S2a and b). In all three winter seasons, the standard Crocus model largely overestimates the period with snow on the ground (Figs. 3, S2a and b). For example, Crocus predicts the formation of a continuous snowpack starting on 14 October 2004 and lasting until 4 January 2005 due to several small snowfall events in October and November. However, the snow height records and albedo measurements show that during this period the fresh snow regularly melts within a day after precipitation. The onset of the seasonal winter snowpack at the end of January 2005, corresponding to the longest period with continuous snow on the ground, is well represented by Crocus because the observed snowpack heights are used to construct the precipitation time series. In contrast, observed snowpack heights start to decrease mid-February 2005 and are interrupted only by additional accumulation in mid-March, until the snow disappears before the end of March 2005. In contrast, the winter snowpack remains intact in the Crocus simu-
Crocus for the years 2005/2006 and 2006/07 with a period with snow on the ground is similarly overestimated by the standard Crocus model. The observed snow height on 10 June 2005. In summary, while the observed total period of the snowpack shows a much stronger dynamic with faster drops in the snow height compared to the standard model. Moreover, fresh snow in the fall and early winter season is not conserved for more than 24 h (Figs. S2a and S2b). The simulated duration of the snow cover is reduced between 54 and 103 days compared to the standard Crocus model. Nevertheless, the period with snow on the ground is still overestimated by 57, 37, and 66 days for the years 2004/2005, 2005/2006, and 2006/2007 relative to the observations.

The different behavior of the standard and the upgraded model is related to the calculated albedo and the corresponding energy absorbed by the snowpack. Figure 3 shows a comparison of the simulated albedo for 2004/2005 together with observed albedo derived from the ratio of the up- and downwelling shortwave radiation. A large part of the differences between observed and simulated albedo concerning all model results is related to the overestimation of the simulated periods with snow. Apparently, the model delivers high albedo values for the period when snow is still present, while the observations correspond to the low values of the soil after the melting of the snow.

Figure 3 illustrates further differences in the simulated albedo of the two model versions and the impact of increasing the BC concentrations. In the standard model, the albedo rises with each precipitation event to values around 0.9 before it slowly decreases due to the albedo parameterization related to the aging of the snow. Since only the properties of the top snow layer are considered in the standard model, the simulated albedo is not affected by the thickness of the snowpack and the parameterized albedo is similar regardless of the snow height. In contrast, the effect of a thin snowpack is better reproduced by the upgraded model. Here, the SWE of each snowpack layer is an important variable and leads in the case of a thin snowpack to strongly reduced albedo values as can be seen in the cases of snowfall before December 2004 or after June 2005 (Fig. 3). During these events the simulated albedo remains between 0.2 and 0.7, causing a stronger absorption of the incoming solar radiation and, thus, a complete melting of the snow.

In all model versions, the precipitation in late January leads to the formation of the seasonal winter snowpack (Fig. 2) with an albedo between 0.6 and 0.9. These albedo values of the fresh snow are relatively well reproduced by both model versions (Fig. 3). However, neither model captures the relatively strong decrease of the albedo to 0.3 until 10 March before a new snowfall event increases the observed albedo to more than 0.8. In both model versions the overestimation of the period with snow on the ground is directly linked to the positive bias in the simulated albedo. Similar results are obtained for the years 2005/2006 and 2006/2007 (Figs. S3a and b). A statistical analysis of the comparison between observed and simulated albedo including bias, root mean squared errors (RMSE), and correlation coefficients for all three winter seasons is compiled in the Supplementary material (Table S2). The results show an improvement of the simulated albedo using the upgraded Crocus model, which improves further after increasing the BC concentrations from 0 to 100 or 300 ppb. On average for all three winter seasons, the bias and RMSE are below 0.11 and 0.18 in the best model runs, while the correlation coefficient is as high as 0.5. Considering only the first month of each winter season, the bias and RMSE decrease to below 0.01 and 0.09, while the correlation coefficient increases only slightly. Similarly, Shrestha et al. (2012) simulated a delayed melting of the snow and overestimated the springtime snow-covered area in the Dudhkhoshi region with a three-layer snow model.
They also attributed a large part of the model bias to the used simplified albedo parameterization. This corresponds well to results from previous snow model comparisons indicating that the albedo parameterization is a crucial component for snow models (Etchevers et al., 2004).

Although an important part of the positive bias in the albedo is reduced in the presence of absorbing impurities, strong differences between observed and simulated albedo remain, especially in the later part of the winter season including the melting period. Sensitivity runs with varying amounts of solid precipitations show only small differences in the snow-covered periods (Fig. S5 and S6) and in the simulated albedo. Moreover, the impact on the bias, RMSE, and correlation coefficients of the simulated albedo remained negligible (Table S3). Therefore, the uncertainty in the estimated precipitation cannot explain the overestimation of the snow-covered period and the albedo.

