Abstract. Iron (Fe) delivery by the Antarctic Ice Sheet (AIS) through ice shelf and iceberg melting enhances primary productivity in the largely iron-limited Southern Ocean (SO). To explore this fertilization capacity, we implement a simple representation of the AIS iron source in the global ocean biogeochemical model NEMO-PISCES. We evaluate the response of Fe, surface chlorophyll, primary production, and carbon (C) export to the magnitude and hypothesized vertical distributions of the AIS Fe fluxes. Surface Fe and chlorophyll concentrations are increased up to 24 % and 12 %, respectively, over the whole SO. The AIS Fe delivery is found to have a relatively modest impact on SO primary production and C export, which are increased by $0.063 \pm 0.036 \text{ PgC yr}^{-1}$ and 0.028 ± 0.016 , respectively. However, in highly fertilized areas, primary production and C export can be increased by up to 30 % and 42 %, respectively. Icebergs are predicted to have a much larger impact on Fe, surface chlorophyll, and primary productivity than ice shelves in the SO. The response of surface Fe and chlorophyll is maximum in the Atlantic sector, northeast of the tip of the Antarctic Peninsula, and along the East Antarctic coast. The iceberg Fe delivery below the mixed layer may, depending on its assumed vertical distribution, fuel a non-negligible subsurface reservoir of Fe. The AIS Fe supply is effective all year round. The seasonal variations of the iceberg Fe fluxes have regional impacts that are small for annual mean primary productivity and C export at the scale of the SO.

1 Introduction

Iron (Fe) is a vital micronutrient for phytoplankton photosynthesis and marine life. While being the fourth most abundant element in the continental crust (Wedepohl, 1995), Fe is present at extremely low concentrations in most of the oceans. In the Southern Ocean (SO), the largest high-nutrient low-chlorophyll (HNLC) region, this trace metal exerts with light a strong limitation on primary productivity (Martin et al., 1990; Smetacek, 2001; Coale et al., 2004; Boyd et al., 2007). Iron supply therefore modulates the intensity of the biological carbon pump in the SO (Bowie et al., 2001; Blain et al., 2007; Boyd et al., 2007) and possibly plays a key role in the glacial–interglacial carbon-cycle regulation of climate (Martin, 1990).

Several sources contribute to the Fe pool in the SO: atmospheric dust deposition (Wagener et al., 2008; Tagliabue et al., 2009; Boyd et al., 2010a, 2012; Hooper et al., 2019; Ito et al., 2019), sediment resuspension and dissolution (Dulaiova et al., 2009; Tagliabue et al., 2009; de Jong et al., 2013; Borrione et al., 2014), hydrothermal activity (Tagliabue et al., 2010), iceberg calving and melting (Smith et al., 2007; Lin et al., 2011; Duprat et al., 2016; Raiswell et al., 2016), ice shelves (Gerringa et al., 2012; Herraiz-Borreguero et al., 2016; St-Laurent et al., 2017), and sea ice (Lannuzel et al., 2007, 2010, 2016; Lancelot et al., 2009). Modeling studies have highlighted the different levels of significance of these Fe sources to sustain primary productivity in the SO (Lancelot et al., 2009; Tagliabue et al., 2009, 2014a;

Borrione et al., 2014; Death et al., 2014; Wadley et al., 2014; Wang et al., 2014; Laufkötter et al., 2018). Nevertheless, large uncertainties remain in their fertilization capacity due to an important lack of data, hampering their integration in biogeochemical and climate models (Tagliabue et al., 2016).

Among the Fe sources in the SO, icebergs and ice shelves have been largely overlooked in ocean biogeochemical models. For instance, none of the models participating in the FeMIP exercise include these glacial iron sources (Tagliabue et al., 2016), while observations estimate the total mean flux of potentially bioavailable Fe from SO icebergs to span 1 to 3 orders of magnitude higher than from dust deposition (Shaw et al., 2011; Raiswell et al., 2016) ranging from 3.2 to 25 Gmoles yr⁻¹ for icebergs and from 0.0 to 0.02 Gmoles yr⁻¹ for atmospheric dust (Raiswell et al., 2016). The few modeling studies conducted to date scaled the contribution of the AIS Fe source in the same order of magnitude as atmospheric dust (Lancelot et al., 2009; Death et al., 2014) or 1 order of magnitude higher (Wadley et al., 2014; Laufkötter et al., 2018) but with a larger uncertainty in the biological response to its fertilization effect. Thus, the iceberg Fe source is estimated to increase the SO primary production by 6% to 10% in Wadley et al. (2014), while Death et al. (2014) evaluated the iceberg and subglacial contribution to primary production to be up to 40%. Recently, Laufkötter et al. (2018) estimated, in a preindustrial context, the AIS Fe source to sustain 30% of the marine particle export production in the SO, consequently reducing the carbon outgassing in this region by 30%.

Icebergs and ice shelves contain higher Fe concentrations than seawater (de Baar et al., 1995; Lin et al., 2011; Shaw et al., 2011; Herraiz-Borreguero et al., 2016), mainly as lithogenic material from glacial sediments (Raiswell et al., 2006; Shaw et al., 2011; Hopwood et al., 2017). The melting of icebergs and ice shelves releases Fe to seawater as particulate, dissolved, and potentially dissolvable forms (Raiswell et al., 2008, 2016; Hawkings et al., 2014; Herraiz-Borreguero et al., 2016; Hodson et al., 2017), fueling the water column in Fe (Lin et al., 2011; De Jong et al., 2015). In the 1930s, Hart (1934) speculated that a link may exist between the phytoplankton populations observed in the Weddell Sea and potential Fe from the large number of debris-rich icebergs. Raiswell et al. (2006) showed that glacial sedimentary Fe contains nanoparticulate Fe, a small fraction of which can be biogeochemically reactive and potentially bioavailable to phytoplankton. The iron fertilization capacity of icebergs has been evidenced from in situ observations (Smith et al., 2007; Lin et al., 2011; Biddle et al., 2015), and hotspots of primary productivity have been observed by satellites in the wake of drifting icebergs (Schwarz and Schodlok, 2009; Duprat et al., 2016; Wu and Hou, 2017). In coastal regions, the under-ice-shelf delivery of bioavailable Fe can be significant to sustain primary productivity as highlighted in the Amundsen Sea (Gerringa et al., 2012; St-Laurent et al., 2017, 2019) and in Prydz Bay (Herraiz-Borreguero et al., 2016). The meltwa-

ter pump is also estimated as a significant Fe supply mechanism in polynyas (St-Laurent et al., 2017, 2019) and in coastal regions (Cape et al., 2019). However, the mean supply of the bioavailable Fe fraction from icebergs and ice shelves is difficult to quantify because of the heterogeneous nature of the Fe distribution in these sources (Raiswell et al., 2016; Hopwood et al., 2017). Until recent years, very few data were available. Estimates of iceberg Fe fluxes were based on only six samples (Raiswell et al., 2008) and, to our knowledge, no representative data are available for ice shelves. New observations, largely from Greenland icebergs, increased the set of iceberg data to about 50 glacial samples (Raiswell et al., 2016), offering the opportunity to better constrain the Fe supply from ice sheets to seawater and its effect on primary productivity in biogeochemical models.

Quantifying the AIS contribution to the iron pool in the SO is of great interest for marine biogeochemistry as this source may be influenced by global warming. Indeed, the SO is a large sink of anthropogenic carbon (Sabine et al., 2004; Khatiwala et al., 2013) whose physical environment is evaluated to be severely affected by climate change (Rintoul et al., 2018). The AIS has already lost a significant amount of its mass over the period 1992–2017. The total loss of ice mass is 2720 ± 1390 billion tons and is particularly strong in West Antarctica and in the Antarctic Peninsula region, where annual melting rates have increased by factors of 3 and 5, respectively (The IMBIE team, 2018). In a business-as-usual scenario, the glacial coverage in Antarctica is estimated to be massively altered with a possible 23% reduction of the ice shelf volume by 2070 (DeConto and Pollard, 2016; Rintoul et al., 2018). The projected AIS decline could increase the release of Fe from ice shelves and icebergs, with possible impacts on SO marine productivity and biogeochemical cycles, yet this would depend on how Fe inputs relate to productivity and carbon (C) export.

In this study, we assess the AIS impacts on Fe concentrations and marine primary productivity in the SO and investigate their sensitivity to the main characteristics of the iron delivery from icebergs and ice shelves. Firstly, we focus on the magnitude of the AIS Fe supply. For this purpose, different soluble fractions of sedimentary Fe are assumed in the ocean biogeochemical model NEMO-PISCES, associated with recent iceberg and ice shelf freshwater flux estimates. Secondly, because the distribution of released Fe from icebergs through the water column is largely undocumented, we explore several possible vertical distributions of iceberg Fe delivery to seawater to encompass this large uncertainty. Thirdly, the effects of the seasonal variations in the iceberg Fe supply are evaluated against an annual mean climatology of the iceberg Fe fluxes. Finally, we assess the relative contributions of ice shelves and icebergs to the SO Fe pool.

2 Method

2.1 NEMO-PISCES model description

We use the hydrodynamical and biogeochemical model NEMO-PISCES version 3.6 (Madec, 2008). This modeling platform is based on the ocean dynamical core OPA (Madec, 2008), the marine biogeochemistry model PISCES-v2 (Aumont et al., 2015), and the Louvain-La-Neuve sea ice model LIM3 version 3.6 (Rousset et al., 2015). We use a global configuration of NEMO-PISCES at 1° horizontal resolution on an isotropic mercator grid with a local meridional refinement up to $1/3^\circ$ at the Equator. The vertical grid follows a partial-step z -coordinate scheme and has 75 levels with 25 levels in the upper 100 m. Lateral mixing is computed along isoneutral surfaces (Madec, 2008). Mesoscale eddy-induced turbulence follows the Gent and McWilliams (1990) parameterization, and vertical mixing is parameterized using the turbulent kinetic energy scheme (Blanke and Delecluse, 1993) as modified by Madec (2008). The biogeochemical model PISCES simulates two phytoplankton functional types (diatoms and nanophytoplankton), two zooplankton size classes (microzooplankton and mesozooplankton), the biogeochemical cycles of five limiting nutrients (NO_3 , PO_4 , NH_4 , $\text{Si}(\text{OH})_4$, and Fe), dissolved oxygen, dissolved inorganic carbon, total alkalinity, dissolved organic matter, and small and large organic particles. Different external sources of Fe are included: atmospheric dust deposition, sediment mobilization, rivers, and sea ice. The implementation of these Fe sources in NEMO-PISCES is fully described in Aumont et al. (2015).

