Comparative vertical migration of twenty one isolates of the insect parasitic nematode Heterorhabditis spp. in sand at 20 °C

Paula R. Westermann
Friesland College of Agriculture (AHoF), Van Hall Institute, P.O. Box 1528, 8901 BV Leeuwarden, The Netherlands.

Accepted for publication 28 April 1994.

Summary - Twenty-one heterorhabditid isolates, most likely belonging to six taxonomic groups and originating from ten countries, were tested for downward migration in 9 cm vertical sand columns at 20 °C with or without a larva of the greater wax moth, Galleria mellonella, at the bottom. The fractions of nematodes in the top layer (1.5 cm), middle section (6 cm) and bottom layer (1.5 cm) of the columns were determined at intervals over 8 h and occasionally at 48 h. All isolates except Heterorhabditis zealandica NZH3 migrated better than isolates of H. bacteriophora. Differences in migration were congruent with putative taxonomic groups within the genus. In most cases, the presence of a G. mellonella larva increased the downward movement. Nematodes of the North West European isolates were the most mobile. However, migration also varied between batches of the same isolate. In the presence of G. mellonella, 95 to 99 % of the nematodes of a number of Dutch isolates left the top layer of the sand column and were recovered from the bottom layer 6 h later.

Résumé – Migration verticale comparée de vingt et un isolats du nématode entomoparasite Heterorhabditis, dans le sable, à 20 °C – Vingt et un isolats d'Hétérorhabditides, appartenant principalement à six groupes taxonomiques et provenant de dix pays différents, ont été testés pour leur migration vers le bas, à 20 °C, dans des colonnes remplies de sable et pourvues ou non d'une larve de Galleria mellonella déposée au fond. Les nématodes présents dans la couche supérieure (1,5 cm), la partie médiane (6 cm) et la partie inférieure (1,5 cm) des colonnes sont dénombrés à des intervalles de 8 h et, occasionnellement, de 48 h. Tous les isolats, à l'exception d'Heterorhabditis zealandica NZH3, migrent plus aisément que les isolats de H. bacteriophora. Les différences observées dans la migration sont en accord avec les groupes supposés taxonomiques définis à l'intérieur du genre. Dans la plupart des cas, la présence d'une larve de G. mellonella augmente la migration vers le bas. Les nématodes appartenant aux isolats du Nord-Ouest de l'Europe sont les plus mobiles, encore que la migration puisse varier entre les différents lots d'un même isolat. En présence de G. mellonella, 95 à 99 % des nématodes de la plupart des isolats néerlandais quittent la couche superficielle de la colonne de sable et sont récupérés au fond 6 h plus tard.

Key-words : Heterorhabditis, insect parasitic nematodes, migration, activity, migration rate, Galleria mellonella.

Insect parasitic nematodes of the genus Heterorhabditis Poinar are used commercially in the Netherlands and other North West European countries for control of the black vine weevil, Otiorhynchus sulcatus F., in indoor ornamentals. The larvae of this weevil cause serious damage to the root system and base of the plants. The insect parasitic nematodes, which naturally inhabit the soil, favour a dark and moist environment and are eminently suited for control of this type of soil-dwelling pest.

The normal practice in horticulture is to apply nematodes to the soil surface as a curative biological insecticide. Quick movement of the nematodes into the soil is necessary to escape solar radiation and desiccation (Gaugler, 1988). Since the nematodes search actively for their hosts, their use for controlling soil-borne insects has an advantage over chemical pesticides whose contact with the insect depends on diffusion, water percolation or insect movement. However, application of insect parasitic nematodes must result in high levels of parasitism even when the host insects are scarce in order to be economically attractive. This makes exacting demands on the ability of the nematodes to search for and reach the host. A high host searching ability is generally regarded as the prime requisite of an effective natural enemy (Doutt & DeBach, 1964). Westerman and Stapel (1992) found that migration of the Dutch heterorhabditid HFr86 was related to the degree of efficacy against the black vine weevil. No data are available yet to allow extrapolation of this relationship to other heterorhabditid species and isolates.

