# IFREMER

Monsieur le Chairman, Messieurs les Directeurs, Mesdames et Messieurs, je suis heureux de vous accueillir à Paris, au nom de l'IFREMER, à l'occasion des travaux de la VIème Conférence internationale de l'IIFET. Cette Conférence coïncide avec le dixième anniversaire de l'IIFET et je voudrais en profiter pour rappeler brièvement quelques unes des missions de cette institution.

Créée en 1982, sa vocation première aura été de promouvoir le développement d'échanges internationaux en matière de recherche et de coopération dans le monde du commerce des produits de la mer et des politiques de pêche. Ces dix premières années d'existence ont suffi à générer des dynamiques internationales et les 50 pays représentés à l'IIFET en témoignent aujourd'hui. Ce sont en réalité plus de 300 personnes, représentants d'organismes internationaux gouvernementaux, universitaires et professionnels des secteurs public et privé qui se retrouvent associés à l'IIFET. A partir de ces motivations, l'IIFET a su proposer tous les deux ans dans un lieu différent l'un des forums internationaux les plus attendu sur les questions relatives à l'économie des pêches et de l'aquaculture. Veillant à permettre la confrontation des recherches, des expériences de régulation, des pratiques professionnelles, l'IIFET a misé sur l'analyse économique pour prolonger l'analyse des questions de gestion des ressources renouvelables en essayant de susciter chez les autres disciplines des sciences sociales une motivation à venir s'atteler à ces problématiques. J'y vois pour ma part une rigueur certaine sur le chemin de la multi-disciplinarité. L'IIFET a donc joué un rôle important pour stimuler les recherches en sciences sociales qui doivent être un maillon essentiel du processus de prise de décision.

Mais l'IIFET ne s'est pas limité à cela. Trois pôles d'intérêt ont donné lieu à ce jour à la constitution de groupes ou de réseaux qui ont vocation à fonctionner en continu, bénéficiant tous les deux ans de l'opportunité de

Mr. Chairman, Fellow Directors, Ladies and Gentlemen, I am very pleased to welcome you to Paris, on behalf of IFREMER, for the Sixth International Conference of the IIFET. This Conference coincides with the tenth anniversary of the IIFET and I would like to take the opportunity to briefly recall some of the missions which have been entrusted to this institution.

At the time of its creation in 1982, IIFET's primary vocation was to promote international exchange in research and co-operation in the field of fisheries and the trade of sea production. The preceding decade has provided opportunities to generate dynamic international relations and the presence of 50 countries here today is living proof of this reality. In point of fact, more than 300 individuals, representing international government agencies, universities and professional entities from both the public and private sectors are currently associated to the IIFET. Taking into account these different concerns, IIFET has shown itself capable of organizing international forums every two years in different locations, each dealing with pertinent questions related to fisheries and aquaculture economics. Through the encouragement of comparative approaches to research, regulation and professional practises, IIFET has concentrated on economic analysis as a means for assessing the management of renewable resources and has sought to elicit the other disciplines of the social sciences to focus upon this domain. For my part, I believe this rigorous process has been a key to paving the way for more multi-disciplinarity. IIFET has thus played an important role in stimulating research in the social sciences as an essential element in the decision-making process.

However, IIFET has not limited itself to these concerns. Permanent groups or networks have focused on three major topics, acting as bridges and taking advantage of the possibility of meeting every other year within the framework of the Conference. The world market for

rencontres offerte par la Conférence. Le marché mondial des poissons de fond, la salmoniculture et les statistiques des échanges internationaux sont en effet traités au sein de groupes de travail avec des rythmes de publications et de fonctionnement distincts sous un principe commun de large ouverture. Cette Conférence marquera peut-être la naissance d'un sous groupe thématique nouveau qui pourrrait faire de la question des relations Nord-Sud ou encore de la Politique Commune des Pêches des axes de réflexion et de recherche complémentaires. D'autres thèmes encore mériteront certainement au terme de vos débats la poursuite d'une action commune pour laquelle l'IIFET pourrait tenir lieu de fédérateur. Je ne veux pour autant anticiper sur les conclusions de vos travaux. Je resterai attentif, sachez le, à vos propositions dans ce sens.

L'IIFET a encore ceci de particulier, que sa création est intervenue à un moment où les concepts d'aménagement des pêches entraient dans une phase nouvelle. La Convention des Nations Unies sur le Droit de la Mer allait marquer définitivement la reconnaissance à l'échelle internationale de zones d'appropriation de l'espace marin. A un moment où la pleine exploitation générale du potentiel halieutique mondial était admise, cette réforme majeure du Droit International allait poser avec davantage d'acuité encore la question de la gestion des pêcheries, du partage des espaces, des ressources et des richesses qui en découlent. Les récents arbitrages internationaux que la France a connus et le souhait de certains états côtiers de s'approprier des zones maritimes au delà de leurs 200 milles montrent à quel point encore la question de l'appropriation des espaces et des ressources marines reste d'actualité. L'ensemble des questions a fait évoluer la problématique de la gestion des ressources dès la seconde moitié de ce siècle d'un primat de la biologie marine à la pleine reconnaissance des dimensions sociales et politiques de cette question. L'écologie viendra dans le même temps prendre une place nouvelle dans l'explication des causes de diminution des stocks. Plus généralement les relations entre l'exploitation des ressources marines (la pêche et l'aquaculture) et l'environnement marin posent des problèmes nouveaux comme l'ont montré les travaux du CIEM lors de la dernière Conférence de la Rochelle en 1991 et bien sûr les débats de la Conférence de Rio sur l'environnement et le développement. Ces problèmes ne peuvent laisser les sciences sociales indifférentes.

Comme vous l'aurez compris, cette Conférence témoigne de l'importance qu'accorde l'IFREMER aux questions d'économie liées non seulement à l'exploitation des ressources marines vivantes mais aussi, et vous le savez, à leur valorisation, aux marchés qui en dépendent, aux espaces qui les contiennent. C'est cet attachement

deep-sea fishing, salmon farming and statistics dealing with international exchange are thus treated within these work groups, with specific publication and organizational time frames, all operating with the same open-minded principle. This Conference will perhaps spawn a new sub-group which will concentrate on North-South relations or Common Fisheries Policies as a focus for reflection and complementary research. Other subjects may, at the conclusion of your debates, appear as worthy of your attention, with IIFET acting as the federating force. I do not want to anticipate on the conclusions which will result from your work. Allow me simply to say that I will remain open to your proposals in this spirit.

IIFET benefits from another specific advantage since it was created at a time when the organizational and management concepts relating to fisheries were entering a new phase of development. The United Nations Convention on Maritime Law was a decisive step in the recognition, at an international level, of appropriation zones for the maritime environment. At a time when the full general exploitation of the world's fisheries resources became an accepted principle, this major reform of International Law was a determining factor in accurately posing the fundamental question of the management of fisheries and the ensuing share of space, resources and wealth. Recent international arbitration involving France and the desire of certain coastal countries to appropriate maritime zones beyond their 200-mile limits demonstrate that the questions of space and resource appropriations remain critical issues. These questions taken as a whole have influenced the management of resources in this second half of the century to evolve and, what were previously preoccupations limited to the field of marine biology, have now been recognized in terms of their overall social and political impact. Ecological concerns have simultaneously contributed to the explanation of the reduction of stocks. On a more general basis, the relation between the exploitation of maritime resources (fisheries and aquaculture) and the maritime environment poses new questions, as demonstrated by the discussions of the ICES during their last Conference in La Rochelle in 1991 and, of course, the debates of the Rio de Janeiro Conference on Development and the Environment. These questions cannot be ignored by the social sciences.

You are certainly aware of the fact that IFREMER, as this Conference demonstrates, is not only sensitive to questions linked to the exploitation of living marine resources, but also, as you know, to what we term their value enhancement and derivative industrial applications in the markets and the zones involved. This involvement was in fact the reason why IFREMER, from its very

qui avait d'ailleurs conduit l'IFREMER à se doter, dès sa création, d'une équipe d'économistes spécialisés sur ces questions. Sans cette initiative, cette VIème Conférence ne se déroulerait certainement pas en France aujourd'hui.

Lorsque l'IFREMER s'est porté candidat dès 1988 à l'organisation de cette sixième Conférence, nous savions que ce rendez-vous se ferait à un moment où l'Europe des pêches s'avance vers des étapes majeures de sa construction. Nous ne pouvions prévoir par contre qu'entre temps, d'autres événements ajouteraient à l'opportunité de vos travaux en ce lieu, à cette date.

Pour n'en retenir que quelques uns, j'évoquerai tout d'abord les évolutions historiques que connaissent les pays de l'Est. Le redécoupage des anciennes Républiques Soviétiques et l'unification de l'Allemagne s'accompagnent en effet de la remise en cause des fondements économiques internes à partir desquels se déterminaient les choix et les modes de production tout autant que les flux d'approvisionnement et d'échanges de ces pays. Lorsque l'on sait le poids de ces pays dans l'exploitation des ressources marines vivantes, le volume de la demande potentielle qu'ils représentent, leur position dominante sur certains marchés, les zones d'activité de leurs flottilles dans certains PED, on entrevoit aisément l'ampleur des ajustements à attendre. Un pas définitif est franchi qui rapproche maintenant l'ensemble des pays producteurs face à des principes de régulation et de partage identiques. Il est intéressant de noter à ce propos que là où les pays à économie planifiée avaient intégré les mécanismes de marché pour accéder à des droits de pêche, les pays à économie capitaliste, et c'est notamment le cas dans la C.E.E., se sont engagés eux dans la voie de l'interventionnisme public pour contraindre les mécanismes de marché.

Un autre événement sur lequel l'actualité récente nous interpelle ces jours ci, est le processus de ratification du Traité sur l'Union Européenne. On savait, et vous aborderez cet aspect de la Politique Communautaire lors de vos débats, que le calendrier européen pour les Pêches marquait en cette fin d'année 1992 l'entrée dans la préparation de 1996 et 2002. Le rapport intermédiaire de 1991 sur la Politique des Pêches en est le trait d'union. Le traité de Maastricht en toile de fond vient ajouter une dimension à certaines interrogations que soulevaient déjà avec acuité les questions de gestion des ressources marines. La subsidiarité telle qu'elle est définie dans le texte du Traité ainsi que le principe de précaution de l'article 130R (Titre XVI sur l'environnement) ne manquent pas de nous interpeller dans ces temps où la place de l'avis scientifique et l'avis des économistes sont de plus en plus sollicités et où chacun des Etats, chacune des structures professionnelles du secteur s'interroge sur

creation, included a team of specialized economists working on these questions. Without this initiative, this Sixth Conference would certainly not be taking place in France today.

When IFREMER submitted its candidacy as of 1998, to organize this Sixth Conference, we knew then that this meeting would occur at a time when European fisheries would advance toward major stages in its construction. We could not however foresee at the time that other events would take place which would add to the significance of our work at this time and in this place.

Without being exhaustive, it is important to mention major events such as the historic changes that have taken place in the countries of Central and Eastern Europe. The redefinition of the former Soviet Republics and the reunification of Germany have occurred at the same time as the reassessment of internal economic foundations which determine both the modes of production and the supply and exchange flows between these countries.

When we consider the weight of these countries in the exploitation of living marine resources, the potential volume of demand that they represent, their dominant position on certain markets and the activity zones of their fishing fleets in certain developing countries, it is possible to have an idea of the necessary adjustments that will have to be made. A decisive step has been taken in that all producing countries have operated a rapprochement in applying identical regulatory and sharing principles. It is interesting to note in this respect that the countries with planned economies had integrated certain market mechanisms to gain fishing rights while capitalist countries, and notably the EEC, committed themselves to interventionist policies to constrain the effects of the market.