2.2 Modeling the Antarctic Ice Sheet Fe supply

To represent the AIS Fe supply to seawater in our model, we use recent freshwater flux climatologies of ice shelves and icebergs based on Depoorter et al. (2013). The modeled annual mean freshwater flux from the AIS is estimated as $\sim 2790 \text{ Gt yr}^{-1}$ partitioned into a liquid and a solid phase of about the same magnitude with an annual release of $\sim 1439 \text{ Gt yr}^{-1}$ from ice shelves and $\sim 1351 \text{ Gt yr}^{-1}$ from icebergs. The climatology of the coastal runoff estimate of Antarctic ice shelves is assumed to be a steady freshwater flux through the year. For icebergs, we use a model-based seasonal climatology of iceberg melting over the SO (Fig. 1) from Merino et al. (2016). The monthly climatology distribution of freshwater flux from icebergs was estimated using an improved version of the Lagrangian iceberg model NEMO-ICB (Marsh et al., 2015) coupled to a $1/4^\circ$ global configuration of NEMO (Merino et al., 2016). The ocean model was forced by a climatological repeated-year atmospheric forcing based on ERA-Interim and by recent estimates of Antarctic freshwater (Depoorter et al., 2013).

In our model configuration, the cavities below the ice shelves are not opened. We use the parameterization of Mathiot et al. (2017) to mimic the overturning circulation driven

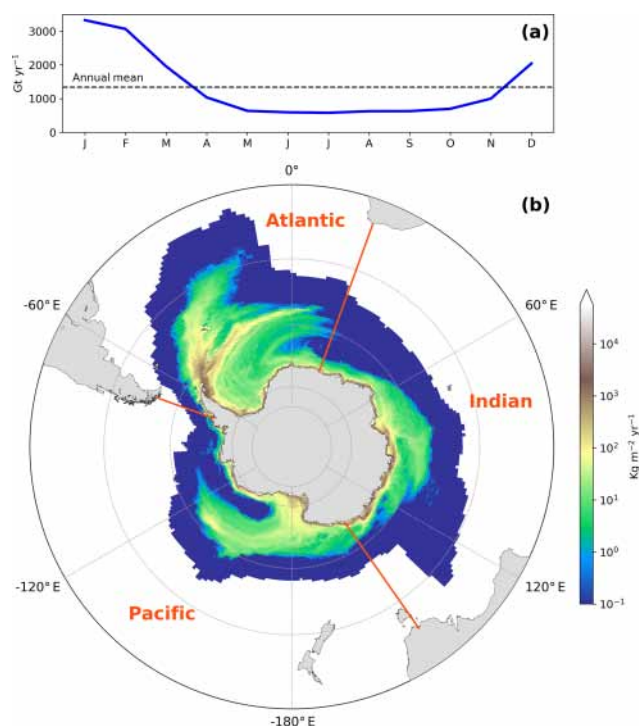

Figure 1. (a) Seasonal cycle of iceberg freshwater fluxes over the Southern Ocean from the climatology of Merino et al. (2016). (b) Annual mean freshwater fluxes from icebergs (Merino et al., 2016) and ice shelves (Depoorter et al., 2013) over the Southern Ocean, south of 30°S , used to represent the Fe supply from the Antarctic Ice Sheet in our study. Displayed in orange are the Atlantic (70°W – 20°E), Indian (20 – 145°E), and Pacific (145°E – 70°W) sectors of the Southern Ocean. Note the logarithmic scale.

by the unresolved ice shelves. The meltwater flux of ice shelves is uniformly distributed over the depth and width of the unresolved cavities, from the mean ice front base down to the seabed or the grounding line depth if shallower. This parameterization of the ice shelf melting drives a buoyant overturning circulation along the coast similar to that simulated by cavities when they are explicitly resolved. The so-called meltwater pump driven by this mechanism is pointed out to play an important role in the supply and delivery of Fe to polynyas (St-Laurent et al., 2017, 2019) and coastal regions (Cape et al., 2019). For icebergs, a similar mechanism may occur (Helly et al., 2011; Stephenson et al., 2011) but the scale of that process is small (Biddle et al., 2015). This subgrid-scale mechanism is not represented in the coupled iceberg–ocean model used to produce the iceberg meltwater climatology (Marsh et al., 2015; Merino et al., 2016) and not relevant with our model setup of 1° resolution.

The iceberg-hosted sediment content, while poorly constrained by observations, is estimated to range from 0.4 to 1.2 g L^{-1} (Anderson et al., 1980; Shaw et al., 2011). To simulate the Fe fluxes delivered by melting icebergs and ice shelves in the SO, we associate with the freshwater flux

climatologies a sediment content of 0.5 g L^{-1} as used in Raiswell et al. (2006) and Death et al. (2014) assuming, as a crude assumption, that sediment content in icebergs and ice shelves is roughly equivalent. The content of ferrihydrite, the most soluble Fe in iceberg-hosted sediments and thus potentially bioavailable, has been recently estimated to range from 0.03 wt % to 0.194 wt % with a mean content of 0.076 wt % (Raiswell et al., 2016). Shaw et al. (2011) estimated a range of ferrihydrite of 0.04 wt % to 0.4 wt % for free-drifting icebergs in the Weddell Sea. In our study, we set the mean sediment content in ferrihydrite to be 0.1 %. A conservative value of the fraction of ferrihydrite that can be biologically available as Fe nanoparticles (i.e., the soluble fraction of ferrihydrite) is around 10 % (Raiswell et al., 2008; Death et al., 2014). However, ice–water–mineral reactions may profoundly alter the bioavailability percentage of Fe in glacial sediments (Hawkings et al., 2018; Raiswell et al., 2010, 2018). In order to account for the uncertainty of the bioavailable fraction of glacial Fe (Boyd et al., 2012; Raiswell et al., 2010, 2018), we use a solubility within a range of 1 % to 10 %, which corresponds to a total annual Fe flux of 0.25 to $2.5 \text{ Gmoles yr}^{-1}$ (Table 1). The range of the modeled iceberg Fe fluxes is relatively similar to other modeling studies (Death et al., 2014; Laufkötter et al., 2018) and lies within the lower range of previously published estimates based on observations (Raiswell et al., 2008, 2016; Shaw et al., 2011). To our knowledge, no observational data are available that allow ice shelf Fe fluxes from the AIS to be constrained. However, the modeled ice shelf Fe fluxes are in the lower range of estimates by Hawkings et al. (2014) for the AIS, as extrapolated from Greenland Ice Sheet data.

2.3 Experimental design

We design nine model experiments with different Fe solubilities for both ice shelves and icebergs, as well as different vertical distributions of delivered Fe from icebergs (Table 2). For consistency with the climatological forcing of the Antarctic freshwater release, all these experiments are run in a climatological setup using the CORE-I normal year atmospheric forcing (Griffies et al., 2009) and are initialized from a 120-year-long spin-up simulation. They all include external sources of Fe from dust, sediments, sea ice, and rivers even though the latter does not contribute to the iron pool in the SO. Each experiment is run for 20 years to achieve a sufficient equilibrium state for the Fe cycle in the framework of our sensitivity study.

The control experiment (CTL) is used as a reference run in the rest of the study and does not take into account any Fe source from the AIS. Figure 2 shows the annual mean distribution of surface Fe concentrations over the SO simulated by the CTL experiment. This distribution is contrasted with regions showing high surface Fe concentrations in coastal regions around the Antarctic continent, in the surrounding waters of SO islands, such as South Georgia, the Crozet

Figure 2. Annual mean of surface Fe concentrations in the Southern Ocean, south of 45° S , in the CTL experiment.

archipelago, and the Kerguelen Plateau, and with large areas in the open ocean displaying very low values. The modeled surface distribution of Fe concentrations reflects the main contribution of sediments among the different external iron sources currently implemented in the standard version of the PISCES model (Aumont et al., 2015). The Fe distribution of the NEMO-PISCES model has been validated at the global scale in Tagliabue et al. (2016) and over the SO in Person et al. (2018), showing reasonable performance compared to available data (Tagliabue et al., 2012).

Three different solubilities of Fe from icebergs and ice shelves are tested in the SOLUB1, SOLUB5, and SOLUB10 experiments, imposing 1 %, 5 %, and 10 %, respectively. The corresponding annual Fe fluxes amount to 0.25, 1.25, and $2.5 \text{ Gmoles yr}^{-1}$, respectively, with similar contributions from both glacial sources (Table 1). The ISF, ICB-SURF, ICB-ML, ICB-KEEL, and ICB-ANNUAL experiments have an iceberg and ice shelf Fe solubility of 5 % as in the SOLUB5 experiment. The ISF experiment only includes the Fe source from ice shelves in order to assess its contribution relative to icebergs.

Different vertical distributions of the iceberg Fe fluxes are explored. In the SOLUB1, SOLUB5, SOLUB10, and ICB-ANNUAL experiments, Fe is homogeneously released from icebergs over the top 120 m of the water column. This value corresponds to the average depth of the submerged part of the five size classes of icebergs modeled by the NEMO-ICB model (Marsh et al., 2015) and computed by applying the formulation of Rackow et al. (2017) to the average thickness of the modeled icebergs. In the ICB-SURF experiment, the whole iceberg Fe supply is released at the surface, i.e., in the first vertical level of our model, which is 1 m thick. In the

Table 1. Annual estimates of Fe fluxes from observational and modeling studies in the SO. The iceberg Fe flux from Raiswell et al. (2016) is calculated by applying an Fe solubility of 10 % to their estimates of potentially bioavailable Fe fluxes.