In the present study, downward movement by twenty-one Heterorhabditis isolates originating from ten countries, including a large number of isolates from NW Europe (the Netherlands, U.K., Germany and Ireland), were measured in sand columns at 20 °C in the presence and absence of a larva of the greater wax moth, Galleria mellonella (L.).
Materials and methods

Nematode cultures

The isolates of *Heterorhabditis* tested (Table 1) were grouped according to their currently proposed taxonomic status (Smits et al., 1991; Dix et al., 1992; Joyce et al., 1994). All nematodes were propagated on *G. mellonella* at 20 °C and harvested in modified White traps (Poinar, 1975). Nematode suspensions were cleaned by decanting and adding fresh tap water, after which the nematodes were allowed to migrate overnight through a cotton-wool filter into a water film below. The infective juveniles were stored in 500 ml water in 11 bottles in a dark cold room at 4-5 °C under constant aeration with sterile-filtered air. Eight isolates (B1, NC1, V16, HDa, HP88, HI82, NZH3 and M198), however, were stored at 9-12 °C, because 4-5 °C proved lethal to them (Westerman, unpubl.). Three days after preparation, cylinders with and without a last layer of nematodes were allowed to migrate overnight through a cylinder with synthetic modelling clay. The cylinders (diam. 4.5 cm), made of six, 1.5 cm rings, were filled with fine sterile sand (particle size; 72% 180-300 μm, 21% 300-425 μm), moistened with demineralized water (8% w/w), and kept at 20 °C. Immediately after preparation, cylinders with and without a last larva of *G. mellonella* at the bottom, were inoculated on top with approximately 2000 living nematodes in 0.5 ml water and covered with a Petri dish lid. After 2-8 h or 48 h at 20 °C the rings were separated and the number of nematodes in each layer was calculated, based on the number of recovered nematodes per cylinder. Nematodes found in a ring were considered to have moved halfway through the ring. Accordingly, migration was defined here as the average distance migrated:

\[
migration = \frac{0.75R_0 + 4.5R_{2-5} + 8.25R_6}{R_0 + R_{2-5} + R_6} \text{ cm},
\]

where \(R_0\), \(R_{2-5}\), and \(R_6\) are the numbers of nematodes recovered at 4 h in ring 1, rings 2-5, and ring 6, respectively. Migration and the average migration rate at 4 h \([\text{migration}/4 \text{ (cm/h)}]\) were used to compare migration and rates of migration among isolates and different batches of isolates tested.

Migration

Nematode migration was assessed in 9 cm high PVC cylinders (diam. 4.5 cm), made of six, 1.5 cm rings, connected with adhesive tape. The bottom of the cylinder consisted of a Petri dish (5.5 cm diam.) fixed to the bottom ring with synthetic modelling clay. The cylinders were filled with fine sterile sand (particle size; 72% 180-300 μm, 21% 300-425 μm), moistened with demineralized water (8% w/w), and kept at 20 °C. Immediately after preparation, cylinders with and without a last instar larva of *G. mellonella* at the bottom, were inoculated on top with approximately 2000 living nematodes in 0.5 ml water and covered with a Petri dish lid. After 2-8 h or 48 h at 20 °C the rings were separated and the sand of each ring was rinsed in 50 ml water. The number of nematodes in ring 1, rings 2-5 and ring 6 were determined by counting the nematodes in four samples of 3 ml of the rinse water. Fifty to 60% of the applied nematodes were recovered, except after a period of 48 h when only 20 to 40% were recovered. The percentage of nematodes in each layer was calculated, based on the number of recovered nematodes per cylinder. Nematodes found in a ring were considered to have moved halfway through the ring. Accordingly, migration was defined here as the average distance migrated:

\[
migration = \frac{0.75R_0 + 4.5R_{2-5} + 8.25R_6}{R_0 + R_{2-5} + R_6} \text{ cm},
\]

where \(R_0\), \(R_{2-5}\), and \(R_6\) are the numbers of nematodes recovered at 4 h in ring 1, rings 2-5, and ring 6, respectively. Migration and the average migration rate at 4 h \([\text{migration}/4 \text{ (cm/h)}]\) were used to compare migration and rates of migration among isolates and different batches of isolates tested.