The statistical analysis of the simulated albedo indicates that the albedo values earlier in the season are better represented by the radiative transfer theory, while the fast decrease of the albedo during the melting period is still not captured by the model. These differences are further illustrated in Fig. 4, which shows daily averaged albedo values for two periods after fresh snowfall events. While the absolute observed albedo as well as its trend is reasonably well reproduced by the upgraded model for the winter season after 16 February 2007, the comparison for the melting period after 26 April 2006 still shows large deviations. These two periods are characterized by large differences in the average (−11.8 vs. −2.5°C) and maximum air temperatures (−2.6 to 3.5°C). These results demonstrate that the performance of the upgraded model is still limited during the melting of the snowpack. This may concern internal processes like the metamorphism of wet snow as well as meltwater formation and percolation, which are challenging to reproduce in snowpack models (e.g., Brun et al., 1992). Another important process currently not implemented in the model is the vertical redistribution of the absorbing impurities. Due to a range of processes like dry deposition, flushing out, or enrichment during melting, the absorbers may be concentrated in certain layers leading to potentially higher concentrations as encountered in the snow samples and further reducing the snow albedo. Nevertheless, a successful representation of such processes impacting impurities in the snow requires first an improved description of liquid water formation and movement inside the snowpack and can probably only be addressed in the next generation of snowpack models.

Differences between observations and simulations may also be related to the available observations. For example, the spatial variability of the meteorological as well as the snow conditions in the rugged terrain of the Himalayas may not be captured by the point measurements used here to drive and validate the snow model. The atmospheric and snow observations at the field site may only represent localized and non-ideal conditions introducing additional variability that cannot be represented by the simulations. This variability as well as further uncertainties in the observations directly translate into errors in the snowpack simulations, contributing also to the differences between simulations and observations.

### 3.3 Impact of BC on snow albedo

Despite the uncertainty in the simulations during the melting period, we studied the simulated impact of BC present in the snow based on the runs with different BC concentrations. We selected concentrations of 100 and 300 ppb covering the range of the maximum BC concentration reported here, including their uncertainty. Figure 5 shows the simulated albedo for the three different BC concentrations (0, 100, and 300 ppb) during the period 21 to 31 January 2005. Between 21 and 23 January, several snowfall events led to the initial formation of the winter snowpack. As a result, the observed albedo increased from values below 0.2 on 21 January to more than 0.8 the following day and to even higher values on 23 January. It followed a period of 7 days without further precipitation and slightly decreasing albedo values. Similar results are obtained in the simulations, during which a maximum albedo was reached early on 24 January with a subsequent decrease in the calculated albedo. Additional fresh snow during the night from 30 to 31 January increased the albedo values in the observations and simulations. Figure 5 shows that several short-term features in the observations are well reproduced in the simulations: the diurnal cycle of the albedo with morning and evening maxima (26 and 27 January), the continuous decrease on 24 January, or the unusual behavior on 28 January. The model is also capable of simulating a positive feedback loop between albedo, snow temperature, and grain size in the presence of BC, referred to as the first indirect effect (Painter et al., 2007). Initial conditions in the snowpack with different BC concentrations are very sim-
The sensitivity of the albedo towards BC depends further on the season with the smallest impact on the snowpack in December 2006 and the strongest in the March to May 2006 period. The seasonal dependence of the sensitivity is linked to the radiation intensity, which is lowest in December and increases until June, and the positive feedback between BC, snow temperature, grain size, and albedo as described above.
until these events, a fast shift in the melting date is observed. The relationship between the melting date and the BC concentrations is not always linear and decreases for example on the timing of the precipitation events.

Figure 6. Top: simulated average albedo for several periods with continuous snow higher than 10 cm as a function of BC concentration. Bottom: normalized albedo as differences of the averaged albedo minus albedo at BC = 0. The lines correspond to the best fit of a quadratic polynomial forced through zero for each set of the normalized albedo.