ICB-KEEL experiment, this flux is released at ~ 120 m, i.e., at the mean depth of the keel of modeled icebergs. The ICB-KEEL experiment is set up to evaluate the contribution of a theoretical distribution of iceberg Fe fluxes delivered only at the base of icebergs. The ICB-KEEL experiment can be seen as the mirror experiment of the ICB-SURF experiment, keeping in mind that this distribution is most probably unrealistic as the potential buoyancy effect tends to upwell the iceberg meltwater to the surface (Smith et al., 2007; Helly et al., 2011; Stephenson et al., 2011). The different vertical distributions of iceberg Fe fluxes prescribed in our experiments offer an indirect means to explore the potential impact of that mechanism on ocean biogeochemistry. In order to evaluate the role played by the iceberg Fe fluxes distributed below the mixed layer (ML), that is, the fraction not directly available for surface primary productivity, we design the ICB-ML experiment in which this fraction is removed. Thus, the iceberg Fe fluxes in the ICB-ML experiment are distributed throughout the water column, i.e., until a depth of 120 m, as in the SOLUB5 experiment, but the iceberg Fe flux values below the mixed layer depth (MLD) are set to zero unlike in the SOLUB5 experiment. Finally, in the ICB-ANNUAL experiment, an annual mean climatology of the iceberg Fe fluxes is

used instead of the monthly climatology to assess the impact of the seasonal variability in the supply of Fe from icebergs in the SO.

3 Results

3.1 Contribution of the Antarctic Ice Sheet to the spatial distribution of Fe

3.1.1 Sensitivity to the magnitude of the Antarctic Ice Sheet Fe supply

The uncertainty in the magnitude of the AIS Fe source is estimated to span at least 1 order of magnitude (Table 1). We assess the impact of this range on the spatial distribution of Fe in the SO by imposing three different soluble fractions of Fe: 1 %, 5 %, and 10 % (Table 2). The Fe supply from the AIS increases the Fe concentrations in the first 120 m in the SOLUB1, SOLUB5, and SOLUB10 experiments compared to the CTL experiment, respectively, and the surface anomaly increases with the Fe solubility (Fig. 3).

Higher surface Fe concentrations are simulated in coastal regions all around the Antarctic continent. The most notice-

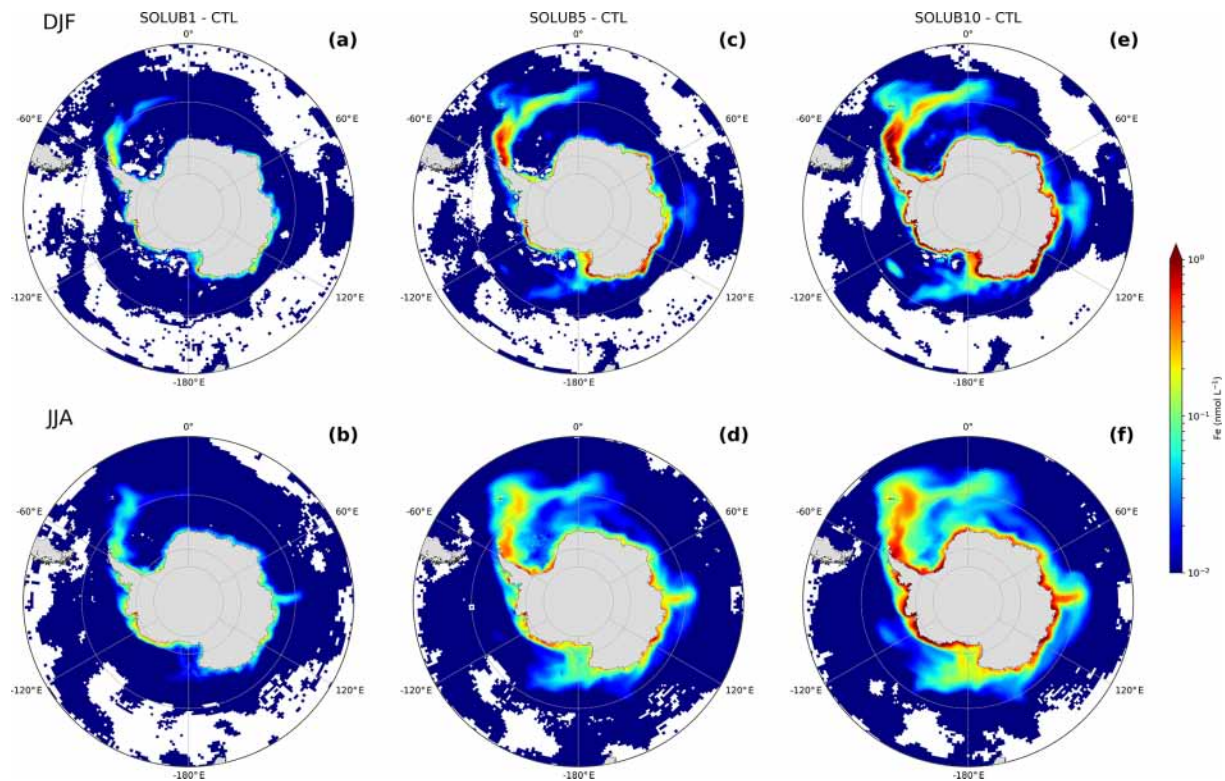

Figure 3. Difference in surface Fe concentrations between the (a, b) SOLUB1, (c, d) SOLUB5, and (e, f) SOLUB10 experiments and the CTL experiment (experiments minus CTL) in (a, c, e) summer (December, January, and February) and (b, d, f) winter (June, July, and August) in the Southern Ocean, south of 45° S. White areas are regions with nonsignificant changes. Note the logarithmic scale.

able Fe anomaly is a marked plume northeast of the Antarctic Peninsula that expands until 50° S in the Atlantic sector and reaches the western sector of the Indian Ocean (Fig. 3c–f). The spatial extent of the Fe anomalies becomes larger as the Fe solubility increases, particularly in the Atlantic sector and in the Ross Sea, which appear to be the offshore areas that are the most greatly influenced by the AIS Fe source. The SOLUB1 experiment simulates a moderate impact with annual mean surface Fe concentrations increased by $\sim 0.026 \text{ nmol L}^{-1}$ over the SO, south of 50° S, relative to the CTL experiment, i.e., 3% more. The supply in the Atlantic plume increases the surface Fe concentrations by up to 0.16 nmol L^{-1} in summer (Fig. 3a). The highest Fe values are found in winter along the coasts of the Ross Sea and the Amundsen Sea with surface Fe anomalies that reach 1 nmol L^{-1} (Fig. 3b). In the SOLUB5 experiment, the contribution of the AIS Fe source is more significant, with mean surface Fe concentrations that are $\sim 0.12 \text{ nmol L}^{-1}$ higher, i.e., 13% more than in the CTL experiment (Fig. 3c and d). The Atlantic plume is clearly marked and extends further eastward until 10° E with surface Fe concentrations in summer up to $\sim 0.8 \text{ nmol L}^{-1}$ higher (Fig. 3c). Along the Antarctic coast, the AIS supply in winter increases the surface Fe anomalies by up to 3.8 nmol L^{-1} , particularly in the Indian and Pacific sectors (Fig. 3d). Two additional plumes emerge:

a large one north of the Ross Sea and a smaller one in the vicinity of South Georgia (Fig. 3c and d). The SOLUB10 experiment strengthens the seasonal and spatial patterns of the surface Fe anomalies simulated in SOLUB5 with extensive Fe anomalies in the Atlantic plume, in the Ross Sea, in the Weddell Sea, and all along the Antarctic coast (Fig. 3e and f). Over the SO, south of 50° S, the annual mean Fe concentrations are $\sim 0.21 \text{ nmol L}^{-1}$ higher than in the CTL experiment, an increase of 24%. The surface Fe concentrations in the Atlantic plume and along the Antarctic coast are up to ~ 1.4 and $\sim 6.3 \text{ nmol L}^{-1}$ higher, respectively. These Fe concentrations are difficult to compare to observations in these areas due to the scarcity of data. However, they are probably at the upper limit of Fe concentrations in the open ocean but still potentially realistic in coastal regions (de Jong et al., 2012). With an Fe solubility of 10%, the SOLUB10 experiment predicts an important contribution of the AIS source to the SO Fe pool (Fig. 3e), which is even larger near the coasts in winter (Fig. 3f).

The AIS significantly alters the surface Fe concentrations both in summer and winter (Fig. 3). The spatial patterns between these two seasons exhibit noticeable differences. In summer, surface Fe anomalies are marked and intense (Fig. 3c and e), whereas in winter they extend over larger areas and are more diffuse (Fig. 3d and f), showing lower

maximum values but having higher mean levels. These seasonal differences reflect two different dynamics in the supply of Fe from the AIS and its subsequent loss from the surface. In summer, the release of Fe associated with more intense iceberg freshwater fluxes drives surface Fe concentrations to high values. Environmental conditions are favorable for phytoplankton growth and the intense biological activity efficiently consumes the supplied Fe, preventing it from being transported over large distances, especially in iron-limited areas. In winter, biological activity is much weaker due to strong light limitation and the delivered Fe from the AIS can be advected further away. Furthermore, in winter, deep mixing entrains to the surface Fe that was released in summer below the euphotic zone and that escaped consumption by phytoplankton due to the lack of light. This unconsumed fraction is also advected over significant distances by the intense ocean circulation in the SO. This explains the much sharper gradients simulated in summer, particularly noticeable in the SOLUB5 and SOLUB10 experiments.

3.1.2 Sensitivity to vertical distributions of the iceberg Fe supply

It is well established that ice shelf meltwater is injected at depth into the ocean (Depoorter et al., 2013; Mathiot et al., 2017). The basal melting is driven by the properties of water masses that enter the ocean cavities underneath ice shelves (Jacobs et al., 1992), contributing directly and indirectly to the supply of Fe to the upper layer of the water column (St-Laurent et al., 2017, 2019). While the iceberg Fe supply has been evidenced by in situ observations (Lin et al., 2011; Shaw et al., 2011; De Jong et al., 2015), almost nothing is known to our knowledge about where the Fe delivery occurs along the immersed part of icebergs and where this input is predominately available to phytoplankton. Nonetheless, Fitz-Maurice et al. (2017) recently pointed out that the nonlinear response of iceberg melting leads to meltwater injected near the surface or mixed at depth depending on whether the flow velocity is weak or strong, respectively. Here, we assess the impacts of four different theoretical vertical distributions of iceberg Fe fluxes on surface Fe concentrations over the SO as well as on vertical profiles of Fe in the upper 300 m of a large area highly fertilized by the AIS northeast of the Antarctic Peninsula (36–56° W, 58–63° S). For this purpose, we compare the ICB-SURF, ICB-ML, and ICB-KEEL experiments against the SOLUB5 experiment (Fig. 4).