Five isolates (*H. zealandica* NZH3, *H. bacteriophora* B1, NC1, V16, and HDa) were tested at both a 4 h and 48 h incubation period and were inoculated on the same date with the same batch of nematodes. The batch of HDa was also used in the time series (see below). Five more isolates (H182, HW79, HSH, HKem and M198) were tested at a 4 h incubation period only; M198 was tested twice using different batches. All other isolates, including HDa and batches of NZH3, and B1, were tested in a time series of 2, 4, 6 and 8 h in two to four replicates, with the exception of HL81 and HI82 (which were tested hourly from 2 to 7 h), and HP85 and
B1 (which were not tested at a 2 h period). Of these isolates HF85 and B1, HL81 and HF86, HI82 and HW79, and HDa and HE87 were tested in pairs on the same date. Additional data on migration at 4 h of HF85, HUK211, and K122 were obtained from experiments conducted for other purposes (partly obtained from K. Jung).

Migration data from the time series were analysed separately for each batch on effects of incubation time and of the absence and presence of the host using linear regression analysis. Standard errors of the mean (SEM) were calculated about migration at 4 h to permit comparison among isolates. X² test was used to check for uniform distributions of nematodes in cylinders without G. mellonella.

After completion of the experiments the G. mellonella larvae from the cylinders were usually kept at 20 °C for another 3-4 days and checked for parasitism. Parasitized larvae were recognized by the characteristic colour change induced by the symbiotic bacteria. Occasionally dead larvae were opened after 6-7 days under a dissection microscope to count the number of hermaphrodite nematodes in the cadaver (done for NZH3, HDa, HP88, K122, M145, HO1, HUK211 and HE87 in the time series, and NZH3, B1, NC1, V16 and HDa at both 4 h and 48 h). The numbers of nematodes recovered from the insects were usually small (≤ 50/insect at 8 h) compared to the total numbers recovered (1000-1200) and were not included in calculations of the distance migrated, except for NZH3, B1, NC1, V16 and HDa at the 48 h incubation period and for HE87 in the time series.

### Results

**H. zealandica NZH3**

In the time series 15 % of the recovered NZH3 had migrated from the first layer in the absence of an insect at 8 h; 23 % in the presence of G. mellonella (Fig. 1A). Downward movement was very slow (0.22-0.25 cm/h at 4 h) and the first nematodes reached the bottom layer not earlier than 8 h (≤ 1 % of the recovered nematodes). Both test insects at 8 h contained two hermaphrodites. Migration was not significantly increased by the presence of G. mellonella (e.g. Table 2). The other batch of NZH3 yielded similar results at both 4 h (Table 2) and 48 h (1.0 ± 0.0 cm (x ± SEM) without insect and 1.1 ± 0.1 cm in the presence of G. mellonella). None of the test insects was parasitized.

**H. bacteriophora B1, NC1, V16 and HDa**

In the time series only 5 % of the recovered B1 and 17 % of HDa had dispersed from the first layer in the absence of an insect at 8 h; in the presence of G. mellonella these percentages were 14 % and 23 %, respectively (Fig. 1B, C). Downward movement was slow (0.20-0.25 cm/h at 4 h) and the first nematodes reached the bottom layer at 4 h (B1) and 2 h (HDa). Migration of HDa seemed to increase at 6 h but this was not followed up at 8 h. At 8 h 1 % and 7 % of the recovered B1 and HDa, respectively, were found in the bottom ring. Test insects exposed to HDa at 6 and 8 h contained negligible numbers of hermaphrodites (≤ 7/insect). Migration was not significantly increased by the presence of G. mellonella for either isolate (P ≥ 0.2).