The process of ratification of the Single European Treaty is another major event which will have impact in our field. It is a known fact that in terms of Community Policy, which you will deal with in your discussions, the European fisheries calendar at the end of 1992 is leading toward the preparation of 1996 and 2002. The 1991 intermediate report on Fisheries Policy is a stepping stone in this direction. In the background, the Maastricht Treaty adds another dimension to certain pertinent questions concerning the management of marine resources which were in the process of being examined. Subsidiarity, as defined in the Treaty, as well as the principle of precaution in Article 130R (Heading XVI on the environment) continue to solicit our interest at a time when scientists and economists are increasingly called upon to express their points of view and where States and professional bodies are questioning themselves on the role they will play in the preparation and orientation of

la place qu'ils vont devoir tenir dans la préparation et l'orientation du secteur. Nul doute que tous les acteurs du secteur porteront la plus grande attention à vos conclusions sur ces points.

Enfin, et les professionnels français le savent déjà, si l'actualité mondiale a porté la Conférence de Rio en tête d'affiche durant quelques mois, c'est davantage la revendication écologiste qui va vous conduire en tant qu'économistes des ressources et des espaces marins à prendre de plus en plus en compte de nouvelles options d'usage, de nouvelles revendications sociales. A bien des égards, les questions environnementales portées par de larges effets médiatiques trouvent dans vos acquis et réflexions déjà anciennes des réponses adaptables pour la gestion d'autres ressources communes. Aider à définir des règles de régulation, s'interroger sur les interactions entre politiques publiques et choix individuels, déterminer la valeur de ressources patrimoniales marines... autant de questions pour lesquelles l'ensemble des pays et des décideurs sont en attente de réponses. Les sciences sociales, je le soulignais il y a quelques instants, ont là un vaste champ soumis à leurs investigations. Gageons que vous saurez prolonger vos travaux dans l'avenir pour faciliter leur choix.

Bien d'autres questions encore, j'en suis certain, viendront animer vos débats : le devenir et les potentiels promis par l'aquaculture, le rôle des ressources marines vivantes dans le développement des PED, la place enfin de ces ressources face à la gravité du paradoxe mondial de la malnutrition... Là encore l'avantage et l'intérêt que représente ce forum international doivent porter des fruits.

Je voudrais pour conclure affirmer à nouveau toute l'importance d'une recherche construite sur la plus large coopération internationale et très largement pluridisciplinaire, bénéficiant à tous (pays du Nord et du Sud) et nourrie du plus grand nombre de références face à un monde politique et économique dont les événements récents et les déséquilibres pérennes nous laissent entrevoir encore quelques écueils sérieux sur la route de la compréhension et de la prédiction. Je souhaite, pour finir, un plein succès à vos travaux qui porteront, j'en suis certain, encore plus en avant nos possibilités de coopération.

our sector of activities. There is no question that the actors in our field will be highly attentive to your conclusions on this point.

Finally, it is important to mention a point which French professionals today are aware of and that the Rio de Janeiro Conference brought to the forefront in the last few months: i.e. the increased pressure of ecologists which will lead you as economists dealing with resources and the management of the marine environment, to increasingly take into account new operational options and heightened social demands. In large part, the environmental issues which have been amplified by spectacular media effects are mere reflections of adaptations which you have been carrying out for a long time in the management of other common resources. In helping to define the rules for regulation, in asking questions on the interaction between public policies and individual choices and in determining the value of our marine resource heritage, you are dealing with questions for which all countries and their decision-makers are seeking responses. The social sciences, as I mentioned earlier, are a vast domain which can benefit from your investigations. I am willing to wager that you will be capable of extending your work in the future to facilitate their choices.

I am convinced that there are many other questions, which will enliven your debates: the future and potential of aquaculture, the role of living marine resources in the developing countries and finally the influence of resources in the grave and paradoxical problem of malnutrition in the world. In this regard, the advantages and interest of this international Forum should bear its fruits.

I would like to conclude by affirming once again the importance of research built upon the widest degree of international co-operation, as multi-disciplinary as possible, benefiting all countries in both the North and the South and enhanced by the greatest number of references in a highly political and economic world where recent events and lasting imbalances continue to demonstrate that there are serious shortcomings in our attempts at comprehension and prediction. I would like to wish you, finally, great success in your work which, I am convinced, will further contribute to our possibilities for co-operation.

# Joseph Catanzano
# Chairman Scientific Committee VI Conference, 1992 Paris

En préparant cette Conférence, lors de voyages dans des pays extérieurs à la Communauté Européenne, j'ai pu constater avec satisfaction mais aussi avec étonnement en quelques cas, toute l'attention que portaient les économistes et les responsables nationaux des ressources marines au fabuleux chantier et défi que représente la Politique Commune des Pêches. Pour ceux qui sont le plus souvent affairés au cœur même de la construction ou de l'application de cette politique commune, cet intérêt extérieur a permis de mieux prendre conscience de l'ampleur de ce projet au plan international.

Mais cet intérêt particulier ne se limitait pas exclusivement à la question de la gestion des ressources marines vivantes. Il révélait également, à la veille des changements importants placés dans l'agenda communautaire pour 1993, quelques inquiétudes quant au devenir des marchés internationaux, aux évolutions des activités aquacoles et aux étapes de développement des pays les moins avancés.

Pour le Comité Scientifique œuvrant à la préparation et au suivi de cette Conférence, il est apparu très vite que l'Europe Bleue allait nous permettre de décliner la plupart des thèmes de l'économie des pêches et de l'aquaculture ; depuis le fonctionnement des entreprises jusqu'aux politiques publiques de régulation. Ainsi fut-il décidé de consacrer l'ouverture de la Conférence à l'évocation de cette Politique Européenne Commune donnant ainsi aux responsables politiques nationaux, responsables européens et économistes des pêches, l'occasion de débattre de quelques éléments clefs de cette initiative internationale unique.

Au delà de ce thème, le Comité Scientifique a voulu au terme de l'évaluation des propositions d'intervention offrir au plus grand nombre de candidats l'occasion de présenter et discuter leurs travaux de recherche. Il faut dire que la qualité des textes proposés nous a fait rapidement oublier la difficulté qu'allait représenter,

As I was working on this conference, during the trips I have made to non-EC member states, I was pleased and sometimes amazed to note the great attention that economists and national representatives of marine resources were focusing on the Common Fisheries Policy. For those who are busy trying to build or apply this common policy, this external interest has increased awareness of the importance of this project at an international scale.

However, this particular interest went far beyond the question of the management of living marine resources. It has also revealed, on the eve of the important changes occuring in the 1993 EC agenda, some concerns as to the future of international markets, the development of aquaculture activities and the development of the least advanced countries.

For the Scientific Committee which was preparing this conference, it soon became apparent that the "Blue Europe" would enable us to include most of the subjects regarding the economics of fisheries and aquaculture : from the functioning of companies to public regulation policies. Therefore, it was decided to focus the opening of this conference, on CFP thus enabling national political officials, european representatives and fisheries economists to debate of some of the key elements of this unique international initiative.

Apart from this subject, the Scientific Committee intended, at the end of the evaluation of propositions, to give the opportunity to most of the candidates to present and discuss their research work. It is necessary to mention that the quality of the texts proposed made us easily forget the difficulties inherent in programming 115 communications. You can imagine the intellectual enrichment from this, equalled only, I think, by the anxiety at the time of organizers.

As a follow-up step for the conference, the publication of the proceedings has occupied us for more than a year now giving us the opportunity to reinforce the links that we have established with most of you.

inévitablement, la programmation de 115 communications. Vous pouvez imaginer l'enrichissement intellectuel que l'on en a retiré et qui n'a eu d'égal à l'époque, je crois, que l'angoisse des organisateurs.

Prévue dans la continuité de la Conférence, l'édition scientifique des actes nous a occupé plus d'un an nous offrant l'occasion de poursuivre avec la plupart d'entre vous de multiples échanges.

Aujourd'hui, l'ensemble de ces communications est contenu dans deux tomes qui s'organisent en référence au déroulement réel de la Conférence, selon douze sessions distinctes.

Ces deux tomes qui regroupent les textes exposés à Paris, fournissent une revue exceptionnelle en économie à propos des questions d'aquaculture, de consommation, de demande, de valorisation, de distribution et d'échanges internationaux des produits de la mer, d'outils de régulation pour les systèmes pêche (production et marchés). Y sont traitées également les questions de modélisation des pêches, de conflits d'usage ou d'appropriation, les méthodes de mesure de la valeur des ressources, les questions enfin du développement et celles de la Politique Commune des Pêches.

Ils sont enrichis d'une grande diversité de cas qui vous permettront sur chacune des questions de mettre en comparaison vos propres références et les situations rencontrées sur les divers Océans pour l'ensemble des continents de la Planète.

Afin de disposer d'une présentation sommaire du contenu des sessions, nous avons retenu le principe de livrer avant chacune d'entre elles, un texte introductif court, destiné à vous renseigner brièvement sur l'état de l'art à propos de ces sujets mais aussi sur les questions spécifiques abordées par chacun des auteurs.

Ainsi, vous pourrez disposer à ce niveau d'une vision synthétique de chacune des sessions. Je suis convaincu que celle-ci vous engagera très vite à la lecture des textes rassemblés, vous facilitant par la suite l'utilisation continue de ces documents.

Participant à ces rédactions, des chercheurs ont bien voulu prolonger à nos côtés leur engagement initial et je pense que l'usage que vous saurez faire de ces deux tomes durant les années à venir, sera, pour eux, à côté des remerciements que nous leur renouvelons ici, la meilleure des reconnaissances.

Now, the complete set of papers as been compiled into 2 volumes which have been organized into 12 distinct sessions, according to the presentation of the conference.

These 2 volumes give an exceptionnal economic review regarding the questions of aquaculture, consumption, demand, marketing, distribution and international exchange of maritime products and methods of regulation of the fisheries systems (production and distribution). They also deal with the issues of modelling of fisheries, use and appropriation conflicts, methods of resource valuation and finally with the questions of development and the CFP.

They are enhanced by a wide variety of case-studies which will enable comparisons to be made between the situation in your aera and that in other aeras of the world.

In order to give a summary presentation of the content, we present before every session, a brief introductory text giving you concise information about the state of art and the specific questions dealt with by each authors.

This will give you a overview of each session which, I am convinced, will help you read the texts, thus facilitating at a later stage the regular utilization of these documents.

By contributing to these volumes, researchers have continued their initial engagement with us and I think that your best vote of thanks for their efforts will be the use that you will make of their work now and in the future.

# Intervention de Monsieur Charles Josselin Secrétaire d'Etat à la Mer, France

Monsieur le Président, Mesdames, Messieurs

Je suis particulièrement heureux de pouvoir faire part de réflexions qu'inspirent, à l'homme politique que je suis, les principaux enjeux de l'économie des pêches maritimes mondiales, devant une assemblée d'experts de toutes les régions du globe.

Des économistes du monde entier sont en effet venus ici confronter leurs expériences, informer de l'état d'avancement de leurs travaux théoriques et rechercher ensemble les solutions au problème majeur de la pêche mondiale : la gestion de la ressource. Il s'agit d'un patrimoine collectif commun, heureusement renouvelable. Le bilan établi en septembre 1991 à la Toja près de Vigo par les Ministres des pays les plus concernés par la pêche, avait déjà mis en évidence deux conclusions essentielles en ce domaine :

d'une part, l'économie des pêches maritimes s'est mondialisée depuis dix ans,

d'autre part, la production s'est considérablement accrue depuis quarante ans : elle était de 15 millions de tonnes en 1950 ; elle avoisine les cent millions de tonnes en 1990.