The surface distribution of the iceberg Fe fluxes in the ICB-SURF experiment results in a large excess of surface Fe concentrations in summer compared to the volume distribution applied in the SOLUB5 experiment (Fig. 4a). This excess is regionally important, with surface Fe concentrations up to 1.5 nmol L⁻¹ higher in the large plume of the Atlantic sector and up to 27 nmol L⁻¹ higher in coastal areas than in the SOLUB5 experiment. Such maximum coastal concentrations of surface Fe are rarely observed except in a nearshore

area north of the Antarctic Peninsula (de Jong et al., 2012). In the ICB-SURF experiment, the iceberg Fe supply in the mixed layer is maximum and is not sensitive to the depth of the mixed layer. By contrast, when the Fe flux is distributed over the upper 120 m (SOLUB5), the shallow pycnocline in summer severely limits the iceberg Fe supply in the mixed layer, with most of this supply being injected below the MLD. The differences between the two experiments in winter are significantly less marked, with large patterns of positive and negative differences in surface Fe concentrations highlighting the role played by the interactions between the seasonal variations of the MLD and the injection of Fe at depth (Fig. 4b). When the MLD is deeper than 120 m, the ICB-SURF experiment simulates slightly lower Fe concentrations up to ~0.04 nmol L⁻¹ lower than in SOLUB5 in the Atlantic sector south of 60° S and regionally around the Antarctic coast. The boundary zone between positive and negative values in the Atlantic sector is driven by the interplay between an MLD shallower than 120 m (Fig. 5) and the oceanic circulation, resulting in Fe concentrations up to 1.5 nmol L⁻¹ higher in the ICB-SURF experiment than in SOLUB5 along the eastern coasts of the Antarctic Peninsula. Higher Fe concentrations are also simulated in ICB-SURF in localized areas in the Ross, Amundsen, and Bellingshausen seas, as well as near the coasts of the Indian sector between 70 and 85° E but without a clear correlation with the MLD.

The vertical profiles of Fe in the highly fertilized area of the Atlantic plume northeast of the Antarctic Peninsula (36–56° W, 58–63° S) illustrate the different dynamic in the seasonal supply of Fe to the upper ocean in both experiments (Fig. 6). In summer, these vertical profiles are very different (Fig. 6a). In the mixed layer, Fe concentrations are higher in ICB-SURF than in SOLUB5 by a factor of 2.2. Below the MLD, the ICB-SURF experiment simulates Fe concentrations that decrease strongly until 70 m. In the SOLUB5 experiment, Fe concentrations increase significantly from below 30 until 120 m and from there decrease until 150 m. Below 150 m, both experiments converge to the same vertical profile of Fe. In winter, the vertical profiles are qualitatively similar in the upper 300 m (Fig. 6b). Yet, the ICB-SURF experiment displays a smaller vertical gradient in the upper 150 m than in SOLUB5. The scarcity of data makes it challenging to discriminate whether the ICB-SURF experiment or the SOLUB5 experiment simulates a realistic vertical distribution of Fe.

The ICB-ML experiment permits the assessment of the influence of the iceberg Fe supplied below the MLD, i.e., the importance of the nondirectly available fraction of the iceberg Fe source, on the spatial distribution of Fe over the SO. Surface Fe concentrations in the ICB-ML experiment are lower than in the SOLUB5 experiment in both seasons and over the whole SO (Fig. 4c and d). Surface Fe values in summer and winter are up to ~0.55 and ~0.4 nmol L⁻¹ lower, respectively, than in the SOLUB5 experiment. This comparison suggests that the Fe fraction delivered by icebergs below

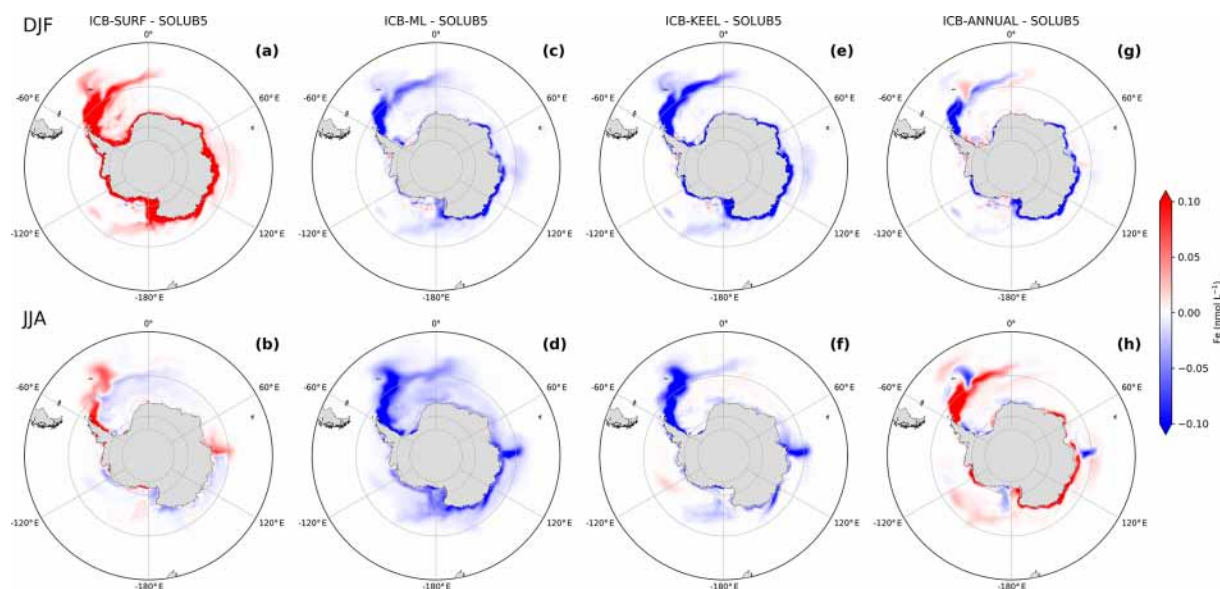

Figure 4. Difference in surface Fe concentrations between the (a, b) ICB-SURF, (c, d) ICB-ML, (e, f) ICB-KEEL, and (g, h) ICB-ANNUAL experiments and the SOLUB5 experiment (experiments minus SOLUB5) in (a, c, e, g) summer (December, January, and February) and (b, d, f, h) winter (June, July, and August) in the Southern Ocean, south of 45° S. Positive values in red are regions with surface Fe concentrations higher than in the SOLUB5 experiment, and negative values in blue are regions with surface Fe concentrations lower than in the SOLUB5 experiment.

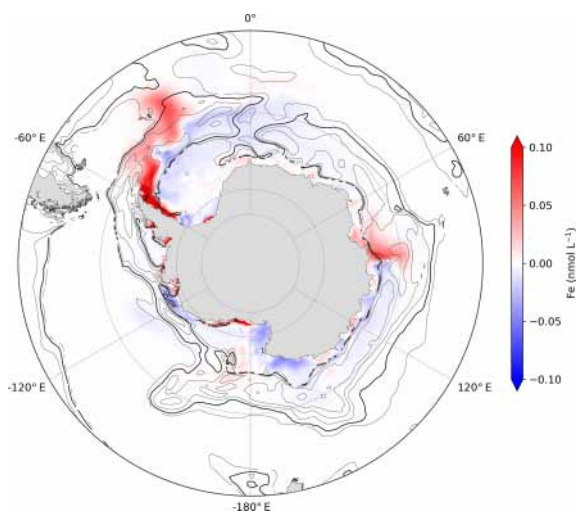

Figure 5. Difference in surface Fe concentrations between the ICB-SURF and the SOLUB5 experiments in winter (June, July, and August) in the Southern Ocean, south of 45° S. The black isoline represents the mixed layer depth at 120 m, and the gray isolines represent mixed layer depth shallower than 120 m.

the MLD is not completely scavenged and constitutes an Fe pool that can supply surface waters with Fe as soon as the mixed layer deepens.

The seasonal evolution of the vertical Fe profiles supports the important role of the subsurface additional pool of Fe due to iceberg melting (Fig. 6). In summer, the

SOLUB5 experiment has Fe concentrations in the mixed layer $\sim 0.1 \text{ nmol L}^{-1}$ higher than in the ICB-ML experiment (Fig. 6a). Below the MLD, Fe concentrations in SOLUB5 display a local maximum between 30 and 150 m that the ICB-ML experiment does not simulate. In winter, Fe profiles in SOLUB5 and ICB-ML are qualitatively similar except that Fe levels in ICB-ML are about 0.06 nmol L^{-1} higher (Fig. 6b). This comparison illustrates that the Fe released by icebergs in summer below the MLD may represent a significant subsurface reservoir that can supply Fe to the surface layer through intraseasonal events such as storms (Swart et al., 2015; Nicholson et al., 2016), strong mesoscale and sub-mesoscale activities (Swart et al., 2015; Rosso et al., 2016), and deep mixing in winter (Tagliabue et al., 2014b).