The nematodes of the other batch of B1, tested at 4 h, migrated better than those used in the time series; 2 % and 10 % of the recovered nematodes were found in the bottom layer at 4 h in cylinders without and with G. mellonella, respectively, resulting in higher distances migrated (Table 2). The mean distance migrated by NC1, V16 and HDa at 4 h did not differ from that of either batch of B1 at 4 h (Table 2). Two and 5 % of the recovered nematodes were found in the bottom layer for NC1 and V16, respectively. Test insects either survived exposure to the nematodes in sand columns (HDa and V16) or they contained ≤ 1 hermaphrodite per insect (B1 and NC1).

Data of the four isolates tested at 48 h were less reliable than those at 4 h since percentage recovery from
Fig. 1. Percentage of recovered nematodes in the course of time in three sections of 9 cm high sand columns, in the absence (−) and presence (+) of a last instar of Galleria mellonella at the bottom of the cylinders, after application of approximately 2000 living heterorhabditid nematodes on top of the cylinders. A: Heterorhabditis zealandica NZH3; B: H. bacteriophora B1; C: H. bacteriophora HDa; D: HP88; E: K122; F: M145.

The sand was low (20-40%). In the absence of G. mellonella 10, 21, 2 and 16% of the nematodes were found in the bottom layer for B1, NC1, V16 and HDa, respectively (mean distances migrated (x ± sem); 2.0 ± 0.4 cm, 2.7 ± 0.2 cm, 1.2 ± 0.2 cm, and 2.5 ± 0.6 cm, respectively). Relatively high numbers of hermaphrodites were recovered from the insect cadavers (x ± sem); 45 ± 6, 281 ± 49, 144 ± 25, and 184 ± 58 for B1, NC1, V16 and HDa, respectively, thus boosting the values for migration in these cylinders (2.8 ± 0.2 cm, 4.0 ± 0.4 cm, 3.4 ± 0.3 cm and 2.9 ± 0.5 cm, respectively).

HP88 and H182

In the time series 53% and 68% of HP88 had left the top layer of sand at 8 h in the absence and presence of G. mellonella, respectively (Fig. 1D). At the same time 4% and 33%, respectively, were found in the bottom layer. The nematodes moved slowly (0.3-0.5 cm/h at 4 h). Ten hermaphrodites were recovered from the one insect killed at 6 h and one and two hermaphrodites from the
two insects killed at 8 h. The mean distance covered by HP88 significantly increased in the presence of G. mellonella (P ≤ 0.02) and in time (P ≤ 0.05). Fewer nematodes of H182 had left the top layer at 4 h (22-46%), but they moved at a higher rate (0.5-0.9 cm/h at 4 h), resulting in higher migration compared to HP88 (Table 2).

The Irish isolates M145, K122 and M198

In the time series only 34-35% of K122 and 20-21% of M145 had left the top layer at 8 h (Fig. 1E, F), and nematodes moved slowly (0.6 cm/h and 0.3 cm/h at 4 h for K122 and M145, respectively). The percentage of recovered nematodes that remained in the top layer stabilized at 60% for K122 and 80% for M145. At 8 h, 30% of K122 reached the bottom layer, compared with 8-11% for M145. Test insects exposed to K122 were killed from 4 h onwards and contained 1.5, 10 and 11 hermaphrodites per insect at 4, 6 and 8 h, respectively. Those exposed to M145 contained 7 ± 3 (± sem) hermaphrodites per insect at 6 and 8 h. In the additional experiments, more nematodes of K122 had left the top layer at 4 h (52-86%), resulting in higher distances covered (Table 3). Migration of K122 was enhanced by the presence of G. mellonella, but only in the additional experiments (Table 3). One batch of M198 dispersed better than the other two Irish isolates, but the other batch did not (Table 2).