L'afflux constant des nouvelles capacités de capture et le progrès spectaculaire des technologies donc de la productivité, expliquent cette évolution. Mais – et c'est un signal pour nous tous – la production mondiale a, pour la première fois, régressée en 1990, le mouvement se confirmant en 1991. Je suis pourtant convaincu que ni le développement des initiatives, ni la modernisation des technologies ne constituent en eux-mêmes un danger. Ils ne le deviennent que si le mouvement est incontrôlé, si les captures deviennent excessives au regard du potentiel offert par la biomasse – et le problème est loin d'être seulement européen – !

La nouvelle donne de la pêche mondiale dans les années 1990 doit par conséquent être dominée par la maîtrise équilibrée entre les capacités de capture et les stocks. Pour cela il est clair qu'on ne peut s'en remettre uniquement au jeu du marché. Il doit donc y avoir des règles et des normes. Il doit donc y avoir des outils de régulation de la ressource. Ces constatations valent pour l'ensemble des pêches du globe et c'est dans cet esprit que le principe d'une Conférence Mondiale de la Ressource en 1993 en Inde a été retenu. Mais elles valent aussi en Europe, dont la politique commune des pêches constitue pour vous un laboratoire de ce que peut être un régime de gestion et de conservation des ressources halieutiques. C'est dans ce cadre que je voudrais inscrire mes réflexions. Même si l'importance de la pêche dans l'économie européenne peut paraître réduite son poids relatif est en fait beaucoup plus important. L'activité de pêche se concentre en effet dans des zones littorales et insulaires dont elle est le support principal pour le maintien du tissu économique et social.

Toute stratégie de régulation de la ressource se heurte ainsi dès l'abord, et parce que son impact est considérable, à cette redoutable gageure de la nécessité de préserver une activité économique, tout en assurant la bonne gestion d'une ressource halieutique dont la principale caractéristique est d'être limitée.

En d'autres termes, la pêche est constituée d'hommes et d'entreprises qui ont des aspirations, des ressorts psychologiques et économiques : gagner de l'argent pour investir, préserver l'emploi, vivre décemment de leur travail, innover. En outre l'économie des pêches maritimes doit également prendre en considération des aspects périphériques mais essentiels liés par exemple à l'environnement et à l'aménagement du territoire. Sans même parler à ce stade d'outils techniques, toute régulation de la ressource qui ne s'appuierait pas sur ces motivations, ou pire encore irait à leur encontre, ne peut courir qu'à l'échec. Ce sont ces aspects, qui donnent une dimension politique à ces problèmes et qui sensibilisent fortement le Ministre de la Mer. Dès lors, nous ne pourrons avancer en ce domaine qu'à deux conditions :

1. que toutes les décisions publiques soient fondées sur des données scientifiques incontestables. Ouvrir trop grand le parapluie de la prudence pour masquer l'ignorance de phénomènes mal maîtrisés ou sacrifier à des théories insuffisamment fondées n'est pas acceptable. Il serait d'ailleurs souhaitable que les associations qui se donnent la juste cause de la défense de l'environnement se dotent dans le domaine des pêches d'un solide appareil scientifique ;

2. que les professionnels de la pêche soient associés, au préalable, aux décisions.

D'abord parce que leur point de vue complète souvent très utilement celui des scientifiques, ensuite parce qu'aucune décision ne peut être sérieusement appliquée si elle n'est pas perçue comme nécessaire et génératrice de progrès à terme. Il est par conséquent de la responsabilité des décideurs, comme de celle des scientifiques, de faire preuve de la plus grande pédagogie afin que le message, quel qu'il soit, pour être reçu, soit clair, simple et incontestable. C'est dans cet esprit que je n'ai pas hésité à reprendre à mon compte l'initiative de mon prédécesseur Jean Yves Le Drian, de réunir des Etats Régionaux de la Ressource.

Ces Assemblées, qui associent au niveau régional l'ensemble des parties prenantes – professionnels, scientifiques, élus, administration – dans le domaine de la pêche, devront d'ici l'automne prochain dresser le bilan des difficultés de gestion de la ressource – côtière ou communautaire – auxquelles elles se trouvent confrontées, et formuler des propositions d'amélioration.

Je tenais avant d'évoquer les thèmes qui sont l'objet de votre débat, à poser les principes qu'il me paraît essentiel de conserver à l'esprit.

La réflexion proprement dite sur les modalités de gestion des pêcheries me semble comporter au moins trois volets :

une réflexion sur les outils de régulation de la ressource ;

une réflexion sur les institutions le plus aptes à les mettre en œuvre ;

une réflexion sur les moyens de contrôle nécessaires à leur efficacité.

Les réflexions qui sont les miennes sur ces différents sujets seront nécessairement marquées par l'exemple européen, que je vis tous les jours, de la politique commune des pêches.

Les outils de régulation actuellement en usage peuvent se décomposer en deux familles :

les outils de gestion de la ressource (Tacs, quotas, mesures techniques...) ;

les outils d'accès à la ressource et de maîtrise de l'effort de pêche (permis de mise en exploitation, licences, quotas individuels, quotas individuels transférables).

Le système des Tacs et des quotas, ainsi que les mesures techniques de conservation de la ressource – maillages notamment – représentent les mécanismes les plus traditionnels qui ont fait leurs preuves, même s'il est possible d'améliorer leur efficacité.

De ce point de vue, la réflexion actuellement engagée en Europe porte sur la fixation de quotas sur une base pluriannuelle et non plus annuelle et sur les quotas multispécifiques. Cette idée semble répondre à une nécessité pour le pêcheur, dont l'entreprise a besoin de perspectives de fonctionnement sur une durée suffisamment longue. Il convient toutefois qu'une analyse et une expérimentation suffisamment approfondies d'un tel mécanisme confirment ou infirment sa validité. La détermination des mesures techniques quant à elle, pour être comprise donc admise par le pêcheur, doit reposer sur des données scientifiques incontestables. Mais la rigueur, la souplesse, la progressivité doivent aussi présider à leur fixation, par exemple lorsqu'il s'agit des problèmes de maillage.

Il est indispensable en second lieu, pour adapter les capacités de capture aux stocks disponibles, de contrôler l'accès à la ressource.

Les programmes d'orientation pluriannuels définissent ainsi, pour chaque Etat-membre de la C.E.E. et sur une période de cinq ans, le taux de réduction des flottilles.

C'est dans le même ordre d'idée que la France a, au titre des mécanismes d'entrée en flotte, mis en œuvre depuis plusieurs années un permis de mise en exploitation. Les critères retenus à cet effet combinent les indications liées à l'état

de la ressource et la productivité des différents types de navires. La segmentation peut en effet paraître une solution opportune, dans la mesure où elle différencie l'évolution nécessaire des flottilles s'adressant à des ressources dont l'état n'est pas uniforme. Il convient toutefois de prendre garde aux limites d'une telle approche :

la première pourrait être l'incertitude relative des connaissances scientifiques. Jusqu'ici l'évaluation des stocks déterminait seulement la fixation des prises maximales. Avec la segmentation prenons garde à ne pas figer la maquette d'évolution de différentes flottilles pour de nombreuses années, les investissements conduits, compte tenu de leur importance, engageant le long terme. Est-on sûr que les connaissances scientifiques soient assez précises pour fonder des conséquences aussi lourdes?

La seconde limite à respecter est l'indispensable souplesse de l'activité de pêche : une segmentation trop détaillée peut bloquer le redéploiement des entreprises vers de nouveaux métiers, de nouvelles ressources. On voit bien que par ce biais nous atteignons déjà un niveau plus grand de contraintes qui est celui des licences dont l'objet n'est plus seulement de contrôler les entrées en flotte mais l'ensemble des navires en flotte. Un troisième et un quatrième degré en la matière est constitué par l'instauration de quotas individuels voire de quotas individuels transférables qui en établissant une forme d'appropriation de la ressource, rompent avec la tradition qui en fait une "res communis" et posent la redoutable question de sa patrimonialisation. Prenons garde au risque majeur que constitue la fixation étroite de situations acquises : toutes les sociétés européennes souffrent encore de l'existence de secteurs économiques où, généralement sur la base des meilleures intentions – éviter une surproduction, protéger les consommateurs ou les producteurs – on a artificiellement créé des droits d'exploitation exclusifs.

L'initiative et la compétition deviennent impossibles, l'accès à la profession est mis aux enchères. Demeurons attentifs également aux difficultés de gestion et aux incohérences économiques qui résulteraient d'une régulation des captures par les temps de pêche. Comment imaginer en effet qu'une entreprise ne s'efforce pas d'utiliser à plein l'instrument dans lequel elle a investi, et dont le coût — en termes de fonctionnement et d'amortissement – oblige au contraire à optimiser son activité. Doit-on s'orienter dans cette voie ou au contraire privilégier pour l'adaptation durable des capacités de capture le strict contrôle des entrées en flotte, et quand c'est nécessaire, l'incitation à l'arrêt définitif, gérée aussi bien que possible du point de vue économique et social ? Ces questions font actuellement l'objet de débats dans bien des enceintes scientifiques et politiques. Je souhaite que vos travaux d'aujourd'hui permettent d'avancer dans la connaissance et l'analyse de ces mécanismes et de leurs effets afin d'éclairer les décisions que les politiques ont (ou auront) à prendre en ces matières. Les responsables politiques doivent pour leur part faire prévaloir une organisation à l'accès à la profession et à la ressource, qui s'appuie sur les capacités professionnelles et la formation des pêcheurs, sur la qualité de leurs projets, du point de vue de la ressource et des perspectives économiques, et sur l'équilibre des entreprises existantes.

Vos travaux portent également sur les institutions les plus aptes à mettre en œuvre ces outils.

De ce point de vue, il semble préférable que leur gestion obéisse au principe de subsidiarité récemment affirmé au niveau communautaire, qui consiste à en attribuer la responsabilité à l'échelon de compétence – communautaire, national ou régional – le plus adapté.

S'il existe une responsabilité qui, à l'évidence relève du niveau national, c'est le contrôle.

Mais l'enjeu du contrôle, déterminant pour le succès de toute politique de régulation de la ressource, lui aussi doit au préalable et dans l'esprit que j'évoquais tout à l'heure, être compris de tous, qu'il s'agisse du professionnel, pêcheur ou partenaire de la filière, du consommateur, voire du juge.

En clair il est nécessaire que l'opinion publique prenne conscience du préjudice que causent les infractions à l'économie des pêches, et par là même à la collectivité toute entière. Il faut aussi que le contrôle soit crédible et donc réellement dissuasif. Il convient enfin que soit respecté le grand principe des libertés publiques selon lequel toute limitation d'une liberté doit être strictement proportionnée à son objectif. Les nouvelles technologies de contrôle – satellite notamment – ne peuvent éluder les questions relatives à leur bilan coûts-résultats, ou celles qui se posent en termes de coût social – liberté individuelle, protection du savoir-faire –.

Je ne voudrais pas terminer mon propos sans évoquer une question qui, tout en étant à la périphérie de la régulation de la ressource, en constitue pourtant un point central, tant il est vrai que la gestion de la ressource doit être conçue en synergie avec les aspects liés au marché. Il est en effet tout à fait essentiel, au moment où la situation de la ressource et l'adaptation des capacités contractent les débarquements en volume, de rechercher, sans relâche, la valorisation.