The iceberg Fe supply at depth in the ICB-KEEL experiment shows a significant decrease in surface Fe concentrations compared to the SOLUB5 experiment in both seasons (Fig. 4e and f). In summer, surface Fe concentrations are up to $\sim 2.8 \text{ nmol L}^{-1}$ lower than in the SOLUB5 experiment in the Atlantic plume and all around the Antarctic coast (Fig. 4e). In winter, the difference is weaker than in summer, with surface Fe concentrations up to $\sim 0.8 \text{ nmol L}^{-1}$ lower than in the SOLUB5 experiment (Fig. 4f). Moreover, the spatial differences between the two experiments in the open ocean in winter are less widespread than in the ICB-ML experiment (Fig. 4d) in which the iceberg fertilization effect is less effective south of the Atlantic plume and, more generally, south of 60° S offshore of the Antarctic coast. While

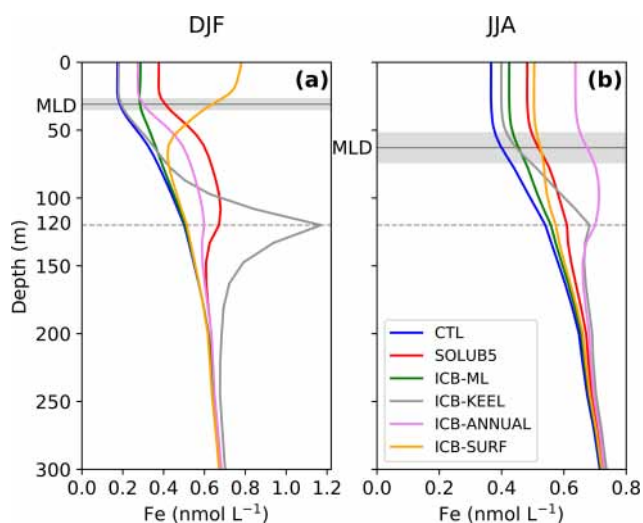

Figure 6. Vertical profiles of Fe concentrations until 300 m northeast of the Antarctic Peninsula (36–56° W, 58–63° S) in the CTL (blue), SOLUB5 (red), ICB-ML (green), ICB-KEEL (gray), ICB-ANNUAL (pink), and ICB-SURF (orange) experiments in (a) summer (December, January, and February) and in (b) winter (June, July, and August). The solid light gray line is the mixed layer depth (MLD) in (a) summer and (b) winter averaged over the region, in gray shading is the standard deviation of the MLD over the region in (a) summer and (b) winter, and the dashed gray line is the 120 m isobath.

low, the supply of Fe from icebergs at depth can have a large area of influence on surface Fe concentrations in winter.

The vertical profile of Fe in the Atlantic plume presents a marked peak at a depth of 120 m, which corresponds to the depth at which Fe is released from iceberg melting. At this depth, Fe concentrations reach 1.2 nmol L^{-1} in summer, which is 0.5 nmol L^{-1} higher than in the SOLUB5 experiment (Fig. 6a). In the upper layer, Fe concentrations are lower by $\sim 0.2 \text{ nmol L}^{-1}$ than in the SOLUB5 experiment and almost equal to the CTL experiment. The vertical gradient is the strongest of all the experiments. In winter, surface Fe concentrations in the mixed layer are $\sim 0.09 \text{ nmol L}^{-1}$ lower than in the SOLUB5 experiment and slightly higher than in the CTL experiment (Fig. 6b). The vertical gradient between the surface and 120 m remains stronger than in any other experiments but the difference is weaker. Below 120 m and down to about 200 m, differences with the other experiments are significantly smaller than in summer. These results show that a predominant supply of Fe at the base of icebergs will generate an important subsurface reservoir of Fe that can be entrained to the surface by the deepening of the MLD. The role of the subsurface reservoir of Fe is pointed out to be critical to sustain the iron supply to surface waters (Tagliabue et al., 2014b).

3.1.3 Sensitivity to the seasonal variations of the iceberg Fe supply

The variations of the AIS Fe fluxes due to the seasonal variability of iceberg calving and melting (Fig. 1a) impact the seasonal cycle of Fe over the SO. To assess to what extent these variations are significant for the SO Fe pool, we compare the ICB-ANNUAL experiment to the SOLUB5 experiment. Over the whole SO, the surface Fe concentrations in the ICB-ANNUAL experiment and the SOLUB5 experiment are increased by 9 % and 13 % in summer and by 15 % and 13 % in winter, respectively, relative to the CTL experiment. Imposing an annual mean iceberg supply of Fe also leads to differences in the spatial distribution of Fe (Fig. 4g and h). In ICB-ANNUAL, surface Fe concentrations in summer are lower in the Atlantic sector and around the Antarctic coast than in the SOLUB5 experiment, with values up to $\sim 1.9 \text{ nmol L}^{-1}$ lower (Fig. 4g). On the other hand, some other areas such as downstream of South Georgia, in the Weddell Sea, and in the Ross Sea are predicted to have higher Fe concentrations. In the Weddell Sea, along the east coasts of the Antarctic Peninsula, the Fe values in the ICB-ANNUAL experiment are up to 0.2 nmol L^{-1} higher than in the SOLUB5 experiment. In winter, an opposite spatial pattern is simulated (Fig. 4h). Surface Fe concentrations in the Atlantic plume and along the east coasts are up to $\sim 0.75 \text{ nmol L}^{-1}$ higher in the ICB-ANNUAL experiment, whereas downstream of South Georgia, in the Weddell Sea, in the Ross Sea, and offshore of 80° E these concentrations are up to $\sim 0.45 \text{ nmol L}^{-1}$ lower. When looking at the vertical Fe distribution in the Atlantic plume, vertical profiles in summer have almost the same shape in both experiments (Fig. 6a). However, Fe concentrations in ICB-ANNUAL are lower by $\sim 0.1 \text{ nmol L}^{-1}$ in the upper 120 m than in SOLUB5. In winter, the vertical profile of Fe in ICB-ANNUAL is noticeably different, with Fe concentrations higher by $\sim 0.18 \text{ nmol L}^{-1}$ in the upper 50 m and with values that increase and then decrease by $\sim 0.1 \text{ nmol L}^{-1}$ between 50 and 150 m, whereas Fe concentrations in the SOLUB5 experiment increase gradually in this depth range (Fig. 6b). Thus, when the seasonal variations of iceberg Fe are not considered, the seasonal amplitude of the Fe cycle over the SO is increased, with Fe concentrations higher in winter and lower in summer (Fig. S2a), leading to significant regional differences in the surface distribution of Fe.

3.1.4 Evaluation of the ice shelf contribution

The AIS Fe supply occurs through two main processes: (1) the basal melting of ice shelves, which is coastal, and (2) the calving and melting of icebergs, which is more widespread over the SO. Both freshwater sources are estimated to be of the same order of magnitude (Depoorter et al., 2013). In addition, ice shelf melting contributes indirectly to the supply of Fe to the upper layer of the water column

Figure 7. Difference in surface Fe concentrations between the (a, b) SOLUB5 and (c, d) ISF experiments and the CTL experiment (experiments minus CTL) in (a, c) summer (December, January, and February) and (b, d) winter (June, July, and August) in the Southern Ocean, south of 45° S. White areas are regions with nonsignificant changes. Note the logarithmic scale.

through the meltwater pump driven by the buoyancy overturning circulation near the ice shelf fronts (St-Laurent et al., 2017, 2019). The relative contribution of each source of Fe to the SO iron pool is not known, mainly due to the lack of data for ice shelves. Here, we compare the ISF experiment, which only accounts for the ice shelf Fe source, against the SOLUB5 experiment, which encompasses both sources of Fe from the AIS. The surface Fe anomalies in the ISF experiment differ remarkably from the SOLUB5 experiment (Fig. 7). The ice shelf contribution is trapped near the Antarctic coast, extending further offshore in winter (Fig. 7c and d), whereas the spatial contribution of icebergs spreads the influence of the AIS Fe source more widely over the SO until 50° S (Fig. 7a and b).

The surface Fe concentrations in the ISF experiment are increased by 1 % and 3 % compared to the CTL experiment in summer and winter, respectively. The contribution of ice

shelves to the SO Fe pool is 1 order of magnitude lower than in the SOLUB5 experiment, which simulates surface Fe concentrations that are increased by 13 % in both seasons. The comparison between the two Fe sources highlights the higher fertilization capacity of icebergs due to a delivery at larger spatial scales. It also suggests that the direct and indirect supplies of Fe to surface waters from ice shelf melting are significantly limited by the stratification of the mixed layer. Moreover, the ice shelf supply occurs in coastal regions already highly fertilized by sediments and where elevated Fe concentrations experience intense scavenging. The additional Fe from ice shelves is therefore rapidly scavenged and lost from surface waters.

3.2 Fertilization effect of the Antarctic Ice Sheet on surface chlorophyll

The SO is the largest HNLC region where Fe is the main limiting micronutrient for primary productivity. We show that the Fe supply by ice shelf and iceberg melting can fertilize the surface waters all year round (Fig. 3). This additional input of Fe can be used at the blooming season by phytoplankton from November to February. Here, we qualitatively evaluate the fertilization effect of the AIS on surface chlorophyll concentrations (SChl) in summer (December, January, and February). First of all, we briefly compare the SChl climatology from satellite observations of the MODIS Aqua ocean color product estimated by Johnson et al. (2013) to the CTL experiment (Fig. 8a and b). At the scale of the SO, two main qualitative characteristics can be observed. The CTL experiment represents with a rather good approximation the SChl distribution in summer around the Antarctic continent, from the Antarctic coast until 65° S. But, in the open ocean north of 65° S, quite large differences between observations and the standard version of the model are seen, especially in the Atlantic sector and in the Pacific sector north of the Ross Sea where large spatial patterns of SChl are not simulated.

To assess the fertilization effect of the AIS on SChl, we compute the SChl difference between the eight experiments and the CTL experiment (Fig. 9). The AIS impact on SChl is mostly apparent in the Atlantic sector northeast of the Antarctic Peninsula, along the Antarctic coast in the Indian and Pacific sectors, and, more moderately, north of the Ross Sea. The fertilization effect increases with the Fe solubility, with SChl higher by 2%, 7%, and 12% in the SOLUB1, SOLUB5, and SOLUB10 experiments, respectively (Fig. 9a–c). The main features driven by the intensity of the AIS Fe source are the extension of an Atlantic plume until the Indian sector and the increased SChl along the coasts from 80° E until the Ross Sea. In the SOLUB1 experiment, the impact on SChl is particularly low, restricted to the Atlantic sector and in coastal areas around 135° E (Fig. 9a). The Atlantic plume has the smallest extent from the Antarctic Peninsula until the South Orkney Islands where SChl values are up to $\sim 0.4 \text{ mg m}^{-3}$ higher than in the CTL experiment. The Fe solubility of 5% implemented in the SOLUB5 experiment significantly increases the impact of the AIS on SChl (Fig. 9b). The Atlantic plume extends eastward, far from the Antarctic Peninsula and the South Orkney Islands. The blooms along the Antarctic coast in the eastern sector and in the Ross Sea get more intense, and two modest plumes emerge north of the Ross Sea and around 90° E. The maximum contribution to SChl between the Antarctic Peninsula and the South Orkney Islands is $\sim 1 \text{ mg m}^{-3}$ higher than in the CTL experiment and 2.2 mg m^{-3} higher in the coastal area around 135° E. The SOLUB10 experiment emphasizes the spatial patterns described in the SOLUB5 experiment, with SChl higher by $\sim 1.2 \text{ mg m}^{-3}$ in the Atlantic sector until Bouvet Island and up to $\sim 2.4 \text{ mg m}^{-3}$ higher along the

coasts in the eastern sector of the SO (Fig. 9c). The plume that extends northward from the Ross Sea until 60° S has more elevated SChl levels, about $\sim 0.3 \text{ mg m}^{-3}$ higher than in the CTL experiment.