H. megidis HO1

At 8 h 59 and 68% of H. megidis HO1 had left the top layer in the absence and presence of G. mellonella, respectively (Fig. 2A). In the presence of G. mellonella 59% of the recovered nematodes were found in the bottom layer. These nematodes moved relatively fast (1.3 cm/h). From 4 h onwards all test insects were killed and contained equal numbers of hermaphrodites per insect (35 ± 7 (± sem)). In the cylinders without G. mellonella, a more or less stable situation was reached at 4 h with 45% in the top layer, 40% in the middle part and 15% in the bottom layer. HO1 responded significantly to the presence of G. mellonella and to time (P ≤ 0.002).

The NW European isolates

Migration of the six Dutch isolates and the British HUK211 in the time series resembled that of H. megidis HO1, but the fractions of nematodes leaving the first layer of sand at 8 h were much greater, except for HUK211 (Figs. 2, 3). Sixteen and 55% of HUK211 had left the top layer at 8 h in the absence and presence of G. mellonella, respectively (Fig. 2B). In the presence of G. mellonella virtually all nematodes (95-99%) of HL81, HF85, HF86 and HNB87 left the first layer within 4 h and arrived in the bottom layer at 6 h. These nematodes moved fast (1.7-1.9 cm/h at 4 h). Since nematodes were already found in the bottom layer at 2 h, some individuals “raced” through the cylinder at an average rate of 4.5 cm/h. Test insects exposed to HE87 in the time series contained 3 ± 3, 58 ± 19, 256 ± 21 and 337 ± 120 (± sem) hermaphrodites per insect at 2, 4, 6, and 8 h, respectively. Unfortunately only test insects exposed to HE87 were dissected. The fraction of recovered nematodes leaving the top layer in cylinders without G. mellonella varied from 31% for HF85 to 77% for HL81 and HF86. Additional results on other batches of HF85 at 4 h demonstrated a considerable variation in migration (Table 3). Migration of the German HSH, the Russian HKem and the Dutch HW79 at 4 h was comparable to that of the other NW European isolates.
Table 3. Migration (x; average distance covered (cm)), with standard error of the mean (sem), at 20°C in 4 h of a number of batches of three isolates of Heterorhabditis in a number of 9 cm sand columns (n) without (-) and with (+) a G. mellonella larva at the bottom. (For each isolate migration data followed by different letters are significantly different from each other, P = 0.05).

* Data obtained from K. Jurg, Friesland College of Agriculture, Leeuwarden, The Netherlands.
q Versus to evaluation of quality (see text).

(Table 2). In the time series all Dutch isolates and HUK211 responded significantly to the presence of the host insect (P ≤ 0.001). In fact, all except HF85, responded more than proportionally to G. mellonella in the course of time (host x time interaction, P ≤ 0.05).

Variation in migration between experiments was assessed for isolates that were tested frequently. Variance of mean migration between experiments was generally larger than within experiments; e.g. 2.12 versus 0.90 for HF85 (n = 5), 3.44 versus 0.12 for K122 (n = 4), and 1.34 versus 0.09 for HUK211 (n = 3).

The isolates could be roughly ranked in order of descending migration at 4 h; NW European group (except HUK211) = H. megidis > Irish group ≥ HF88, H182, H. bacteriophora > H. zealandica.

Uniform dispersal would result in a 1:4:1 ratio in the number of nematodes in the three layers of a cylinder. Although this distribution was never found (χ²-test, P ≤ 0.05), the distributions of H81L (1:2.3:1.2), HFr86 (1.1:2.3:1) and H1887 (1.3:2.5:1) in the absence of G. mellonella came very near. However, relatively large proportions of the nematodes were consistently recovered from both ends of the cylinder for these most rapidly migrating isolates.

Discussion

In NW Europe O. suclatus is an increasingly serious pest of nursery stock, ornamentals and soft fruit such as strawberries. Hanula (1993) demonstrated that a biological control agent must penetrate to depths of 15 cm to be 95% effective against larvae of O. suclatus on field grown yews. Although the actual vertical distribution of larvae may vary with plant species, the above data illustrate the need for actively migrating nematodes if insect parasitic nematodes were to be applied for effective black vine weevil control.