Celle-ci passe à l'évidence par une meilleure connaissance des marchés alimentaires des produits de la mer, et par une action cohérente de tous les acteurs de la filière, pour y adapter les processus de production et de commercialisation. Elle suppose également :

> une politique d'adaptation des captures et de programmation des débarquements que peuvent soutenir des mécanismes comme ceux qui sont en vigueur au titre de l'organisation commune des marchés ;
>
> une politique de qualité à bord, en criée et dans les circuits de commercialisation : les techniques de conservation, de débarquement, de vente, de transformation doivent assurer à cet effet le consommateur d'une qualité régulière, qui peut d'ailleurs faire l'objet d'une certification, comme on commence à le voir dans certains ports de Bretagne et de Méditerranée. Les règles sanitaires européennes comme la politique de qualité récemment initiée au niveau communautaire, participent de cette logique. On l'a vu, le défi est majeur, les solutions nombreuses mais difficiles à mettre en œuvre et s'adressent le plus souvent à une population dont le maintien de l'activité de pêche est une condition de survie économique. Il est de notre responsabilité de décideurs de concilier le souhaitable et le possible en appréciant au préalable l'impact économique et social des mesures prises, quel que soit leur bien-fondé.

Vos travaux constituent à cet égard une base indispensable à la prise de décision. Je suis convaincu qu'une telle conférence peut largement contribuer à cet objectif. Je tenais en concluant mon propos à vous en remercier. Je souhaite une pleine réussite à vos travaux.

# The Common Fishery Policy
# by
# J. Catanzano

La Politique Commune des Pêches (PCP), s'impose au plan international comme l'un des exemples majeurs sur la voie de la recherche de modalités fonctionnelles viables, équitables et communes à plusieurs pays dont la finalité globale s'expose en termes de recherche d'adéquation entre système de production, dynamique des ressources halieutiques et dynamiques des marchés.

Trouvant son autonomie de définition et de mise en œuvre à partir de la Politique Agricole Commune et sur les fondements du Traité de Rome, la PCP représente aujourd'hui l'un des projets les plus ambitieux de la construction européenne, étant à certains moments de l'élargissement de la Communauté l'un des dossiers les plus sensibles (Espagne et Portugal hier, Islande et Norvège demain). Sorte de « mal nécessaire » aux dires de certains, il n'est aucun des pays qui puisse aujourd'hui renoncer à ce cadre de traitement des problèmes de la pêche tant il est vrai que les changements du contexte juridique international (Nouveau Droit de la Mer), ont forcé définitivement à la mise en commun des ressources européennes contraignant encore davantage les possibilités de redéploiement de flottilles excédentaires des pays membres.

Sur cette voie d'une politique commune, les difficultés que rencontrent les institutions européennes tiennent :

1 - d'une part aux embûches inhérentes à la complexité du projet - qui vise à mettre en commun pour gérer, des ressources non appropriées -,

2 - et d'autre part aux effets multiplicateurs qui tendent à rendre encore plus complexes, variés et étendus, les problèmes afférents aux modes de production, aux marchés, aux institutions, aux stocks, aux contextes socio-politico-économique... Là où déjà, classiquement, sur le cas de simples pêcheries

The Common Fisheries Policy is seen, at an international scale, as one of the major examples in the search for functional methods that are viable, impartial and common to many countries whose general purpose is to balance production systems, dynamics of fisheries resources and markets.

Deriving its definition and implementation from the Common Agricultural Policy and the foundations of the Treaty of Rome, the CFP represents one of the most ambitious projects of European construction: it is one of the most delicate items at a time when the community is extending (first the adhesion of Spain and Portugal and, in the future, Iceland and Norway). None of the countries is able nowadays to avoid dealing with fisheries problems in such a context which is considered by some as a "necessary evil". Besides, the changes which have occurred in the international judicial context (New Law of the Sea) have compelled the sharing of European resources, thus limiting further the possibility of redeploying the surplus of member states fleets.

In their objective to reach a common policy, European institutions are encountering two major difficulties:

1 - obstacles inherent to the complexity of the project which aims at sharing non appropriated resources in order to manage them;

2 - multiplying effects which tend to increase the complexity, variety and range of problems relative to productive means, markets, institutions, stocks, socieconomic and political context... In the classical case of national fisheries, we find it hard to deal with complex systems subject to intense variabilities and to situations managed with great uncertainty; but in the CFP, we have a case study which is extraordinarily developed in the process of multiplying complex phenomena.

nationales on souffre d'avoir à traiter de systèmes complexes soumis à de fortes variabilités, à des situations régies sous incertitude, on trouve au travers de la PCP un cas d'observation extraordinairement avancé sur la voie de la démultiplication de phénomènes complexes.

A la fin de sa deuxième décennie d'existence et à la veille de l'entrée en vigueur du grand marché européen (1er janvier 93), il apparaissait opportun de profiter de cette conférence pour mettre en auscultation la PCP. L'occasion offerte allait trouver son originalité dans la confrontation directe de responsables européens (Directeurs des volets Structures, Marché et Ressources Internes de la Direction Générale des Pêches de la Communauté Européenne), les responsables nationaux chargés de sa préparation et de sa mise en œuvre (Direction des Pêches en France), les acteurs professionnels du secteur et enfin les économistes des pêches intéressés, ici ou ailleurs, aux problèmes de la gestion des pêches.

Au travers de cette session il nous est donné de mieux comprendre les critiques adressées à la PCP par chacun des observateurs, acteur du système ou extérieur totalement à ses institutions. Ces propos rejoignent souvent le rapport 1991 de la Commission, sorte d'introspection à partir de laquelle P. Andersen mettra en exergue les voies d'évolution proposées pour améliorer globalement l'efficience des mécanismes européens. On y retrouve posé comme principe de réforme :

(i) la mise en œuvre effective de la subsidiarité dont on sait qu'elle renvoie en préalable à l'identification d'unités d'aménagement et à une meilleure connaissance des institutions et des mécanismes qui sous-tendent leurs actions,

(ii) la reconnaissance d'un *numerus clausus* concrétisé au travers d'une licence européenne, supposant en préalable une amélioration des modes de contrôle, de plus fortes incitations au respect des règles existantes, une meilleure programmation de la politique structurelle placée dans le cadre général des Fonds Structurels européens et enfin une réflexion sur les effets nés de la combinaison de licences et de quotas.

On peut imaginer à l'énoncé de ces seuls principes et à l'inventaire des préalables qui s'y rattachent, les nombreux chantiers qui s'ouvrent aux économistes. De part les questions posées, on prend conscience des imbrications qui existent entre mécanismes décisionnels avec les présupposés politiques qui les accompagnent, et recommandations d'experts économistes. P. Andersen s'interroge à ce propos sur les faibles échos donnés à ces recommandations. S'il semble que la réponse se trouve

At the end of the second decade of the existence of the CFP and on the eve of the implementation of the European Market (January 1st, 1993), this conference provided the opportunity to examine the CFP in depth. One original aspect of the conference consisted in the direct confrontation of European officials (Directors for Structures, Market and Internal Resources of the General Department of Fisheries of the European Community), national officials in charge of its preparation and implementation (Fisheries Department in France), professionals of the sector and fisheries economists involved, here and elsewhere, in the problems of the management of fisheries.

As a result of this session, we are able to understand much better the criticisms of the CFP by observers, both internal or external to the system's institutions. These observations often agree with the 1991 report of the Commission, and led P. Andersen to emphasize the ways in which the efficiency of European mechanisms might be improved. Two principles were proposed as a basis for reform:

(i) the effective implementation of subsidiarity which, as we know, requires the identification of management units and a better understanding of the institutions and mechanisms which underpin management;

(ii) the recognition of a *numerus clausus* in the form of a European licence. It implies, as a prerequisite:

- an improvement in enforcement,
- stricter inducements to respect existing regulations,
- better planning of the structural policy placed in the general context of European Structural Funds,
- finally, a discussion of the effects of combining licences and quotas.

Even with such a small number of principles and their prerequisites, we can imagine the numerous fields opened to economists. By taking into account the questions stated, we become aware of the linkages which exist between decision mechanisms including their political presuppositions and the recommendations of economists. P. Andersen notes the lack of attention paid to such recommendations. If the reason is to be found in the complexity of the institutional road which leads from the opinion to the decision, it is important to note that, this raises an obscure question often ignored because it is difficult to fit in the formal representation preferred by economists. The contribution of other disciplines may clarify this question which is at the heart of the decision process.

dans la complexité du chemin institutionnel qui conduit de l'avis à la décision, il est plus important de noter que du même coup se trouve révélée une zone d'ombre fondamentale souvent ignorée des observateurs car de nature peu propice à la réprésentation formelle des économistes. Le regard d'autres disciplines pourrait éclairer en partie cette zone au cœur même des processus de décision.

En pensant à cela et toujours dans cette sorte d'introspection, des responsables nationaux et européens s'expriment sur les mécanismes, les enjeux, les dysfonctionnements de la PCP nous permettant ainsi de conforter sous un autre angle les points de réforme envisagés face à un constat relativement critique des mécanimes en œuvre (C. Bernet, E. Mastracchio, D. I A Steel). Si on retrouve bien en toîle de fond les principes premiers de la PCP, on perçoit les limites d'application à partir desquelles se greffent les propositions des auteurs ; qu'il s'agisse de la réduction de l'effort, de la segmentation et du maintien de la flexibilité ou des enjeux de pouvoir entre Parlement et Commission. Le point commun de ces avis se trouve certainement dans une remise en cause d'une vision par trop mécaniste des solutions à opposer à la dynamique de surpêche. On pressent mieux la prise de conscience générale qui s'exprime par la nécessité de trouver et de mettre en œuvre des processus plus participatifs, mieux localisés institutionnellement au plus près des acteurs professionnels, plus incitatifs du respect des règles, davantage fondés sur une co-responsabilisation voire une autorégulation de sous-ensembles homogènes participant de la définition du secteur soumis à la PCP. Les travaux des économistes présentés dans ce cadre vont permettre d'illustrer ce mouvement de pensée s'agissant du rôle des organisations de producteurs (CEMARE), de la compréhension des stratégies des pêcheurs au travers d'une recherche sur les liens entre capacité de capture et effort (SFIA), ou encore des impacts socio-économiques de la PCP (IREPA), dans un souci de différenciation d'espaces fortement dépendant de la pêche. A partir de ces travaux quelques idées fortes se trouvent énoncées qui confortent en bien des cas les problématiques privilégiées.

La première de ces idées concerne le comportement du producteur qui apparait plus distant du cadre de rationalité stéréotypé par lequel trop souvent on réduit la fonction d'objectif des individus à une recherche de maximisation du profit. Comme le confirme les travaux de G. Valatin, il est en fait plus difficile de déterminer après intégration de paramètres qualitatifs (en rapport par exemple au patron de pêche ou aux équipages), une mesure de la capacité d'utilisation de chaque unité de pêche donc, de la capacité de capture et par voie de conséquence de l'effort. A cela s'oppose dans les faits un

Within the same theme, national and European leaders spoke about the mechanisms, the stakes and dysfunctions of the CFP. This enables us to confirm, from a different viewpoint, envisaged points of reform, given a relatively critical assessment of the mechanisms in use (C. Bernet, E. Mastracchio, D I A Steel). While the major principles of the CFP remain in the background, we can perceive the problems that lead to the authors' propositions: for instance, effort reduction, segmentation, maintainance of flexibility or the power struggle between the Parliament and the Commission. What these opinions have in common is to warn against a too mechanistic vision of the solutions to the dynamics of overfishing. We can clearly see a general awareness expressed by the necessity to find and bring into play processes with (i) more "involvement", (ii) better institutional localization close to the professional actors, (iii) better incentives to compliance, more based upon a co-responsibility or even on autoregulation of homogeneous sub-groups in accordance with the definition of the sector submitted to the CFP. The economists' works presented in this context illustrate the trend of opinion concerning the role of producers'organizations (CEMARE), the understanding of fishermen' strategies by trying to find the links existing between fishing capacity and effort (SFIA), or even the socioeconomic impacts of the CFP (IREPA). These works put forward some important ideas which in most cases relate to the main problem areas.

