

## CHARACTERISTICS OF THE GOLD OCCURRENCES IN THE SANTA VICTORIA DISTRICT, PROVINCIA DE SALTA, ARGENTINA

Pedro Argañaraz, Michel Fornari, Alfredo L. Castillo, Ricardo R. Battaglia

**Abstract:** The primary "in rock" gold occurrences crop out at higher elevations in the Sierra de Santa Victoria which forms part of the Eastern Cordillera itself located between the "Puna" geological province to the west and the Sub Andean foothills to the East (fig.1)

The geomorphic appearance corresponds to smooth sloped hilly countryside with a altitude of about 4000 m. Towards the East, elevations decrease rapidly towards the Andean foreland basin and in this area, auriferous gold placers occur in the watersheds of the Pilcomayo and the Bermejo rivers, both of which form part of the La Plata drainage basin.

The predominant lithologic formations are fine marine deposits of upper Proterozoic to lower Paleozoic. Gold mineralization occurs as narrow quartz veins with minor hematite and copper which are part of the Pb, Zn, Ag, Cu metallic province of La Quica. Gold forms free particles in the quartz and contains between 5% and 25% of silver.

Detrital gold of the alluvium averages between 0,08g/m<sup>3</sup> and 0,61g/m<sup>3</sup> but is highly variable depending on sample location. Gold particles are small and generally show irregular shapes. Flatness index values indicate short transport distances for about 25% of the gold particles and show transport distances of more than 30 km for the others particles. Gold particles exhibit thin external silver depleted rims indicative of "in situ" alteration.

### INTRODUCTION

The Santa Victoria area contains several Pb, Zn, Ag, Cu occurrences mainly as quartz or barytine veins [1]. Some of these veins have been worked in the past, but by now mining activity decreased, except for then occasional exploitation of barites.