H. bacteriophora (syn. H. heliopathis, see Poinar, 1990) and HP88, which are so far the only heterorhabditids included in studies on migration, generally outperformed steinernematids (e.g. Georgi & Poinar, 1983 a, b, c; Alatorre-Rosas & Kaya, 1990). However, the present study showed that most heterorhabditids tested in this study, except H. zealandica NZ13, outperformed H. bacteriophora in the ability to migrate through a sand column at 20°C, both in the rate of migration and in the proportion of actively migrating nematodes. In fact, the four H. bacteriophora isolates used here, including the type strains B1 and NC1, migrated better than previously reported for H. bacteriophora or H. heliopathis in sandy loam (20-25°C, five days; Georgi & Poinar, 1983 c). Soil type, isolate or quality of the batch used may all partially explain the observed differences.

Up to 99% of some of the heterorhabditids migrated when placed on a sand surface, contradicting Kaya's (1990) generalization that only a small proportion of steinernematid or heterorhabditid populations disperse when placed on the soil surface. Inactivity of a certain proportion of a population of nematodes is well documented among insect parasitic nematodes (Ishibashi & Kondo, 1990), and is assumed to be a survival strategy. When inactive, they can be stimulated to become active by various mechanical and chemical stimuli, such as CO₂ and other attractants from insects (Ishibashi & Kondo, 1990). In the present study activation by substances released by G. mellonella may have contributed to the increase in the percentage actively migrating nematodes that most isolates exhibited when G. mellonella was present (chemo-orthokinesis).

Most heterorhabditid isolates tested here migrated at a higher rate than H. bacteriophora or H. zealandica: an 8 h period was generally sufficient to follow a large proportion of the population down to the bottom layer of the 9 cm sand column. The nematodes of most NW European isolates migrated at an incredible rate. The rapid downward migration could not have resulted from passive movement caused by water drainage or gravity, because low water content (8%) in the sand did not allow water to drain. In fact, upward migration to a higher rate than isolates with short infective juveniles (NW European group, Irish group, H. megidis) generally migrated more rapidly than isolates with short infectives (H. bacteriophora, H.
Migration of Heterorhabditis spp.

Fig. 2. Percentage of recovered nematodes in the course of time in three sections of 9 cm high sand columns or inside Galleria mellonella, in the absence (−) and presence (+) of a last instar of G. mellonella at the bottom of the cylinders, after application of approximately 2000 living heterorhabditid nematodes on top of the cylinders. A: Heterorhabditis megidis HO1; B: HUK211; C: HB1'87; D: HN887; E: HF85; F: HE87.

zealandica. However, of the related isolates HP88 and HI82, which are both approximately the same size, the former had the highest percentage nematodes leaving the top layer, but the nematodes of the latter isolate migrated more rapidly.

The rate of migration was doubled in the presence of G. mellonella for most isolates, which may have resulted from mechanisms such as chemotaxis and chemo-klinokinesis. Lei et al. (1992) observed that the individuals of

H. zealandica T'327 moved randomly on agar dishes, but their movements became directed in the presence of puparia or larvae of the cabbage maggot, Delia radicum. Similarly, Gaugler et al. (1980) observed that on agar most individuals of S. carpocapsae oriented to a CO₂ gradient. It is likely that the nematodes in this study oriented to a concentration gradient of volatile chemicals since the duration of the experiment was short for the formation of a gradient of water-soluble host cues, ex-
Fig. 3. Percentage of recovered nematodes in the course of time in three sections of 9 cm high sand columns, in the absence (-) and presence (+) of a last instar of Galleria mellonella at the bottom of the cylinders, after application of approximately 2000 living heterorhabditid nematodes on top of the cylinders. A: HL81; B: HFr86.