The first idea refers to producer's behaviour which moves away from the stereotyped vision of rationality wherein the objective function of individuals is limited to profit maximization. As shown by the paper of G. Valatin, it is difficult, after taking into account qualitative parameters (concerning the skipper or the crew for instance), to determine a measure of the capacity of each fishing unit relating to fishing capacity and thence to effort. This goes against the aggregative statutory principle which produces a uniform measure of effort (combination of technical parameters) in the search for a solution to the overfishing problem.

The results presented by CEMARE reinforce the second idea which shows that fishing activity depends on the institutional structure, especially in the European case, where producers' organizations appear to be the key to a system of management naturally divided in territories (fishing zone), biological characteristics (stock and quota) and socially defined (members).

The third fundamental idea brought out by the different attempts to measure the effects of the CFP implies that fishing represents, in some areas, the "source" of a social network which generates important economic and political effects in a context where existing opportunities are

principe agrégatif simple à visée réglementaire qui, dans la recherche de solution à la surpêche, produit une mesure uniforme de l'effort (combinaison de paramètres techniques).

Une seconde idée se trouve confortée à partir des résultats présentés par le CEMARE qui tend à montrer que la pêche ressort d'une logique de structuration institutionnelle de proximité où, dans le cas européen notamment, les organisations de producteurs apparaissent de plus en plus comme la clef de voûte d'un système de gestion naturellement territorialisé (zone de pêche), biologiquement inventorié (stock et quota) et socialement défini (statut d'adhérent).

La troisième idée centrale que l'on peut retenir à l'énoncé des tentatives de mesure des effets de la PCP (IREPA), tient au fait que la pêche constitue en quelques endroits le ferment d'un tissu social dense, diffuseur d'effets économiques et politiques non négligeables dans des contextes d'opportunités souvent peu favorables à des reconversions ou restructurations massives. Cette perception sociale du secteur des pêches, plus courante dans les économies en développement, semble reprendre aujourd'hui d'autant plus de légitimé que les espaces économiques et sociaux se trouvent de plus en plus fortement contraints.

Cette lecture croisée de la PCP dans la préparation de sa prochaine étape d'évolution à l'horizon 2002 permet de mettre en conformité d'un côté les conclusions des débats théoriques de l'économie des pêches, qui incitent globalement à une révision des paradigmes et des concepts, avec d'un autre côté les souhaits d'évolution des pratiques de la régulation qui émanent des responsables politiques.

unfavorable to major change. This social perception of the fisheries sector, more common in the developing economies, seems to be all the more reasonable today as the social and economic environment is increasingly subject to constraints.

This review of the CFP which is preparing for its next evolutionary phase in 2002 enables us to bring together the conclusions of theoretical debates on fisheries economics which generally encourage a revision of paradigms and concepts and the wish for the development of regulatory practice expressed by political leaders.

# The EEC-Common Fisheries Policy and the 1991-Report

**Peder Andersen**

Head of Secretariat, The Danish Economic Council

ABSTRACT

*The paper gives an overview of the EEC-Common Fisheries Policy and of the 1991-report from the EEC-Commission. Furthermore, the paper contains an evaluation of the 1991-report. The conclusion is that the implementation of several of the proposals will improve the exploitation pattern and improve the profitability of the fishing fleet. However the idea of segmentation of the fleet will result in an inoptimal use of the fleet.*

## 1. INTRODUCTION

The fisheries policy in the EEC involves many countries, many fleets, many stocks, many markets, many regional areas and different political systems. Furthermore the policy has developed over more than 20 years and many problems are still unsolved. The fact is that several of the todays problems in the fisheries are worse than 10 or 20 years ago. After more than a decade with extensive regulations we are facing the fundamental problem why more and more regulations does not improve the economic performance of the fishing industry.

The Common Fisheries Policy is one of world largest experiments in international coorporation of managing renewable and common property resources.

The EEC is now in the very middle of changing the fisheries policy. It is therefore of great interest for all of us to learn more about the EEC-fisheries policy experiment. In the following I will give a short introduction to the past and the future of the Common Fisheries Policy.

## 2. BASIC ELEMENTS IN CFP

The basic elements in the EEC-fisheries policy (CFP) are :

i) market organization, the first component of the CFP set in place by the Council in 1970, based on the same principles and presenting many similarities with the Common Agricultural Policy ;

ii) structural policy, also in place since 1970, with the objective of rational development of the fishing industry to ensure a fair standard of living for fishermen ;

iii) conservation and management of resources, involving - in the interests of fishermen and consumers alike - rules on the use and allocation of resources, technical conservation measures, special measures for inshore fishing and supervisory measures ;

iv) relation with non-Community countries and international organizations. Fishing agreements with non-Community countries have enabled the essential interests of the Community and its Member States to be safeguarded, restored or developed in the waters of non-Community countries and certain international waters covered by international organizations.

In January 1983 the EEC adopted a package of rules on conservation and management based on the following principles :

i) equal access to fishing grounds ;

ii) the use of total allowable catches (TACs) and allocation of TACs into national quotas. TACs are fixed in the light of scientific advice ;

iii) the principle of relative stability. The rule of fixed percentage per stock for each member was established in the 1983 agrement ;

iv) various technical conservation measures ;

v) Multiannual Guidance Programs (MGP). The idea behind this was to adjust fleet capacity to available resources.

## 3. THE LAST 10 YEARS

The major findings according to the management of the exploitation of the fish resources in EEC-waters during the last 10 years can be summarized as follows :

i) most species are overexploited from a biological as well as an economic point of view ;

ii) the ecomomic net return from the fishery is very low. In many fisheries the resource rent is negative ;

iii) the fleet capacity is too high and has been increasing during the last 10 years in spite of the fact that significant financial resources have been used on fleet capacity reduction programs.

## 4. THE 1991-REPORT FROM THE EEC-COMMISSION

The purpose of this report is to stimulate a debate about changes in the fisheries policy. First of all I would like to use this opportunity to gratulate the authors of the 1991-report. It is a report with many new ideas - a least in a EEC-context. Even a fisheries economist can be optimistic by reading the report from the EEC-Commission.

The report states the facts :

- that we have overfishing and a latent sectoral crisis

and concludes

- that present mechanisms are incomplete

and recommends

- regulation and limitation of access to resources.

In the report the list of ideas for the new common fisheries policy are summarized as follows :

i) distribution of responsibility at all levels, in accordance with the subsidiarity principle, conferring responsibility on the parties concerned, in particular the fishermen's organizations which could be given the task of implementing the management measures at the appropriate level ;

ii) more stringent regulation of access to resources by a system of licenses to rationalize fishing effort (by zone, species, fisheries, etc.), cutting back excess capacity and improving the planning of fishing so as to reduce over-investment and economic inefficiency ;

iii) a new classification of fishing activities (multiannual, multispecies, and analytical TACs, as appropriate), definitions being based on existing rights and the economic and social characteristics of each fishery ;

iv) more stringent control mechanisms, using modern technologies for vessel location and communication of information, in order to monitor the movements of certain vessels and inform the authorities concerned, while coordinating the information obtained ;

v) enforcement of compliance with rules which are in the common interest, ideally through economic incentives encouraging good behaviour by fishermen (use of selective gear, compliance with landing standards), and deterrent sanctions at Community level (penalty quotas, withdrawal of licenses, withholding of aid, fines) ;

vi) stronger structural management, by segmentation of the fleet, on the basis of new parameters, providing a basis for the assessment and control of fishing effort, and inclusion of structural measures under the umbrella of the reform of the structural Funds ;

vii) greater synergy between management of internal and external resources, other sources of supply and market management.

## 5. VIEWS ON THE 1991-REPORT

I strongly believe that implementation of several of the ideas presented in the report would significantly improve the exploitation of the EEC-fishery resources - the fish stocks, as well as the capital and human resources.

I do look at the suggestions as an economist, not as an observer of political processes within the EEC.

A ranking of the suggestions would give the idea of using economic incentives the highest priority. In many years several of the incentives in the Common Fisheries Policy have pushed fishermen as well as member states to fish and regulate in such a way that the misuse of the fish stocks is now obvious to all of us and the catch capacity is high above optimal. On that background I wellcome the ideas of positive economic incentives.

The introduction of economic incentives to improve gear selectivity as well as fishing pattern, including a reduction in fishing mortality on juveniles could be a revolution of the Common Fisheries Policy.

The report does not present examples of economic incentives. Let me give some :

i) Catches of small fish should count by a factor larger than one in the catch figures (TAC-figures). Catches of larger fish should count by a factor smaller than one in the catch figures (TAC-figures).

ii) Fishermen should be given a premium for moving their fishery towards larger fish. One way would be to increase trip quotas, monthly vessels quotas and/or to give a price premium.

iii) If a specific gear is proved to be more selective than others fishermen could be given a premium to switch to this type of gear. This idea also applies to specific gear construction.

iv) Economic support could be given to some directed fisheries in a predefined way.

Also the idea of a new classification of fishing activities is of great importance. The implementation of multiannual quotas and multispecies quotas would enforce managers to have a more broad and longer perspective. An direct benefit of multispecies and multiannual quotas is the reduction in discard. There are technical difficulties related to these measures but it is my belief that the introduction of these measures will improve the exploitation.

The third new idea of importance is the principle of subsidiarity. This implies that fishermen's organizations will be much more involved in the management process and hopefully results in decisions which are understand and accepted by the fishermen. This would also reduce the pressure on the enforcement system and increase selfregulation among fishermen.

The idea of using a system of licenses to cut back excess capacity and to improve the use of fleet capacity is unclear presented. If we are talking only about the right to fish, the system will not improve the current system. If it is a individual quote system at EEC-level it could be a violation of the principle of subsidiarity. Also the introduction of an individual quota system can only be succesful if it is an integrated part of the regulation system of the single member state. But EEC could support the implementation of individual quota systems in member states.

Finally, a warning. The report strongly states that the reduction of the fleet capacity and segmentation of the fleet are of great importance in solving the crisis in the fishery. It may be a wrong recommendation as a general fleet reduction may create undercapacity in some fisheries. On the other hand a segmentation of the fleet reduces the flexibility of the fleet. Along with fleet reduction there will be a need for other measures but segmentation is in my view a wrong measure, as it will give an inoptimal use of the fleet.

An economist will always suggest economic measures.

Finally, the report emphasizes the important of increasing use of biological, technical and economic research as the basis for management. I'm sure all of us working in fisheries economics can support that proposal but also that we feel that economic analyses in the past have played a second role and that this could be one of the reasons for the insufficient management over the last decade. Of course, reasons for not having used fisheries economics can be many but perhaps the results have not been applicable or have been to close to the political circle.

However the use of basic bioeconomic findings on management will significantly change the explotation pattern, improve the profitability of the fleet and reduce the need for EEC and/or govermental financial support.

# The Fisheries Structural Policy on the Horizon of the Year "2000"

**Emilio Mastracchio**

Commission of the European Communities, Director Directorate-General for Fisheries,
rue de la Loi 2000, B-1049 Bruxelles, Belgique

## 1. INTRODUCTION

My purpose today is to address you on structures within the common fisheries policy.