3.4 Impact of BC and dust on snow melting

Although the overall impact of BC in the snow on the albedo remains limited, the impact on the melting of the snow can be rather large in the Himalayas as demonstrated in several model studies (e.g., Flanner et al., 2007; Ménégoz et al., 2014). In the presence of BC, the melting of the winter snowpack (corresponding to the longest period with a simulated continuous snowpack of a height of > 2 cm) is shifted to early dates compared to the simulations without BC. This shift corresponds to 3 to 10 days in the presence of 100 ppb BC and increases to 17 to 27 days with 300 ppb BC for the 3 simulated years (Fig. 7). The relationship between the melting date and the BC concentrations is not always linear and depends on the timing of the precipitation events during springtime. If the winter snowpack does not persist until these events, a fast shift in the melting date is observed. One example is the shift of 5 days of the melting in the season 2006/2007 if the BC is increased from 80 to 100 ppb. Besides the impact of the meteorological conditions, the number of days with snow on the ground steadily decreases with increasing BC concentrations. While this decrease shows a relatively large interannual variability, the overall trend is similar in all 3 years with a stronger impact of an incremental increase of BC at higher concentrations compared to lower concentrations in the snow. This behavior is, thus, in contrast to the direct effect of BC on the snow albedo, which is strongest at low concentrations and becomes weaker at higher concentrations (Fig. 6).

Figure 6. Top: simulated average albedo for several periods with continuous snow higher than 10 cm as a function of BC concentration. Bottom: normalized albedo as differences of the averaged albedo minus albedo at BC = 0. The lines correspond to the best fit of a quadratic polynomial forced through zero for each set of the normalized albedo.

Although we did not measure the dust concentration in the surface snow samples, we can assume that dust was also present as previously observed in ice cores from the Himalayas (Thompson et al., 2000; Kaspari et al., 2011; Ginot et al., 2014). To study the impact of dust, we performed calculations with a constant dust concentration of 10 ppm, corresponding to the average observed in the Mera ice core (Ginot et al., 2014) and BC concentrations varying between 0 and 150 ppb and additional calculations without BC, but with dust concentrations up to 15 ppm. In all simulations, the addition of absorbing impurities like BC and dust leads to a reduction of the snow-covered periods. On average the snow-covered period is reduced by $5.6 \times 10^{-2}$ days (ppb BC)$^{-1}$ and $7.6 \times 10^{-4}$ days (ppb dust)$^{-1}$. The impact of the addition of BC increases strongly in the presence of 10 ppm dust compared to pure snow because in these simulations the reduction is enhanced to $8.6 \times 10^{-2}$ days (ppb BC)$^{-1}$. The reduction in the snowpack duration is on average 50% stronger compared to the simulations with only BC. This behavior is similar to the acceleration of the melting of the snow at higher BC concentrations. A linear regression, using only the results for the simulations without dust and 80 ppb $\leq$ BC $\leq$ 250 ppb in Fig. 7, leads to a reduction of $7.9 \times 10^{-2}$ days (ppb BC)$^{-1}$ and is, thus, similar to the impact obtained with a constant dust concentration of 10 ppm. Obviously, the influence of the
The reduction of the snow albedo and the earlier melting of the snowpack leads to a radiative forcing because a larger proportion of the incoming radiation is absorbed at the Earth’s surface. We calculated the radiative forcing using the observed incoming shortwave radiation and the simulated albedo of the snowpack. In the absence of snow, we used a soil albedo of 0.15, corresponding to the observed wintertime albedo without snow on the ground (Fig. 3). All values for the radiative forcing are calculated as the difference in absorbed shortwave radiation with and without absorbing impurities in the snow. Since the radiative forcing can partly be compensated by latent and sensible heat fluxes due to an increased sublimation or evaporation of the snow, a net forcing is calculated after considering these fluxes between the snow and the atmosphere. However, no further feedback mechanisms between the snow and the atmosphere are included because all simulations were driven by the same meteorological data sets.

The calculated radiative (Fig. 7) and net forcing (Fig. S4) show similar, but opposite trends compared to the reduction in snow-covered periods. A reduction of the snow-covered period leads to increased radiative forcing due to the longer exposition of the underlying soil. This effect becomes obvious in the seasonal cycle of the simulated forcing, with 100 ppb BC in the snow shown as an example in Fig. 8. The maximum monthly radiative and net forcing are simulated for the end of the snow-covered period (i.e., May in 2004/2005 and 2005/2006 and April in 2006/2007). A large interannual variability in the forcing is apparent for the annual mean as well as in the seasonal cycle. For example, with 100 ppb BC, the net forcing varied for the 3 simulated years by ±1 W m⁻², while the average forcing remains around 3 W m⁻². An even larger variability becomes apparent in the seasonal cycle (Fig. 8). In April and May, the minimum and maximum forcing can vary between less than 3 and more than 25 W m⁻². In contrast, at the beginning of the snow-covered period the forcing due to the presence of absorbers remains below 5 W m⁻² and is relatively constant during the 3 simulated years. Several factors contribute to the interannual variability like differences in the incoming radiation and the length and timing of the snow-covered period (Fig. 8). However, Fig. 8 also demonstrates that the incoming shortwave radiation is not the major driver for the interannual variability, because in April the largest forcing is observed in the year 2006/2007 while the incoming shortwave radiation was smaller compared to the 2 preceding years. Therefore, the seasonality of the forcing is mainly driven by the timing of the snowfall and the melting of the snow. If solid precipitation occurs early in the winter season like in the simulations for 2006/2007, a forcing can also occur in the period from October to December, which may be comparable or even larger than the forcing calculated for March or April.