cept in case of the 48 h experiments. The presence of G. mellonella corroborated the differences in migration between isolates without essentially altering the order. Lewis et al. (1992, 1993), who investigated the behaviour of steinernematids on an agar surface with respect to host searching strategies, predicted and found that species that moved in search of hosts, such as S. glaseri, would be more responsive to volatile host cues than species that adopted a "sit-and-wait" strategy, such as S. carpocapsae. H. bacteriophora and H. zealandica, although active searchers in comparison to most steiner nematids, would be classified as "sit-and-wait" strategists in comparison to, for instance, heterorhabditid isolates of the NW European group, which were more active and responded more strongly to volatile cues of G. mellonella than H. bacteriophora or H. zealandica. Lewis et al. (1992) further suggested that these actively searching isolates may be better adapted for finding and parasitizing subterranean, sedentary insect larvae such as O. sulcatus.

Mean migration at 4 h, which was chosen to compare migration among all batches tested, was not determined at a stable situation but, for most isolates, during the course of rapid movement. In this way laborious dissecting of insect cadavers could be avoided. However, migration defined in this manner is bound to be variable as it is sensitive to factors that influence the rate of migration or the proportion of actively migrating nematodes, such as subtle changes in the particle size composition, pH, moisture content, solute concentrations, condition, size and attractiveness of the test insects, or condition of the nematodes. Nevertheless, migration of HFr85 (NW European group) proved unaffected by, for instance, particle size (range 105-425 μm) or pH (range 3-10) of the sand (Westerman, unpubl.). Probably variation in migration between replicates of one isolate can mainly be attributed to differences between batches of the nematodes, due to production and storage conditions (Kaya, 1990), as was demonstrated for heterorhabditids by Westerman and Stapel (1992). Moreover, migration will only give an indication of the ability of a batch to migrate at that time. For example, Westerman and Stapel (1992) demonstrated that migration decreased with storage time of the batch used and Lei et al. (1992) observed that newly collected nematodes did not orient to host cues, whereas one-month-old nematodes did.

Differences in mean migration were more or less congruent with putative taxonomic groups within the genus (Tables 2, 3). For example, isolates of the NW European group, with the exception of HUK211, exhibited almost identical courses of migration in time, distinct from those of the other groups. The behaviour of the related H. megidis and Irish isolates (Smits el al., 1991; Dix el al., 1992, Joyce el al., in press) resembled most closely that of the NW European group. The migration curves of the isolates of H. bacteriophora seem to differ from those of the taxonomically different, but closely related, isolate HFr88 and H. zealandica (Dix et al., 1992; Joyce et al., 1994).

Since conditions may have been nearly optimal for migration, the results of this study only give an indication of the migration potential of the isolates examined. Migration and host searching in natural soils will depend on many other factors, such as the distribution and attractiveness of the target insect, soil texture, moisture and particle size composition, the presence and density of root systems and soil temperature. For example, larvae of O. sulcatus were not attractive to some NW European heterorhabditids (Westerman & Godthelp, 1991). Furthermore migration of NW European heterorhabditids is seriously impaired in humous soils (Westerman, unpubl.). Shape and size of the root system of the plant will not only influence the distribution of target insects but may also influence migration and host finding of nematodes, as was demonstrated by Choo et al. (1989) and Choo and Kaya (1991). Although dense roots reduced infectivity of H. bacteriophora NC1 in sandy soils, sparse roots increased nematode infectivity in humic soils. Twenty °C, as chosen in this study, might be close to optimal for application to indoor ornamen-
Acknowledgements

This research was carried out with the generous support of the European Community (ECLAIR AGRE 0002). I would like to thank the researchers who directly or indirectly provided the nematodes from their collections. Furthermore, I would like to thank Ms M.G. van Zeeland, Ms M. ten Klooster, Ms K. Jung and Ms H. Jouisma for technical assistance, and Dr Ir. W. R. Simons, Dr Sj. Gerbrandy, Dr P. B. Rodgers, Dr C. T. Griffin, and Prof. Dr A. F. van der Wal for discussions and comments on the manuscript.