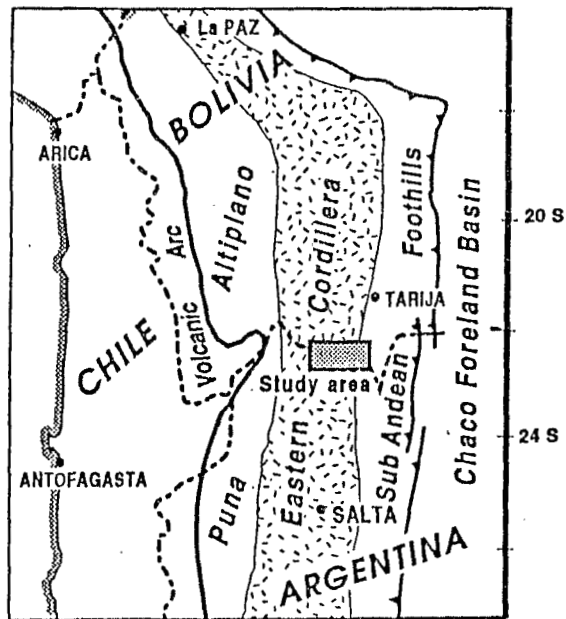

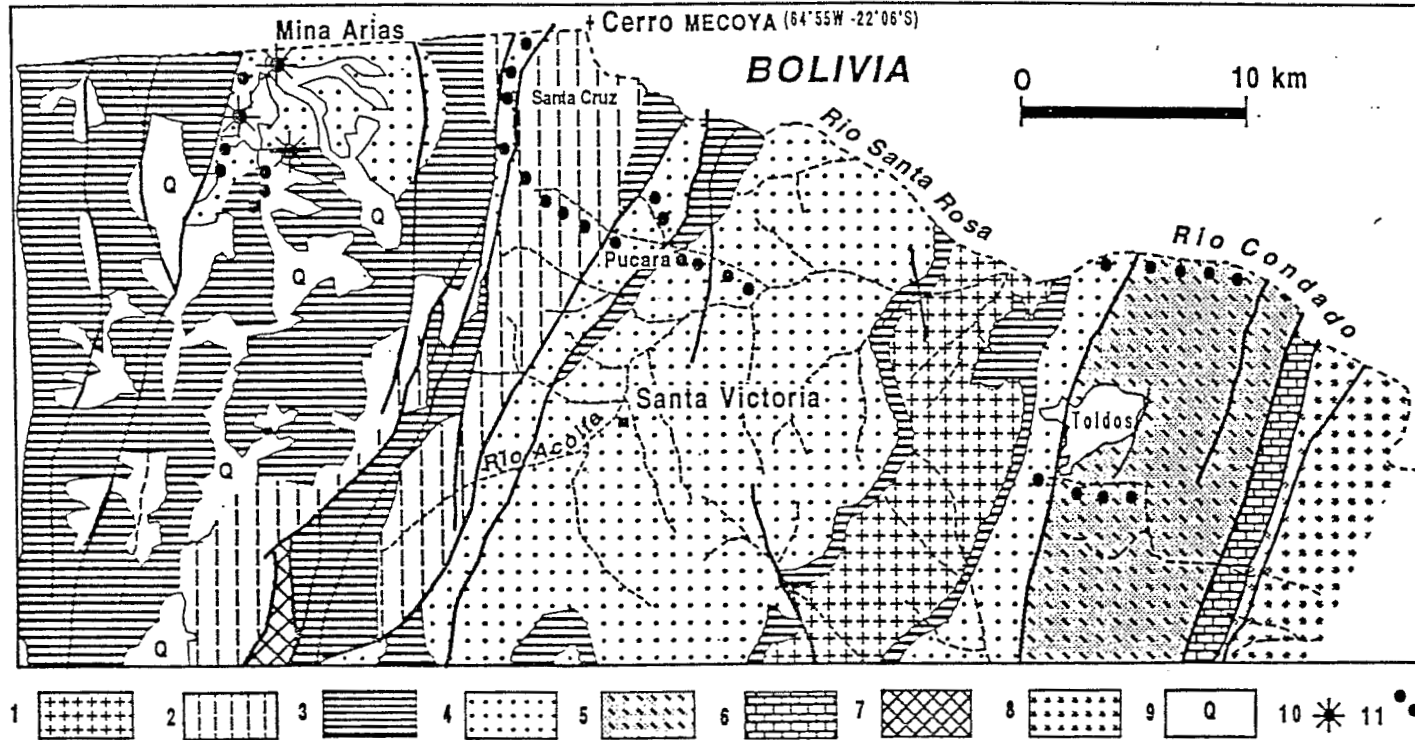

Fig. 1 : location of the study area.

The situation was modified ten years ago (1982) by the discovery of gold. The Dirección General de Minería of the Salta Province developed geological studies under the auspices of the Plan Inventario Minero Provincial and villagers started small scale mining of the detrital gold deposits.

1 = Granite and granodiorite Cañani. 2 = Puncoviscana Formation. 3 = Mezon Group (Cambrian). 4 = Santa Victoria Group (Ordovician)  
 5 = Silurian-Devonian. 6 = Carboniferous -Permian -Triassic -Jurassic. 7 = Salta group, Cretaceous. 8 = continental Cænozoic.  
 9 = Quaternary sediments. 10 = Gold quartz vein mineralization. 11 = Gold-bearing alluvial deposits.

Fig. 2 : simplified geological map of the Santa Victoria area.

Preliminary explorations highlighted several interesting areas such as Viscachani, Minas, Santa Cruz, Pucara, Toldos, within a 60 km long, E-W trending area (fig. 2).

The Viscachani area is located near Bolivian border and the mineralized structures crop out in the "Quebrada Minas" and "Tres Lagunas" [2, 3] which form watershed tributaries to the Pilcomayo River. This paper presents some of the characteristics of the gold mineralization, mainly using data from the Mina Arias vein which appears representative of the area.

#### OUTLINE OF THE GEOLOGY

The area is part of the Eastern Cordillera [4] and consists of smooth hills with mean altitudes about 4000 m. The elevation decreases rapidly toward the Andean foreland basin.

The older lithological units correspond to the Puncoviscana Formation [5] and consist of thick marine turbiditic sediments with limited occurrences of limestones, spanning from upper Proterozoic to Mid Cambrian time interval.

The Puncaviscana rocks are mainly greenish shales, greywackes and quartzitic interbeds containing small intercalations of basic lavas.

The estimated thickness is about 2000 m. The sediments are folded and present low grade metamorphism. They are intruded by the Cañani granodiorite and granite dated between 520 and 535 Ma.

The Cambrian Mezon Group forms extended outcrops of silicic sandstones and lutites of about 3000 m thick and overlies the Puncaviscana Formation with an angular unconformity. This in turn, is covered by the Ordovician Santa Victoria Group with low angular unconformity.

The Santa Victoria group reaches a thickness of 5000 m comprising of grey and greenish pelites of the Tremadocian Santa Rosita Formation and of the Arenig-Llanvirnian Acoite Formation. These lower Ordovician sediments host the gold quartz veins.

Eastward upper Paleozoic, Mesozoic and Tertiary continental sediments form North-South trending outcrops in the fold-thrust belt of the Sub Andean ranges.

The smooth topography of the Eastern Cordillera is in part related to the development of a 9 Ma old regional erosion surface which extends regionally northward in Bolivia and is known as the San Juan de Oro surface, [6]. Recent tectonic uplift is responsible for regional canyon incision and regressive erosion from the eastern foreland basin.