The simulated annual mean of the forcing due to the presence of 100 ppb BC for the 3 years of simulation corresponds to 3 to 4.5 W m⁻² for the radiative forcing (Fig. 7) and 2 to 4 W m⁻² for the net forcing (Fig. S4). In the presence of 10 ppm dust the values increase to 6 to 7 W m⁻² and 5.5 to 7 W m⁻² for the radiative and net forcing. This range corresponds to the detected BC in snow concentrations. Due to the uncertainties in the measurements (see Methods) the correct BC concentrations could be a factor of 3 higher. With 300 ppb BC, the radiative and net forcing increases to 10.5 to 13 and 9 to 12.5 W m⁻².

Using the range of detected BC in snow concentrations (≤ 100 ppb), the radiative forcing obtained with the local model is similar to results from previous global model runs. For example, Flanner et al. (2007) and Ménéguz et al. (2014) have reported annual means of the radiative forcing due to
BC for the Himalayas and the Tibetan Plateau around 3.5 to 4 and 1 to 4 W m\(^{-2}\). These calculations included either no feedbacks (Flanner et al., 2007) or only short adjustments neglecting long-term feedbacks like changes of atmospheric circulation or sea surface temperature (Ménégoz et al., 2014). Ménégoz et al. (2014) also included dust in the snow, while Flanner et al. (2009) calculated that the addition of dust increases the total radiative forcing during springtime by 1 to 2 W m\(^{-2}\) in the considered region. However, in both studies the simulated annual averages of the BC in snow concentrations ranged from 100 to 200 ppb. Since a comparable radiative forcing was obtained with higher BC in snow concentrations, it can be concluded that the sensitivities are lower in the global models compared to our local model. Because the approach to represent the radiative transfer in the snowpack is similar or even the same in all three models, a major reason for the lower sensitivity could be the simplified representation of the snow in the global models, which describe the entire snowpack with a limited number of layers (Flanner et al., 2007; Ménégoz et al., 2014). As a result, the energy budget and the snow temperature profiles may not be well described leading to a bias in the simulation of the snow aging in the presence of the absorbers and of the melting of the snow. Moreover, the coarse spatial resolution of the models does not allow representing the specific local conditions at NCO-P.

Using a further global model, Kopacz et al. (2011) found BC in snow concentrations around 46 ppb in October in the Mt. Everest region. Using simple estimates of the relationship between BC in snow and albedo, they derived an average radiative forcing of 9 W m\(^{-2}\) for October with monthly means ranging from 7.5 to 12 W m\(^{-2}\). While the simulated BC in snow concentrations are more reasonable (although still too high), the applied sensitivities are high compared to our simulations for NCO-P and do not reflect the complex processes occurring in the snowpack.

4 Conclusions

The time series of rBC concentrations in the surface snow in the upper Khumbu Valley reported here indicates a seasonal cycle with maximum concentrations in the pre-monsoon period and low concentrations during the monsoon period. This cycle directly reflects the behavior of atmospheric BC in the same high-altitude region (Marinoni et al., 2010) and is also conserved in ice cores from nearby glaciers (Ginot et al., 2014). Therefore, ice cores can be used to reconstruct historic BC concentrations in these regions. Unfortunately, a large uncertainty remains regarding the absolute BC in snow concentrations. While the SP2 technique delivers precise concentrations of rBC, the melting of the snow samples during transport and storage potentially modified the detected concentrations. This effect probably contributed to discrepancies between the snow concentrations reported here, compared to previously reported results for EC, while the two different techniques also added to the mismatch (Lim et al., 2014).

Further measurements are needed to resolve these discrepancies and to determine actual concentrations. Such accurate data are urgently needed for the validation of global and regional models used to calculate the impact of BC in snow on the regional climate (Qian et al., 2011; Ménégoz et al., 2014). While models simulating the impact of BC in snow on albedo and radiative forcing for a given snowpack exist, the quantification is currently mostly hampered by the uncertainty in BC in snow concentrations.