I propose to present an outline of the policy under the following headings :

i) role and evolution of structures policy,

ii) new concepts and approaches to :

- the fishing fleet,
- aquaculture,
- processing and marketing of the fish,
- the role of fisheries in regional development.

## 2. ROLE AND EVOLUTION OF STRUCTURAL POLICY

Structural policy in the fisheries sector is an integral part of the common fisheries policy. Its main aim is to promote the maintenance of a community fishing fleet which is in equilibrium with available fish resources thereby ensuring that the industry can :

- face up to international competition,
- provide the standard of living for those dependant on fishing,
- guarantee reasonable prices for customer

The institutional objectives are consistant with those laid down in the article 39 of the treaty and establish the basis for policy objectives which are fixed from time to time.

The specific objectives for structural policy now are to :

- control fishing effort,
- ensure maximum financial support for the various measures in operation and particularly those aimed at achieving effort reduction,
- increase the contribution of the fishing industry to the integrated development of regions dependent on the fisheries.

When the common fisheries policy was introduced in 1983, a more comprehensive structural policy was also adopted in parallel [1]. This included the introduction of multiannual guidance programmes which created a framework within which the capacity targets for restructuring the fleet were fixed and the development of aqualculture took place.

Structural policy was extended in a revised Regulation in 1986[2] and multiannual guidance programmes for the fishing fleet in particular were improved by fixing annual targets for fleet capacity reduction to be achieved by 1991 in an atttempt to reverse a trend towards overcapacity in the Community fleet.

The council adopted further amendments to the regulation in 1990 [3] in order to extend certain structural measures to small-scale fisheries and to introduce measures to support the reorientation of fishing activities. These measures reinforced the existing arrangements for permanent cessation of fishing and joint ventures. Two new measures were introduced to accomodate redeployment of vessels outside the Community and for the arrangement of joint entreprises.

The purpose of these amendement was mainly to facilitate an appreciable reduction in fishing effort more rapidly than previously envisaged by supplementing and improving existing measures.

Despite the emphasis on the fishing fleet which was necessary due to the emerging problem of overcapicity and excessive fishing effort, the processing and marketing of fish continued to be supported from 1977 to 1989 under Reg (EEC) n° 355/77 [4]. The main aim of this regulation was to rationalize and develop the sector. It was replaced in 1990 by Reg (EEC) n° 4042/89 [5] which has the same objectives as the previous Regulation, but stresses more modernization and innovation.

## 3. THE FISHING FLEET

### *3.1 Fleet overcapacity*

Nothwithstanding the comprehensive range of measures introduced, fleet overcapacity remains one of the main obstacles to the rational development of the common fisheries policy and represents a threat to the economic welfare of fishing communities. It forces fishing activity to unsustainable levels also and makes it difficult to carry out the stock management objectives of the CFP.

In reporting to the Council in December 1990 [6], the Commission underlined, once again, the problem of overcapacity in the community fleet and stressed the importance of taking initiatives to solve the problems. This gave rise to a debate on the ways and means of improving policy, and arising from this debate new approaches and concepts have been introduced to improve the situation as rapidly as possible.

5. OJ N° L 388, 30.12.1989, p. 1.
6. SEC (90) 2244 final of december 1990.

*3.2 Measurement of fishing effort and segmentation of the fleet*

The Commision was particularly anxious to move toward the measurement of the fishing effort. Reporting again to the council in December 1991 in the so called "1991-Report"[7] , the Commision underlined further the potential crisis arising from overfishing.

After benefiting from these discussions a new generation of multiannual guidance programmes are being developed. These new programmes will be innovative and involve segmentation of the fleets and a framework within which the fishing effort of the different fleets must envolve over the period of the programmes in relation to the state of the fish stocks. The objectives will allow the adjustment of the size of the fishing fleets in every Member State to levels compatible with those of the fish stocks they exploit. A further new element will be the level of reduction required.

The objectives can be achieved by reductions in both capacity and activity, but the reduction in capacity must be predominant.

*3.3 The fishing vessel register of the Community*

Concurrent with these developments, the commission has also been engaged with the Member States in the establishment of a Community register of fishing vessels [8], which will be in the future the main instrument for monitoring the progress of multinannual guidance programmes.

It was established in 1989 and includes details of fishing vessels provided by Member Sates. It provides a description of the vessels and a history of events in relation to each vessel.

It is up-dated continously to reflect changes in the status of individual vessels Member States. At present, a programme is being implemented ; it aims at developing a procedure to permit the monitoring of fishing effort. The system also porvides for Member States to have access to their own data ; this facility is already available to certain Member States and will be shortly in operation in all Member States.

*3.4 Financial support for measures in force*

Despite serious problems of overcapacity in the fishing fleet, the Commission has continued to provide finance, within the framework of Reg (EEC) n° 4028/86, principally for measures aimed at reducing capacity and improving shore and fleet infrastructure.

The measures aimed at directly reducing fleet capacity in Community waters are adjustment of capacity, exploratory fishing, joint ventures, redeployment of vessels and joint entreprises. Fleet improvement is mainly affected by financing modernization and construction projects to a limited extent only.

The financial provisions for these measures show a substantial increase in the overall budget from 178.6 MECU in 1990 to 241.0 MECU in 1991. This demonstrates the importance which the commission places on achieving progress in this sector.

Further, the importance placed on reducing fleet capacity is demonstrated by the increase in the proportion of the total provision on adjustment of capacity and reorientation measures which accounted for 30 % of the total in 1990 while this increased to 63 % in 1991. During the same period, the provision for construction as a proportion of the total provision fell from 24,7 % in 1990 to 3,2 % in 1991.

Modernization projects accounted for 14,7 % of total provision in 1990, 8,8 % in 1991 and 5,3 % in 1992.

The actual budget allocated to the various measures is indicated in the table 1.

7. SEC (91) 2288 final of 18 december 1991.
8. OJ N° L 20, 25.01.1989, p. 5.

## 4. AQUACULTURE STRUCTURAL POLICY

Aquaculture development is also financed under Reg (EEC) n° 4028/86. This sector has grown rapidly in recent years and marine aquaculture is the sector which offers the best prospects for substantial healthy growth in the future. Aquaculture is helping to reduce the Community's trade deficit in fisheries products, and offers a means of stimulating economic development in coastal and rural areas, often in areas where other alternatives are lacking.

The community has played a key role in the process of the development of marine aqualculture through its structural instruments. This instrument provides aid for construction and modernization projects in aquaculture.

Public support for aquaculture is not entering a new phase and the attention should be focused not only on more increases in production. In the future, due to the increasing concern for environment, aquaculture will form an integral part of the economic development of coastal areas.

## 5. PROCESSING AND MARKETING OF FISHERIES PRODUCTS

Improving processing and marketing of fishery and aquaculture products is also an important component of structural policy. It is, up to now, the only element of structural policy in the fisheries sector which is included in the structural funds.

This measure was included in the new framework of the structural funds in 1989 and is operational since the begining of January 1991. It is, in common with Agriculture, included in objectives 5a. The aim is to spend up the adjusment of structures in order to create a viable industry able to compete in an open market inside the Community and with third countries.

The regulation provides financial assistance in the form of capital grants (roughly 220 MIO Ecus for three years (1991-1993) to promote and encourage investments in processing and marketing of fishery and aquaculture products from landing to wholesale markets.

Processing on board of fishing vessels, the retail sector and the fishemeal sector are excluded.

The main priorities are :

- improve hygiene conditions in order to reach the standards established by the hygiene directives adopted by the Council in July 1991,
- improve product quality,
- encourage innovation, new processing techniques.

The mechanism of this financial assistance is the same as that applied in the framework of other structural funds : (Regional Fund, FEOGA, Social Fund). That is to say they are based on subsidiarity, partnership and programming.

There are three stages :

i) Each Member State is required to establish and submit a sectoral plan indicating the strength and weakness of the sector. The programme for investment promoting is outlined and the level of finance required is indicated.

ii) The commission prepares a reply to each plan (a Community support framework), in collaboration with the Member State. In the CSF, the priorities for intervention and the level of financial assistance (Community and national) are fixed for three years. It is a System of co-financing.

iii) Based on the content of the CSF, the Member States establish operational programmes made up of the different individual investment projects. These programmes are adopted by the commission after checking that the projects are in conformity with the priorities and the financial allocations of the CSF.

The implementation of the programme is the task of monitoring Committees chaired by the Member States and, of course, the Commission participants. Decisions are taken by Member States and the Commission

## 6. INTEGRATION OF FISHERIES INTO STRUCTURAL POLICY

The integration of fisheries into structural policy has two objectives :

i) The rationalization of structural measures, which are at present partly outside and partly inside of the structural funds. In 1993, 83 % of the fisheries structural budget will continue to be managed like the Regional Fund and the Social Fund were before 1988. By the beginning of 1994, however, all of the fisheries structural measures will be subject to the rules of operation of the structural funds. By way of analogy with agricultural measures, fisheries structural measures will be included in objectives 5a which will have two distinct aspects :

- agricultural (FEOGA)
- fisheries (FIGF)

The rationalization will have both a legal and financial basis. A draft Regulation has been prepared corresponding to the regulations for the Regional Fund, Social Fund and FEOGA orientation and the fusion of existing financial instrument for guidance of fisheries is proposed (FIGF) so that the Community can serve better the integrated development of coastal regions.

ii) The financing of accompanying socio-economic measures in order to compensate for the negative effects, in coastal regions, of restructuring of the fisheries sector is typically a matter for the regional Fund and the Social Fund. The Edinburgh Council did not support the proposition of a new objective 6 and considered that it was more appropriate to give all the attention needed to regions dependent on fisheries within the framework of the relevent existing objectives. A limited number of areas dependent on fisheries do not as yet have access to structural funds through objectives 1, 2 and 5b. To fill this gap, the Commission has proposed to make the eligibility criteria for objectives 2 and 5b more flexible.

This outline indicates the direction and the achievements today of structural policy, within the framework of the overall objectives of the Common Fisheries Policy (CFP), should be to :

- contribute to the rationalization and the economic soundness of the sector,
- promote investments in the areas of quality product, harbour infrastructure, etc..
- smooth out the effects of the restructuring of the fishing sector,
- decrease the socio-economic costs of the necessary adjustments,
- contribute to the development of the fishing dependent regions.

With respect to the general trend granting of aid of the various structural measures the following can be said :

- With regard to the granting of aid for new constructions of fishing vessels, there is a strong decrease.
- Parallel to this, there is a considerable increase in the amounts for adjustments of capacity.

These two developments reflect the Commision's attitude to continue and to accentuate its policy of decreasing further more the fishing capacity by giving priority to the adjustment of capacity, and definitive withdrawal has been supplemented in 1991 and 1992 by putting the emphasis of the reorientation measures on the establishment of joint entreprises ("sociétés mixtes").

**TABLE 1**
**BUDGETARY COMMITMENTS 1990–1991.**

| MEASURE | 1990 | 1991 |
|---|---|---|
| REG - 4028/86 | | |
| Reorientation | 4,9 | 31,5 |
| - *exploratory fishing* | *3,5* | *1,8* |
| - *redeployment* | - | *0,5* |
| - *associations temporaires* | *1,4* | *1,7* |
| - *sociétés mixtes* | - | *27,5* |
| Modernization | 26,2 | 21,4 |
| Construction | 44,2 | 7,8 |
| Adjustment of capacity | 49,8 | 120,4 |
| - *Definite* | *32,0* | *119,6* |
| - *Temporary* | *17,8* | *0,8* |
| Adjustment of capacity for ex-GDR | - | 5,7 |
| Fishing port equipment | 4,8 | 7,0 |
| Special measures | 1,2 | 2,5 |
| Market research | 0,5 | 0,4 |
| Aquaculture | 47,0 | 39,3 |
| Petite pêche | - | 5,0 |
| TOTAL R. 4028/86 | 178,6 | 241,0 |

In summarizing the above figures, it can be noted that there has been a considerable increase of the yearly budgetary amounts from 178,6 MIO (1990) to 241 MIO Ecu in 1991 and further to 278,5 MIO Ecu in 1992.