In the ICB-SURF experiment, the simulated contribution to SChl is the largest, with an increase of 12% over the whole SO. The maximum SChl values are up to $\sim 1.3 \text{ mg m}^{-3}$ higher in the Atlantic plume and up to $\sim 2.5 \text{ mg m}^{-3}$ higher in the Ross Sea and along the east coasts of Antarctica relative to the CTL experiment (Fig. 9d). Despite a slightly higher intensity of the bloom, the spatial patterns in the ICB-SURF experiment are very similar to the SOLUB10 experiment (Fig. 9c and d). In contrast, in the ICB-KEEL experiment, the iceberg contribution to surface chlorophyll is the lowest, SChl being on average only 2% higher relative to CTL. The Atlantic plume is absent, as are the elevated concentrations along the Antarctic coast and in the Ross Sea (Fig. 9f). Nevertheless, though small, a fertilizing effect is simulated with SChl values that are locally higher by 0.25 mg m^{-3} than in the CTL experiment. The ICB-ML experiment produces SChl anomalies that lie between the SOLUB1 and the SOLUB5 experiments, with maximum SChl up to ~ 0.9 and $\sim 1.6 \text{ mg m}^{-3}$ higher than in the CTL experiment in the Atlantic plume and in local areas along the east coasts of Antarctica, respectively (Fig. 9e). The influenced area is clearly smaller than in the SOLUB5 experiment, demonstrating that the nondirectly available fraction of Fe delivered by melting icebergs may have a non-negligible impact on SChl during the blooming season. The ICB-ANNUAL experiment simulates SChl levels that are on average higher by 6% over the SO compared to the CTL experiment with anomalies higher by $\sim 0.7 \text{ mg m}^{-3}$ in the Atlantic plume and up to $\sim 1.2 \text{ mg m}^{-3}$ along the Antarctic coast (Fig. 9g). Although maximum SChl values in the Atlantic plume are $\sim 0.3 \text{ mg m}^{-3}$ lower, the simulated spatial extent of the SChl anomalies in the Atlantic sector is wider than in the SOLUB5 experiment, the other impacted areas being almost identical in the ICB-ANNUAL and the SOLUB5 experiments. In the ISF experiment, the increase in SChl is very small as a consequence of the weak impact of ice shelf melting on Fe (Fig. 9h, see Sect. 3.1.4).

3.3 Model evaluation

The purpose of this sensitivity study is not to specifically improve the skill of the biogeochemical model at representing the Fe and SChl distributions in the SO but to investigate the uncertainties associated with the external source of Fe from the AIS. However, in order to confirm that large biases are not introduced by the implementation of the new iron source in the biogeochemical model, we perform a statistical model–data comparison for Fe and SChl over the SO, south of 50° S. For Fe, we compare the model experiments to a global database constructed by Tagliabue et al. (2012). For surface chlorophyll concentrations, we use a monthly cli-

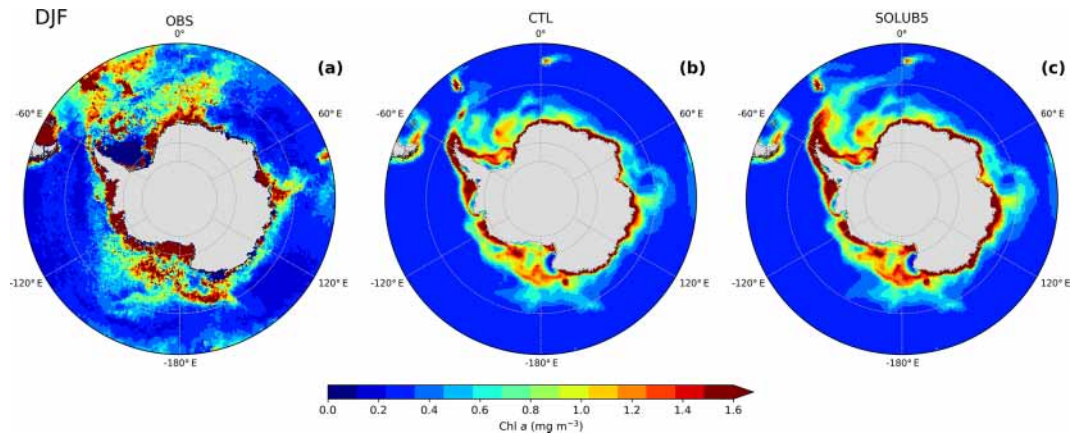

Figure 8. Surface chlorophyll concentrations in summer (December, January, and February) from (a) satellite observations (MODIS Aqua; Johnson et al., 2013), (b) the CTL experiment, and (c) the SOLUB5 experiment in the Southern Ocean, south of 50° S.

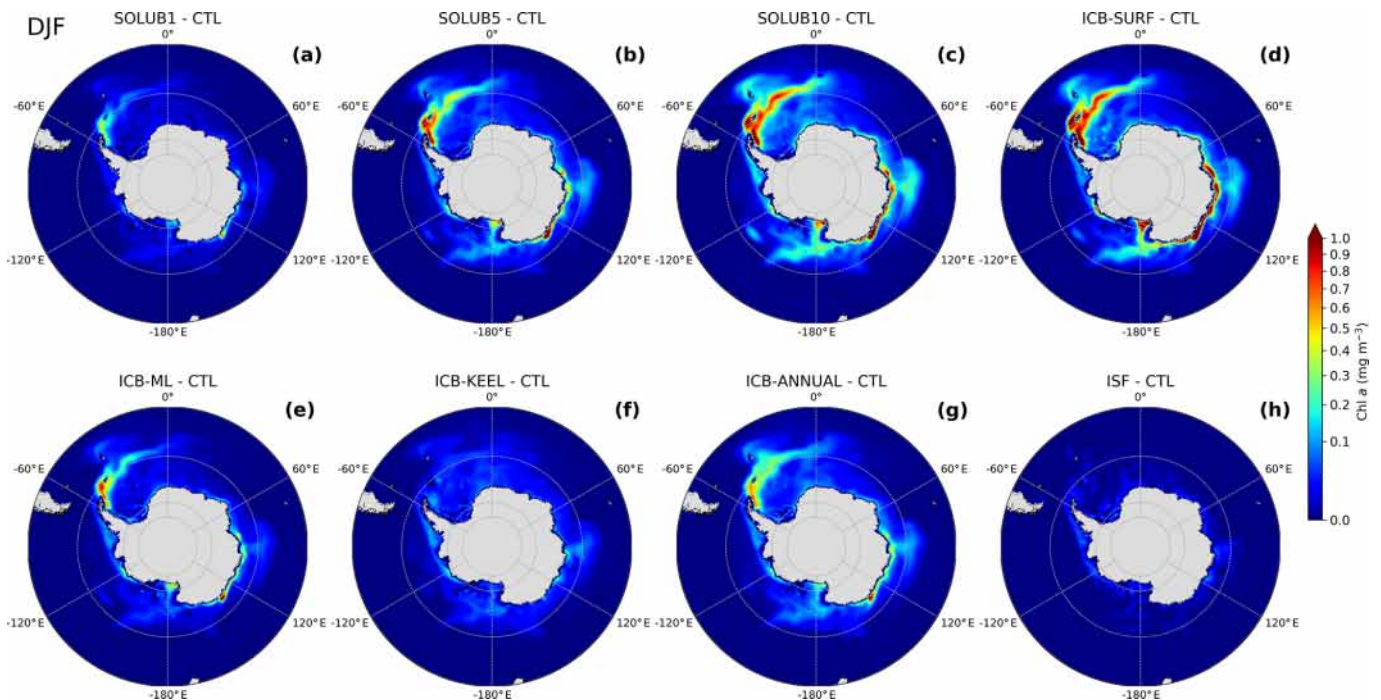

Figure 9. Difference in surface chlorophyll concentrations in summer (December, January, and February) between the (a) SOLUB1, (b) SOLUB5, (c) SOLUB10, (d) ICB-SURF, (e) ICB-ML, (f) ICB-KEEL, (g) ICB-ANNUAL, and (h) ISF experiments and the CTL experiment (experiments minus CTL) in the Southern Ocean, south of 45° S.

matology of satellite-based (MODIS Aqua) estimates from Johnson et al. (2013). The statistical comparison shows that performance scores for annual Fe concentrations integrated over the upper 200 m and surface chlorophyll in summer are similar in all experiments (Tables S1 and S2 in the Supplement). The biases are relatively small, ranging from -0.07 to 0.02 nmol L^{-1} for Fe and -0.13 to -0.07 mg m^{-3} for SChl. The main difference is the increase in the mean Fe and surface chlorophyll concentrations showing a better agreement with observations, such as in the SOLUB5 experiment for

Fe (Table S1) and in the SOLUB10 and ICB-SURF experiments for SChl (Table S2). This statistical analysis reveals no degradation of the performance skill of the standard version of the biogeochemical model when the AIS Fe source is added but also no improvements in the spatial distributions of Fe and chlorophyll concentrations. Thus, the absence of the AIS Fe fluxes is not a major cause that explains the biased representation of Fe and SChl in the NEMO-PISCES model.