In its first application to the snowpack in the Himalayas, the standard Crocus model reveals significant discrepancies compared to observations with a large positive bias in the simulation of the snow-covered period and the albedo. While the Crocus model is well adapted to conditions in the Alps and gives satisfying results in polar regions (Jacobi et al., 2010; Brun et al., 2011; Vionnet et al., 2012), the high radiation intensities in the Himalayas make the model obviously more vulnerable due to the simplified parameterization of the albedo. While simulations were performed for typical conditions at Pyramid, it is likely that this simulated bias can be expected for wider regions of the high-altitude area of the Himalayas. This concerns the simulation of the thin seasonal snowpack with a large contrast in albedo between the snow-free and snow-covered ground. The bias in the standard Crocus model is probably diminished in regions with the formation of a thicker snowpack like in the Western Himalayas (Ménégoz et al., 2013a) and in calculations over glaciers where the underlying firn and ice exhibit a higher albedo than the soil. Furthermore, the parameterization of the ground heat fluxes in the Crocus model may not be well
adapted to the conditions of the Himalayas, possibly contributing to the overestimation of the snowpack especially late and early in the winter season.

The positive bias in the albedo and the snowpack simulations are reduced with the upgraded Crocus model, taking into account the radiative transfer in the snow. This improvement becomes obvious even in simulations without absorbing impurities. The results are further enhanced if BC in the snow is considered and varied in a range constraint by surface snow and previous ice cores measurements (Ginot et al., 2014). Nevertheless, even in these simulations, the albedo of and the length of the period with the seasonal snowpack remain well overestimated. Since the simulations were all performed with constant BC concentrations, any enrichment of BC at the snow surface or in specific layers due to sublimation, dry deposition, melting, and refreezing (Doherty et al., 2013) is not included. Nevertheless, even in the model runs with BC concentrations of 300 ppb, which is more than 3-fold the maximum detected BC concentration in the surface snow as well as the ice core from this region (Ginot et al., 2014), the snowpack is more persistent than observed. Thus, even if any or all of the post-depositional processes leads to an enrichment of more than a factor of 3 throughout the snowpack, differences in the simulations and the observations would remain. Stronger enrichments of BC in certain layers, like reported previously for the Mera glacier (Kaspari et al., 2014) or in the Arctic (Doherty et al., 2013), appear unlikely because they should have been detected in our surface snow samples or in the Mera ice core (Ginot et al., 2014). Moreover, the observed maxima of BC concentrations in the snow can easily be explained by dry deposition alone without invoking any further enrichment processes (Yasunari et al., 2013). These results do not rule out that higher BC in snow concentrations are encountered under different conditions like on glaciers or even higher altitudes, where the snowpack may not melt before April, when the air masses with the highest concentrations in BC finally arrive at the high-altitude region (Fig. 2).

A heterogeneous distribution of absorbing compounds within the snowpack may induce stronger temperature gradients inside the snowpack, further accelerating the snow metamorphism compared to a snowpack with homogeneous concentrations as assumed in our simulations. Variable concentrations can be caused by processes during the melting of the snowpack as described above. Since the absorbing compounds are introduced by dry and wet deposition, concentration gradients inside the snowpack can be expected even in the not-melting snowpack. Moreover, these gradients can be different for different absorbing compounds. Vertical profiles of the absorbing compounds need to be determined to address this point. Whether it can also have a profound impact on the snowpack simulations remains to be seen and will be the subject of further studies.

The simulations with the Crocus model reveal further that dust and probably also other absorbers play a strong role not only for the snow albedo itself, but also for the impact of BC. While the impact of a given amount of an absorber on the snow albedo diminishes in the presence of further impurities, this is the opposite case for the increase of snow-free days and the radiative forcing. Here, the simulations demonstrate that the presence of other absorbers like dust even enhances the effect of BC. Therefore, the role of dust in the snow, together with the role of BC, needs to be studied in the future, and a correct determination of dust and its properties parallel to the determination of BC in the snow is needed. Organic absorbers in the snow (Wang et al., 2013) may also play a role similar to dust and should also be considered in further studies. In summary, a full characterization of all absorbing compounds and their different contributions seems necessary to study the full impact of these compounds on the snow albedo and further related snow properties and processes.

Finally, this study concentrated only on the effect of the albedo for the snowpack simulations. Other processes parameterized in the snow model (e.g., turbulent fluxes, ground heat flux, snow metamorphism, liquid water formation, percolation) and uncertainties in the forcing data may also contribute to differences between simulations and observations. Further detailed observations are needed to improve future snowpack simulations in this sensitive region. This mainly concerns direct observations of the total and solid precipitation, which are crucial parameters in snowpack and hydrological modeling for this sensitive region.