# Définition et mise en œuvre de la Politique Commune des Pêches de la CEE : le point de vue d'un Etat membre

**Claude Bernet**

Directeur des Pêches Maritimes et des Cultures Marines, 3 place de Fontenoy, 75007 Paris, France.

## 1. INTRODUCTION

En m'efforçant d'échapper à la subjectivité, qui consisterait à développer seulement le point de vue français, je traiterai successivement :

i) des modes d'élaboration de la PCP

ii) des critiques auxquelles elle est confrontée

iii) des attentes essentielles des Etats membres

## 2. LA PCP (COMME TOUTE POLITIQUE COMMUNAUTAIRE) EST L'OEUVRE CONJOINTE DE LA COMMISSION ET DES ETATS MEMBRES, ET LE RÉSULTAT D'UN PERMANENT COMPROMIS.

### *2.1 L'articulation des compétences au sein de la CEE*

La Commission a le monopole de la proposition,

Les Etats ont le monopole de la décision (en Conseil),

Toutes les autres institutions (dont le Parlement) ont un rôle consultatif.

### *2.2 Toute décision est donc le fruit de négociations et de compromis*

Rien ne peut se faire sans une initiative de la Commission, précédée ou suivie de contacts entre les Etats et la Commission sur les projets initiaux et des versions amendées.

Toute décision exige une majorité qualifiée, difficile à atteindre (53 voix sur 76), d'où des négociations entre Etats membres et Commission.

*2.3 La PCP est-elle marquée par cette nécessité de compromis ?*

Evidemment oui, ce dont témoigne :

- la longueur du processus de décision (ex. Règlement Mesures Techniques de 1991).
- la nécessaire "modération" des mesures finalement adoptées,
- leur "lisibilité" parfois insuffisante,

mais il faut nuancer ces aspects critiques :

- quand on regarde, à travers le monde, les politiques des pêches mises en oeuvre par des Etats qui décident seuls, on n'a pas toujours l'impression qu'elles sont plus efficaces,
- la construction européenne repose sur l'idée de patiente conciliation des intérêts nationaux pour dégager un intérêt général européen. Chaque fois que l'on veut aller trop vite, on risque un dérapage.

## 3. CRITIQUER LA PCP EST FACILE, LA CONDUIRE EST PLUS DIFFICILE

*3.1 On trouve plus facilement des critiques que des éloges*

Les avantages apportés par la PCP sont considérés comme des acquis, dont la valeur n'est pas réellement estimée et ressentie :

- ouverture mutuelle des zones de pêche (mer communautaire),
- grand marché : pour les producteurs, de plus larges perspectives de commercialisation,
- pour les consommateurs, l'accès à des produits diversifiés et de qualité,
- interventions financières européennes.

Les contraintes sont, au contraire, très sensibles, notamment toutes celles qui visent à résoudre le problème de l'excès de capacité par rapport à la ressource.

*3.2 La construction de la PCP est rendue difficile par des raisons structurelles et conjoncturelles, et aussi par le contexte international.*

Des raisons structurelles, que l'on retrouve dans d'autres politiques communautaires :

- diversité et même rivalité des pêches européennes. Même si ce n'est pas exprimé aussi crûment, les pêcheurs rêvent de conquérir l'espace et les marchés des autres, en défendant leur espace et leur marché.
- diversité des structures et des cultures, qui rend malaisée l'application de mesures uniformes quelques exemples : diversité des systèmes juridiques (ex : sanctions administratives et judiciaires), caractère fédéral de certains Etats membres, structures économiques diverses des secteurs de pêche (ex : pê che industrielle/artisanale ; pêche pour la consommation humaine/pêche minotière).

Une raison conjoncturelle : la crise de la pêche

Une politique des pêches, il y a 10 ou 20 ans, consistait à allouer généreusement des moyens publics au secteur des pêches, pour favoriser son développement.

Partout dans le Monde développé, elle consiste aujourd'hui à limiter l'effort de pêche pour éviter que le progrès technologique ne compromette la ressource, ce qui entraîne une inévitable impopularité, encore accrue par le sentiment d'inégalité dans les efforts.

Enfin le contexte international ne contribue pas à faciliter la PCP :

- accès aux ressources : un monde de plus en plus fermé (les Accords de pêche).
- accès aux marchés : une Communauté de plus en plus ouverte, et marquée par le déclin de la notion de préférence communautaire.

## 4. LES ATTENTES DES ETATS MEMBRES À L'ÉGARD DE LA PCP

L'attente principale est évidemment l'efficacité au meilleur coût : encore faut-il analyser comment les Etats membres apprécient efficacité et coût.

### *4.1 L'efficacité*

C'est d'abord le rétablissement de la santé économique des entreprises, par l'équilibre ressource/capacité (certes il y a d'autres critères, mais celui-ci est primordial).

### *4.2 Au meilleur coût*

- coût financier, bien sûr : le budget de la Communauté n'est autre que le produit des contributions des Etats membres (d'où des différences d'appréciation entre Etats selon leurs contributions)

- coût humain et social

Les Etats sont "au contact" des Professionnels (et des Elus) : ils sont donc naturellement sensibles à leur état d'esprit. Ils ont aussi la charge (première) des conséquences sociales et régionales, aussi bien en termes financiers qu'en termes humains, sociaux et politiques.

La PCP doit être comprise, et autant que possible, admise en attendant d'être, pourquoi pas, soutenue et portée par le secteur. Pour se rapprocher de cet objectif, la PCP doit répondre à plusieurs conditions, classées ici par ordre croissant de difficulté :

- elle doit être progressive et non brutale : un bon exemple a été la solution au problème des mesures techniques en octobre 1991,
- aussi claire et simple que possible : besoin d'explications face à la complexité inhérente à la pêche,
- incitative chaque fois que possible,
- dégagée de considérations étrangères à la pêche,
- cohérente dans ses aspects ressources/structures/marchés,
- adaptable aux diversités,
- tout en étant juste et équitable, ce qui est un dilemme permanent.

La PCP est très loin de satisfaire ces conditions. Il faut donc beaucoup travailler...

# The Relationship between Fleet Capacity and Fishing Effort

**Gregory Valatin**

Sea Fish Industry Authority, 10 Young Street Edinburgh EH2 4JQ United Kingdom

ABSTRACT

*An integral part of the fisheries management policies currently being pursued within the European Community are the structural regulations and targets aimed at controlling fleet capacity. Constraining fleet capacity is usually viewed as essential in order to limit fishing effort and thus fishing mortality. Analyses of variability in fishing effort of vessels in the U.K. fishing fleet are presented, together with evidence from other sources such as a survey of skippers of U.K. fishing vessels. The implications of these results for relating fishing effort to fleet capacity are then outlined.*

## 1. INTRODUCTION

With many important fish stocks in a state of decline, it has become commonplace to hear the view that there are "too many boats and too few fish". Certainly judging by the current state of fish stocks it is evident that at current levels of utilization, a serious mismatch exists between fleet capacity and available fishing opportunities. Therefore in order to halt further decline, this mismatch is a matter which needs to be urgently addressed.

The "obvious" solution is to reduce fishing effort and fleet capacity by restructuring the fleet, using measures such as paying decommissioning grants for boats to leave the industry. In order for such structural policies to be successful in improving the state of a fishery, it is likely that a permanent reduction in fishing effort will be required. This implies that it is likely to be necessary to control both capacity and its utilization, in order to ensure that capacity reductions are not offset by remaining vessels expanding their effort, such that the effort of the fleet as a whole is unchanged.

On closer inspection however, it appears by no means a simple task to quantify how fleet capacity is translated into effort and catches of the particular stocks of interest.

It must be stressed that the following discussion represents a synthesis of ideas at an early stage of evolution. Views expressed are the author's own, and do not necessarily reflect those of any of his colleagues in the Fishery Economics Research Unit.

## 2. FISHING EFFORT AND FLEET CAPACITY

According to the European Commission's recent report (EC-D6XIV, 1991) to the Council and European Parliament on the Common Fisheries Policy (CFP), fish stocks in Community waters are generally "in danger" as a result of over-fishing. As a consequence, the report argues that "substantial" reductions in fishing effort and capacity are now required, with a major obstacle to the rational evolution ofthe CFP being fleet overcapacity. Thus the establishment of "a fleet adapted to available resources" has become a major emphasis in creating the CFP's stated aim of "sustainable fishing".

Before examining the links between effort and capacity, it is helpful to clarify what is to be understood by these terms. When the primary interest is to consider the effects of fishing on particular fish stocks, the most relevant concept is effective (or "output") fishing effort, which measures fishing mortality on particular stocks. Effective effort is usually defined in terms of the proportion of a fish population taken by fishing, or conversely, which survive fishing. Thus effective effort may be thought of in terms of the definition often used for fishing mortality (Cunningham *et al.*, 1985) of :

Effective effort (F) = -natural log (proportion of fish surviving fishing)

In exploring the links between fleet structure and catch, nominal (or "input") fishing effort, provides an important intermediate concept, which is generally more directly related to fleet capacity than is effective effort. It is usually defined in terms of the time and fishing power exerted by the fleet, although it may also be thought of in terms of the area of sea screened in the course of fishing.

Nominal effort is often taken to include only that time that vessels actually spend fishing (e.g. hours fishing), this being most directly related to effective effort. However, ancillary activities such as the time needed to steam between grounds and port, and in searching for fish, are also of considerable importance in determining the effectiveness of a fleet to catch fish, by limiting the time available for fishing. Thus for example, for any period of time and stock level, the further away from fishing ports that fish are located, the more steaming time necessary, and therefore the less time available for fishing and the less fish the fleet could expect to catch (ceteris paribus). While time spent on ancillary activities is important in influencing a fleet's catch, as well as affecting costs and therefore the returns from fishing, it is obviously less easy to relate nominal effort based on such measures as days at sea to effective effort, than it is with those based on measures such as hours fishing.

Where fish are uniformly distributed, nominal effort (in terms of time actually spent fishing) and effective effort are usually closely related for any given size of stock. The relationship between these two concepts being typically characterized by the multiplication by a catchability coefficient (Cunningham *et al.*, 1985), such that :

Effective effort (F) = catchability coefficient (q) x nominal effort (f)

In addition to the problems mentioned above due to ancillary activities aspect of nominal effort, even in the narrow sense of time spent fishing, aggregate nominal effort often cannot be easily translated into overall fishing mortality. Aggregation problems arise as a consequence of differing stock concentrations between grounds, such that different catches are taken in different grounds using the same nominal effort. Of course differences in catch rates between grounds would be of no consequence if they were due solely to purely random factors. However, the existence of such differences can also result from differences in the costs and risks associated with fishing different grounds. Therefore, the distinction between the effective and nominal effort is of importance.

One further effort concept, which by definition is most directly related to fleet capacity, is that of "capacity utilization", which refers to the extent to which fleet capacity is used. For simplicity, this definition of effort will be used in the remaining sections of this paper. The question of how capacity is used will be returned to after first considering how capacity is itself defined and measured.