#### VEIN MINERALIZATIONS

The lower Paleozoic rocks host gold quartz veins such as the Minas Arias vein. They consist of 10-15 cm thick lutitic strata interbedded with quartzitic sandstones of 10 to 40 cm thickness. Occasionally the thickness of the quartzitic beds can reach 1 m. The strata strike NW-SE and dip moderately toward the NE. In the area of the mine the contact with the Cambrian sandstones lacks a corresponding basal conglomerate and does not present a strong unconformity.

The vein named Arias I strikes NE-SW with a steep (80°) dip to the NE. The mean thickness is about 20 cm but when the vein cuts the Cambrian sandstones its thickness decreases and dies out.

The vein consists mainly of quartz with pyrite, arsenopyrite and hematite with traces of copper oxides also being present. The quartz is generally brecciated but microgeodic drusy intergrowth of quartz and pyrite are also present.

PLACER CHARACTERISTICS

Alluvial and eluvial materials cover extended parts of the area. At higher elevations, glacial and fluvio-glacial deposits dominate whereas torrential and fluvio-torrential material are present along the rivers.

Two main levels of terraces are present with another, more limited level, consisting of reworked material with abundant fine sands, clays and organic matter. The latter level may be related to the ultimate Holocene wet stage.

In the area of Las Minas, the river is currently caving the Ordovician bed rock and hence the deposits are about 1-2 m above the actual stream level.

Generally, the terrace deposits consist of heterometric clasts with individual boulders of 1.5 m of diameter. The mean clast diameter ranges between 25-40 cm with clasts showing sub-angular to sub-rounded shapes. The clasts are mainly derived from Ordovician and Cambrian rocks. The matrix consists of silt and clay with yellow and ochre coloration.

Heavy minerals coexisting with the gold are mainly hematite and magnetite and in lower quantities zircon, garnet and rutile. Gold concentrations are highly variable depending on sample location with the average grade ranging between 0,08 g/m<sup>3</sup> and 0,61 g/m<sup>3</sup>

GOLD CHARACTERISTICS

Dissolution of quartz vein fragments in concentrated fluoridric acid enable the recovery of gold particles. SEM examination of the gold particle from oxidized surface sample shown irregular topography with dissolution features. Camebax microprobe analysis of polished sections of gold particles indicate the presence of several types of gold in the vein. One type contains about 25%, one 14% and another 11.5% of silver. cf table 1.

Gold contains traces of As, Fe, Hg, Te and occasionally low concentration of Cu. Others elements such as Bi, Pb, Sb were also investigated but were not detected.

Gold particles from placers in the Minas area are recovered from a area of 800 x 200 m. The size of the particles is generally small, with the majority between 1 and 1.5 mm.

Gold particles present xenomorphic shapes and irregular outlines. They are relatively thick and generally show little evidences of flattening or blunted edges (fig. 3).

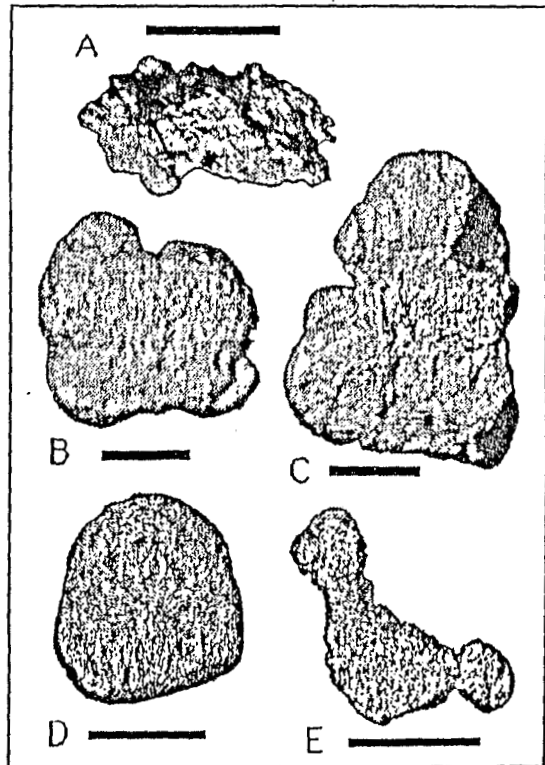

Fig. 3 : morphology of gold particles

A = angular particle with irregular outline, B and C = thick, blunted gold particles with folding. D = flattened and rounded particle, E = irregular outline and folded edge. A, B, C gold from the Mina Arias alluvium. D, E from the Pucara alluvium. Bar scales are 1 mm long.

Table 1: Chemical composition of gold particles using electron microprobe. Camebax at Ecole des Mines de Paris, operating with 25 kV accelerating voltage, current of 15 nA and counting of 40 sec per element. (Bi, Sb, Pb, S were tested by not detected). Samples with V initial letter are from Mina Arias I vein. Samples with A initial letter are from detrital material.