3.4 Contribution of the Antarctic Ice Sheet to primary production and carbon export

At the blooming season, the Fe supply from the AIS stimulates phytoplankton activity, which can be quantified in terms of primary production and carbon (C) export. The increase in the annual primary production of phytoplankton (diatoms and nanophytoplankton) integrated over depth is relatively low in the Fe solubility experiments compared to the total primary production of 2.39 PgC yr^{-1} computed over the SO, south of 50° S , in the CTL experiment (Table 3). The increase in primary production ranges from 0.01 PgC yr^{-1} in the SOLUB1 experiment to 0.12 PgC yr^{-1} in the SOLUB10 experiment, i.e., a difference of 1 order of magnitude between the least and the most impacted cases. In the SOLUB10 experiment, primary production is 5 % higher than in the CTL experiment, a difference that drops to less than 1 % in the SOLUB1 experiment. This slightly enhanced primary productivity increases C export by 1 % in the SOLUB1 experiment and by more than 8 % in the SOLUB10 experiment. With an Fe solubility of 5 %, primary production simulated in the SOLUB5 experiment is $\sim 3 \%$ higher and C export around 5 % higher than in the CTL experiment. Thus, the supply of Fe from the AIS results in a non-negligible but modest increase in C export at the scale of the SO and subsequent sequestration of carbon in the interior of the ocean.

For the other sensitivity experiments, the predicted impacts on primary production and C export all fall between those simulated by the SOLUB1 and SOLUB10 experiments. Releasing Fe at the surface as tested in the ICB-SURF experiment produces changes that are only slightly lower than in the SOLUB10 experiment. This suggests that the efficiency of the AIS Fe source is higher when located at the surface. The comparison of the SOLUB5 experiment with the ICB-ML experiment reveals that the nondirectly available fraction of Fe released from icebergs may increase the impact of the source on primary production and C export by $\sim 40 \%$. The ICB-ANNUAL experiment shows a primary production and a C export almost equal to the SOLUB5 experiment, suggesting no effect of the seasonal variability of iceberg Fe supply on annual primary productivity and C export at the scale of the SO. Finally, when only the ice shelf Fe source is considered in the ISF experiment, primary production and C export are almost unchanged compared to the CTL experiment.

4 Discussion

4.1 Sensitivity of Fe and chlorophyll to the iron source from the Antarctic Ice Sheet

Our sensitivity study aims to delineate the biogeochemical impacts of the uncertainties surrounding the fertilization capacity of the AIS. Different aspects of the AIS Fe fluxes are explored: the intensity of the source, the impact of the iceberg

Fe distribution in the water column, and the contribution of the seasonal variations of the iceberg meltwater.

The Fe supply from the AIS is highly sensitive to the hypothesized solubility of ferrihydrite, revealing strong impacts on the spatial distribution of Fe. The main supply of Fe occurs in the Atlantic sector downstream of the Antarctic Peninsula, along the Antarctic coast, and, more moderately, in the Ross Sea. The iceberg contribution to surface Fe is large and can extend until 50° S , as shown by the large plume expanding from the Antarctic Peninsula until the Indian sector (Fig. 3). The spatial distribution of the surface Fe anomalies in our model setup is in line with Laufkötter et al. (2018) but differs substantially from Death et al. (2014). In Death et al. (2014), the main fertilized area is simulated along the eastern sector of the Antarctic coast, showing a larger offshore extent, the Atlantic plume is clearly much less marked and extended, and the AIS influence in the region of the Ross Sea is weaker. These differences may be linked to the implementation in Death et al. (2014) of basal iceberg sediment loading, which induces high Fe concentrations in the basal layer and very low concentrations above this basal layer, whereas a homogeneous distribution is considered in our study. Their vertically varying distribution of Fe in icebergs may simulate a stronger fertilization effect in the calving regions driven by an important basal melting. Further offshore, once the basal Fe-rich part of icebergs has melted, the release of Fe is strongly decreased due to the lower Fe concentrations in the upper part of icebergs, resulting in a weaker fertilization effect in remote areas of the open ocean such as in the Atlantic sector.

The AIS fertilization impact on surface chlorophyll depends on the intensity of the AIS Fe source as well as on the choice of its vertical distribution (Fig. 9). The efficiency of the fertilization is regionally important, with increased Schl along the east coasts of Antarctica and in the core of the Atlantic plume off the tip of the Antarctic Peninsula. However, at the scale of the SO, south of 50° S , the AIS impact on primary production is quite modest, reaching a maximum increase of 5 % in our set of experiments relative to the control run (Table 3). Our results are similar (lower by 3 %) to Wadley et al. (2014) but contrast sharply with the 30 % increase in primary production estimated in Death et al. (2014). The AIS contribution in Death et al. (2014) is evaluated against atmospheric dust, sediments being not taken into account. The lack of the sedimentary Fe source, estimated to be the largest in the SO (Lancelot et al., 2009; Tagliabue et al., 2009, 2014a; Borrione et al., 2014; Wadley et al., 2014), leads to a significant increase in the fertilization effect of icebergs and ice shelves, particularly in coastal regions where sediment supplies have a large influence. Our study suggests that the AIS fertilization effect is weaker than suggested by Death et al. (2014), especially in coastal areas, as a consequence of the large input of Fe from sediment remobilization.

Table 3. Annual primary production integrated over depth (PP) and C export at a depth of 150 m in the CTL experiment and in the AIS Fe source experiments over the Southern Ocean, south of 50° S. In brackets are the increases in PP and C export relative to the CTL experiment in the highly fertilized plume of the Atlantic sector, northeast of the Antarctic Peninsula (36–56° W, 58–63° S).

ICB-ANNUAL	2.45	2.8 (21)	0.66	4.7 (28)

The enhanced primary production increases the C export by 8.4 % in our most impacted case (Table 3), a result significantly lower than the increase in particle export of 30 % in Laufkötter et al. (2018). The reasons for such a difference are difficult to disentangle as the modeled Fe fluxes from the AIS, atmospheric dust, and sediments are the same order of magnitude between the two studies (Table 1). Potential differences in the two modeling setups may arise from a different treatment of sediment mobilization, in particular in the description of the horizontal and vertical distribution of sediments or from a different relationship between primary production and C export. Indeed, observations suggest that the C export efficiency declines significantly with increasing primary productivity in the SO, although the causes remain unclear (Maiti et al., 2013; Le Moigne et al., 2016). In our model, this relationship, highly variable at local and temporal scales, is not linear in the SO but has a clear trend wherein a higher primary productivity is associated with a higher C export (not shown). In the model used in Laufkötter et al. (2018), a different relationship could explain the differences in the C export. While low at the scale of the SO in our model, the fertilization effect of the AIS on primary productivity and C export can be regionally significant as estimated from data (Smith et al., 2007; Duprat et al., 2016; Herraiz-Borreguero et al., 2016; Wu and Hou, 2017). For instance, in the highly fertilized area of the Atlantic plume, northeast of the Antarctic Peninsula (36–56° W, 58–63° S), primary production and C export are increased by ~ 30 % and ~ 42 %, respectively, in the SOLUB10 experiment compared to the CTL experiment (Table 3), i.e., 5 to 6 times higher than at the scale of the whole SO.

Climatically our study points out that the fertilization effect of the AIS on C export is moderate on timescales of 50 to 100 years. However, when integrated over timescales of thousands of years, the role played by the AIS in carbon sequestration might be a key component alongside atmospheric dust iron for the glacial–interglacial regulation of the carbon cycle (Martin, 1990). In a climate change perspective, our

results suggest that any change in the supply of Fe from increased melting of icebergs and ice shelves should result in a quite moderate impact on ocean biogeochemistry and export production at the scale of the whole SO. Indeed, doubling the AIS Fe fluxes in the SOLUB10 experiment increases the C export by only ~ 3.6 % compared to the SOLUB5 experiment (Table 3). Nevertheless, at a more local scale, the fertilization effect of the AIS induced by global warming could be drastically strengthened, with potentially important consequences for phytoplankton physiology, nutrient availability, and marine ecosystems (Boyd et al., 2010b, 2015; Hopwood et al., 2017; Boyd, 2019).

The choice of the iceberg Fe source distribution leads to significant differences in the magnitude of the fertilization effect of the AIS. In the case of a surface distribution, the effect is maximum. All the Fe delivered by the iceberg meltwater flux to the mixed layer is available to sustain primary productivity in spring and summer and strongly affects the vertical profiles of Fe, particularly in highly fertilized areas (Fig. 6). This theoretical distribution may lead to an overestimated supply of Fe in summer when the mixed layer is highly stratified, particularly in the case of large icebergs, partially ignoring the specific role of the Fe delivered below the MLD. Antarctic icebergs have different shapes (Romanov et al., 2012) and size class categories (Silva et al., 2006; Tournaire et al., 2015, 2016) both evolving during their life cycle (Bouhier et al., 2018). Moreover, the sediment distribution within icebergs is highly heterogeneous (Raiswell et al., 2016; Hopwood et al., 2017). All these features combined with distinct regimes of iceberg melting (FitzMaurice et al., 2017) fully constrain the delivery of Fe through the water column and below the mixed layer. Thus, the inherently heterogeneous nature of icebergs and their temporal evolution is extremely difficult to consider and to implement in a model. The choice of a surface distribution might be inappropriate to represent the iceberg supply in the ocean but without any degree of certainty. In fact, measured vertical profiles of Fe concentrations around icebergs in the Bellingshausen Sea in

summer (De Jong et al., 2015) and in the Weddell Sea in autumn (Lin et al., 2011) suggest that both the ICB-SURF and SOLUB5 experiments simulate vertical distributions of Fe that could be observed in the wake of melting icebergs. At least, based on future observations, the representation of the iceberg Fe source could be better constrained and parameterized in models.

While the iceberg freshwater fluxes vary monthly (Fig. 1a), the AIS contribution to the SO Fe pool is almost equally effective in summer and winter, mainly driven by the balance between high AIS Fe fluxes and phytoplankton consumption in summer and low AIS Fe fluxes and light limitation in winter. However, the seasonal variations of the iceberg Fe fluxes contribute to significant differences in the spatial distributions of Fe (Fig. 4g and h), which have small impacts on annual primary production and C export when integrated over the SO (Table 3). The spatial differences in surface chlorophyll are relatively modest in summer between the SOLUB5 and ICB-ANNUAL experiments. Nevertheless, the larger amplitude of the Fe cycle over the SO in the ICB-ANNUAL experiment (Fig. S2a) modulates the seasonality of surface chlorophyll during the growing season: the bloom initialization occurs earlier, the bloom apex in December is higher, and the bloom decay is faster from January to April (Fig. S2b). Thus, the monthly variations of the iceberg Fe supply alter the seasonal cycle of chlorophyll in the SO.

4.2 Model caveats and uncertainties

A surprising result that may be linked to a potential model deficiency is the absence of the iron fertilization effect in the very close vicinity of the Antarctic coast. This can be observed in the difference of SChl between the SOLUB5 experiment and the CTL experiment (Fig. 9b). In fact, none of the iceberg fertilization experiments show an increase in chlorophyll near the Antarctic shores (Fig. 9). This unexpected result is due to a strong and systematic nutrient limitation in summer simulated by the biogeochemical model (Fig. S1). The seasonal cycles of nutrients at a station near the shore of the Amundsen Sea (106° W, 75° S) in the CTL and SOLUB5 experiments display a marked limitation in NO₃, PO₄, and Si in January and February (Fig. S1a–c), whereas Fe is non-limiting (Fig. S1d). Nutrient limitation strongly affects SChl in both experiments, as shown by their similar seasonal cycles (Fig. S1e). Nutrient limitation may occur locally along the Antarctic coast; however, high levels of primary productivity in spring and summer are observed in large regions such as in the numerous coastal polynyas present in the SO (Arrigo and van Dijken, 2003; Arrigo et al., 2015). This possible biased behavior of our model may result from missing, misrepresented processes or sources that may supply macronutrients in the mixed layer such as the oceanic circulation in ice shelf cavities (Jacobs et al., 2011; Herraiz-Borreguero et al., 2015; White et al., 2019) or the melting of ice shelf and ice sheet (Pritchard et al., 2012; Arrigo et al., 2015, 2017;

Hawkings et al., 2015; Wadham et al., 2016; St-Laurent et al., 2017). Another process that can be advocated is the entrainment of nutrient-rich waters by subglacial discharge plumes induced by basal melting of grounded glaciers, a physical mixing process observed in the western Antarctic Peninsula (Cape et al., 2019) and for Greenland glaciers (Meire et al., 2017; Hopwood et al., 2018; Kanna et al., 2018).

We highlight that the distribution of the iceberg Fe fluxes below the MLD may represent a non-negligible fraction of bioavailable Fe for primary productivity. Indeed, the iceberg Fe delivery at depth in the SOLUB5 and ICB-KEEL experiments feeds a subsurface reservoir of Fe that can supply surface waters by the deepening of the MLD through sub-seasonal storms (Swart et al., 2015; Nicholson et al., 2016) or deep mixing (Tagliabue et al., 2014b). We suggest that this distribution of the iceberg Fe source has to be considered if implemented in biogeochemical models. However, in our sensitivity study, we only apply one average depth of the submerged part of icebergs, whereas several size classes co-exist in the SO where large tabular to small icebergs are observed covering a size range of 0.1–10 000 km² (Tournadre et al., 2015, 2016; Silva et al., 2006). The size evolution of icebergs along their life cycle is poorly documented, but fragmentation is a significant mechanism in the reduction of their size, which increases the iceberg melt (Bouhier et al., 2018). This process impacts the temporal delivery of bioavailable Fe that we have not explored. Moreover, the distribution of the iceberg Fe fluxes in the water column, i.e., around and below icebergs, is probably not homogeneous as reported in De Jong et al. (2015) and Lin et al. (2011), giving an additional uncertainty not investigated here. Another uncertainty relates to the rates of Fe utilization released from melting icebergs along their drift that is estimated to be far less than that potentially supplied (Boyd et al., 2012). The assessment of this utilization is unfortunately impossible because of the contributions from other sources of Fe (sediments and dust). Furthermore, the Fe utilization is computed from satellite-derived net primary production that is associated with large uncertainties (Saba et al., 2011) and significant underestimates of surface chlorophyll in the SO (Johnson et al., 2013).

A large uncertainty in the fertilization capacity of Fe delivered by icebergs and ice shelves comes from the intrinsic nature of this sedimentary source. Indeed, a very large fraction of Fe found in icebergs has a lithogenic origin (Raiswell et al., 2006; Shaw et al., 2011). The supply of lithogenic Fe can be separated into three categories: the most soluble Fe, and thus potentially bioavailable, the semi-labile particulate Fe that will not dissolve rapidly once released to seawater, and the refractory insoluble fraction. We focused our study on the first fraction. However, the semi-labile fraction may have a significant contribution to fertilizing the surface waters of the SO. If lithogenic Fe with a low dissolution rate is not scavenged or experiences low sinking speeds (nanoparticles), this fraction can be maintained in the upper layer and

become bioavailable on long timescales. This residence time may strongly affect the dissolved iron distribution from icebergs over the SO. As particulate lithogenic Fe is a significant pool of Fe in icebergs (Raiswell et al., 2006; Raiswell, 2011; Shaw et al., 2011), the contribution of the nondirectly bioavailable fraction to surface dissolved iron can be higher than actually observed. However, nothing is known about the fraction of lithogenic Fe bioavailable at long timescales or its quantity.

5 Conclusions

We implement in the biogeochemical model NEMO-PISCES (Aumont et al., 2015) the external source of iron from the Antarctic Ice Sheet based on recent estimates of Antarctic meltwater fluxes from icebergs and ice shelves (Depoorter et al., 2013; Merino et al., 2016). The modeled Fe fluxes from the AIS are in the range of previous modeling studies (Death et al., 2014; Laufkötter et al., 2018) and in the lower range of recent estimates from data (Raiswell et al., 2016). The potential indirect supply of Fe by the ice shelf melt-driven circulation, i.e., the meltwater pump (St-Laurent et al., 2017, 2019), is also represented by using the parameterization of Mathiot et al. (2017). We investigate the impacts of different sources of uncertainties related to the AIS iron source on Fe and surface chlorophyll distributions: the solubility of Fe, the vertical distribution of the iceberg source, and its seasonal variability. Large differences in the fertilization effect of the AIS are ultimately attributable to varying Fe solubility (1%–10%), which is currently poorly constrained by observations (Boyd et al., 2012; Raiswell et al., 2010, 2018). The AIS Fe supply is significant in the Atlantic sector northeast of the Antarctic Peninsula and along the Antarctic coast, particularly in the eastern sector, with large implications for the magnitude of phytoplankton blooms. The surface Fe and chlorophyll concentrations are increased by 3% to 24% and by 2% to 12%, respectively, at the scale of the SO. The contribution of Fe released from ice shelves is restricted to coastal areas with limited impact on chlorophyll and primary productivity, whereas modeled Fe fluxes from ice shelves and icebergs are similar. Our results also underline the role played by the vertical distribution of the iceberg Fe source due to the potentially non-negligible contribution of Fe delivered below the MLD. This nondirectly available supply cannot be considered a lost fraction for primary production but as a subsurface reservoir. The variability of the AIS contribution to the SO Fe pool is strongly linked to the interplay between the seasonal variations of meltwater released from icebergs and the physical and biological processes that characterize the dynamics of the SO: light limitation, MLD variations, iron limitation, and Fe consumption by phytoplankton.

At the scale of the SO, the fertilization effect of the AIS on primary production, mainly driven by icebergs, is rela-

tively weak but with a non-negligible contribution to C export. In the most contributive case, primary production (integrated over depth) and C export (at 150 m) are increased by 5% and 8.4%, respectively, compared to our control experiment. However, in highly fertilized regions in the Atlantic sector and along the Antarctic coast, the AIS impact is more important, with primary production and C export being increased by up to 30% and 42%, respectively. The magnitude of the C export simulated here is noticeably lower than the AIS Fe contribution to the marine particle export recently estimated to 30% over the SO in Laufkötter et al. (2018). This large difference emphasizes the necessity to continue exploring the large uncertainties that encompass the AIS Fe source and to understand the mechanisms that explain the very different sensitivity of C export to the AIS Fe fluxes simulated by models. Our results also point out the need to pursue in situ observations to better constrain the distribution of Fe and meltwater throughout the water column in the close vicinity of icebergs, their sediment content, and the range of Fe bioavailability from the AIS. Representing the biogeochemical features of the SO in ocean models is particularly challenging. However, we argue that the implementation of the external source of Fe from the AIS may help to fill the gap of misrepresented regional characteristics and to better represent the complexity of the SO iron cycle (Boyd and Ellwood, 2010; Tagliabue et al., 2017). Given that the Antarctic continental ice sheet has experienced a significant reduction of its mass (The IMBIE team, 2018) that may continue and amplify in the near future (Rintoul et al., 2018), it could be particularly relevant to integrate the AIS Fe source in climate models in order to assess its role for marine ecosystems and its potential negative feedbacks on climate change (Barnes et al., 2018). However, as there is currently limited agreement between models on the sensitivity of ocean biogeochemistry to the AIS Fe supply, the evaluation of climate change impacts on this external source of Fe and the consequences for marine biogeochemistry in the SO would be highly speculative.

Code and data availability. The version code of the NEMO model, including PISCES-v2, used for this study is freely available at <https://www.nemo-ocean.eu/> (last access: 18 September 2019). To access the NEMO svn repository, users should register on the NEMO website at <https://forge.ipsl.jussieu.fr/nemo/register> (last access: 18 September 2019). Model data are available at <https://doi.org/10.5281/zenodo.2633097> (Person, 2019).

Supplement. The supplement related to this article is available online at: <https://doi.org/10.5194/bg-16-3583-2019-supplement>.

Author contributions. The author contributions to this paper are as follows. RP and OA developed the conceptualization. RP conducted the formal analysis. OA and LB acquired funding. All authors con-

tributed to the investigation. RP, OA, and GM prepared the methodology. RP and OA conducted the validation. RP completed the visualization and wrote the original first draft. All authors contributed to the review and final version.

Competing interests. The authors declare that they have no conflict of interest.