Fleet capacity is generally defined as a fleet's capability to catch fish. For administrative purposes, capacity is usually defined in terms of an aggregate of those physical attributes of the vessels in the fleet, which are considered important determinants the fleet's ability to catch fish. For example, the European Community's Multi-Annual Guidance

Programme uses aggregate tonnage and aggregate engine power as measures of fleet capacity. In the U.K. a system of "capacity units" is used, which comprises an aggregate of vessel length, breadth and engine power (Tucker, 1988), such that :

$$\text{vessel capacity units} = \text{length [M]} \times \text{breadth [M]} + 0.45 \times \text{power [KW]}.$$

There can be little doubt that such measures of capacity do indeed help to determine an upper bound to a fleets' ability to catch fish. However, there are several important considerations. These fall into 4 categories :

i) Fleet & fishery heterogeneity

ii) Measurement & aggregation of vessel capacity

iii) Investment dynamics & "Capital Stuffing"

iv) Effective control of capacity & associated costs

Obviously, in order to decide what a fleet's capability to catch is, it is necessary to decide which species and stocks are to be included in assessing this capability. On one hand for simplicity, it is far easier to use aggregate measures of fleet capacity across many fisheries. Such measures also have the advantage that they recognize that one of the critical features of many fishing enterprises is adaptability and their ability to switch fisheries. However on the other, the narrower the range of species and stocks included in defining catch capability, the easier it is likely to prove to effectively manage particular fish stocks. For example, it seems unlikely that managing cod stocks on the basis of capacity measures which include vessels potting for lobsters, or catching sharks, would prove to be very effective.

Following on from the definitional specifics of fleet and species/stocks, the question arises as to which are the characteristics of the fleet that are significant in determining its catching capability. For simplicity, it is easiest to consider initially the capability of an individual vessel, before considering that of the fleet as a whole.

Most obviously the capability of a fishing vessel to catch fish will depend upon its size, engine power, and the type and technical efficiency of gear and other equipment (such as fishfinders) employed. The skill with which the vessel is operated by its skipper and crew, and crew size may also be of importance.

Of course, a vessel's ability to catch fish also depends upon the availability of fish to be caught. For most species this will depend largely on the stock size, although for pelagic stocks, the ability of a vessel to catch fish may be far less dependent on the size of the stock (subject of course to the stock being above a minimum threshold level), and depend more upon seasonal migration patterns.

In any year, the capability of a vessel to catch fish will also depend upon the amount of time that is available for actually fishing. Spatial factors, such as the distance from port of fishing grounds, environmental factors, such as the extent to which tides and heavy seas prevent fishing, and operational factors, such as the amount of time needed for vessel repairs and provisioning, may all be of importance.

Even crewing arrangements and the scope of harbour and onshore facilities servicing the fleet's operations could be expected to be of importance in determining the amount of time available for fishing by affecting the turn-around time needed between trips. For example, the capability to catch fish of vessels based at deep water harbours with sea access unrestricted by tidal, or other sea conditions, could be expected to be greater than otherwise identical vessels based at harbours where boats are frequently unable to get out of the harbour (ceteris paribus). Thus, even harbour improvement schemes may result in an increase in fishing capacity.

However, supposing that the capacity of each vessel in the fleet is adequately assessed, consideration of the Fallacy of Composition suggests caution in assuming that even in the short-run, the capability of the fleet as a whole to catch fish is necessarily equal to the sum of individual vessel capacities. For example, this would be very unlikely to be true if crowding externalities were significant, or conversely, if there was significant information transfer between skippers regarding current stock locations and differences in catch rates between grounds.

Indeed the frequently used definition of effective effort (see above), by implicitly assuming diminishing returns to nominal effort, appears to imply that fleet capacity is less than the sum of individual vessel capacities. Or conversely, that the capability of an individual vessel to catch fish is inversely proportional to the total effort of the fleet and therefore (ceteris paribus) to the size of the fleet.

In addition to the measurement and aggregation problems alluded to, in order to effectively control capacity, it is useful not just to consider how to assess fleet capacity in a static sense, but also to examine the dynamic forces which normally work to influence investment and therefore change capacity. Although comprehensive analysis of this complex area is outwith the scope of this paper, at a very simple level, economic theory suggests that there is a tendency for fishing operations (and thus capacity) to expand until the returns from fishing are equal to opportunity costs. This is due in large part to "The Prisoners' dilemma" aspect of competitive use of a common resource, whereby individual fishermen attempt to increase their own returns even though this implies lower returns for other fishermen. Where catches are controlled, such expansion is often termed "capital stuffing" and frequently results in the dissipation of economic rent despite attempts to regulate fisheries and maintain profitability. "Overcapacity" in terms of fleet capacity being greater than catching opportunities, therefore is usually in large part due to economic forces, although other factors such as investment lags and stock depletion may also be of importance.

Of course the causes of overcapacity may be of mere academic interest to fisheries managers so long as it is possible to adequately control capacity. Certainly in terms of administrative practicality, it is a simple enough exercise to control the number of vessels in the fleet through a licensing scheme, and controlling the size of vessels may pose relatively few problems either. (Although even here problems may arise, such as that encountered in the UK where vessel size was controlled on the basis of registered length, and circumvented by increases in overall length).

However, controlling other important aspects, such as the technical efficiency of operation, or the skill with which a vessel is operated, are likely to prove far more problematic. Controlling the use of increasingly effective electronic gadgetry, such as fish-finders for example, does not appear such an easy administrative task. Increasing technical efficiency is especially difficult to measure and control as it is largely driven by a continuous process of innovation, as fishermen seek new ways of increasing their own catches and returns from fishing. As such, it also represents the element which is likely to expand most rapidly if controls are placed on other aspects of capacity.

Supposing that administrative problems associated with controlling capacity are solved, what then of the costs entailed ? Obviously there are administration and enforcement costs entailed in any management regime, and the more difficult an aspect of capacity to control, the higher the associated administrative costs could be expected to be.

Perhaps less obviously, to the extent that regulations reduce the flexibility of fishing operations, there is an associated cost imposed on the existing fleet. Also, to the extent that a new regulation erects a barrier to new entrants wishing to operate fishing vessels, there would be an associated increase the costs affecting both existing vessel owners wishing to upgrade their vessels, as well as to those wishing to join the fleet subsequently.

For example, controlling capacity might be expected to result in an inflationary impact on prices paid for vessels in the fleet and their associated licences, due to the right to fish acquiring a value in itself and being capitalized in higher vessel prices. While such a price increase would represent a windfall gain to existing vessel owners, it would necessarily make becoming a fishing vessel operator more costly for subsequent entrants. Of course, there might also be expected to be some more immediate gains for the remaining fishermen too, as any reductions in fleet capacity would be expected to increase the profitability of the vessels remaining in the fleet.

New regulations may have other important distributional impacts too. Although all fishermen are covered by a particular regulation, some fishermen may well be more adversely affected than others, thereby introducing distortions into the manner in which the fishing industry operates due to the differences in the costs imposed.

Fishermen often adapt their fishing operations to new regulations. Thus for example, it is quite possible that the cost implications for the fleet of controlling capacity may also have considerable bearing on capacity utilization.

What then determines capacity utilization ? It would certainly be incorrect to assume that vessels of a certain size, engine power and gear engaged in a particular fishery may quite easily be mapped onto taking a particular level of catch, thereby assuming that other factors, or even the skipper, and crew are of no consequence.

Despite the obvious generalization that fishermen go fishing to catch fish, there appears to be very little evidence that volume of catch is the main concern. On the contrary, there is evidence that this is not the case (Valatin, 1991a), and therefore it would be very surprising if capacity utilization was purely a function of capacity.

In a recent survey carried out by the Fishery Economics Research Unit (Valatin, 1991a), only one of the skippers of 227 UK fishing vessels interviewed said that his primary objective in going fishing is to catch as many fish as possible. Just over two-fifths (41 %) said that they aim for maximum, or adequate profits, while over one quarter (28 %) said that their

main objective is grossings (i.e. total revenue). Such findings underlie the assertion that fishing is indeed an economic activity and therefore that the determinants of capacity utilization, as well as of capacity itself, need to be sought in terms of economic factors, rather than purely in terms of the physical characteristics of fishing vessels.

To some extent the measure of capacity used in the UK does recognize this, as the capacity unit formulation was based mainly upon comparing revenue earned, rather than vessel catches (Tucker, 1988), However, once the importance of economic factors is recognized, it obviously becomes far more complex to identify what "a fleet adapted to available resources" would comprise of, than would be the case were the catches of the stocks of interest directly proportional to vessel capacity for any given stock level. For example, crewing arrangements may be of critical importance in determining capacity utilization.

The apparent diversity of skippers is also of interest as it implies not only that capacity may change as a result of changes in the skill with which a vessel is operated, but also capacity utilization may change as a result of a change in objectives, or attitudes of the skipper. Such changes may be most common with a change of skipper, but also as the results of the skippers survey showed, it is not uncommon for a particular skipper's objectives and attitudes to fishing to alter over time too. For example, a decision which obviously affects capacity utilization, is whether to work a vessel full-time, or part-time.

However, fleets seldom operate at full capacity. Indeed, it may be most efficient for a fleet to concentrate operations during seasons when fish are easiest to catch and profitability is high, thereby maintaining some degree of "over-capacity" at other times.

The results of a recent study of the activity levels of fishing vessels carried out by Seafish (Valatin, 1991b) also suggests that trying to identify a stable relationship between capacity and its utilization may be problematic. Although due to data availability and confidentiality constraints, the definition of capacity used was more limited than it might otherwise have been, the results did nonetheless suggest that substantial variation in capacity utilization exists between similar vessels.

In that study, days at sea data was analysed for all vessels in the English and Welsh fleet making landings declarations during 1987, with vessels being classified by length (16 groups), fishing method (9 groups), year built (10 groups) and base port/region (14 groups). The mean number of days at sea during 1987 was found to be 106, with a standard deviation of 78 days. (Vessels built during 1986-87, many of which would not have been fully operational for a full year in 1987, were excluded from the analysis).

The variability in the activity of vessels resulting from these differences was estimated using multiple classification analysis. The results showed the length, age, method and base port/region classifications all to be significant in explaining the variance in days at sea, although significant interaction effects were found to exist.

In order to examine the activity levels of similar vessels, data relating to the 403 vessels in the categories of at least five vessels was retained for further analysis. The distribution of days at sea of these vessels had the same mean and standard deviation (of 106 and 78 days respectively) to that of the fleet as a whole, suggesting that it formed a representative sample. A summary of the variability in days at sea for those vessel categories containing at least 10 vessels is shown in Table 1.

Analysis using a composite length, age, method and base port/region classification suggested about two thirds of the variability in effort was associated with such differences. Thus the results implied that on average, 36 days at sea out of the mean of 106 days were unassociated with differences in length, method, age and base port/region.

As fleets do not generally operate at full capacity and effort cannot be easily related to capacity, in order to prevent an expansion of effort, it is likely to be necessary to control both capacity and capacity utilization. While the existence of a stable relationship between capacity and its utilization may be argued to be of no consequence for fisheries management where it is also proposed to directly regulate capacity utilization, further questions then arise concerning both how capacity utilization may be effectively regulated and also at what cost.

One of the more obvious methods of regulating capacity utilization is to restrict fishing activities on the basis of each individual vessel's level of capacity utilization in the recent past (e.g. based on the number of days a vessel fished during a specified reference period). However, in a similar manner to using catch records as the basis for future quota allocations, such regulatory methods can have the perverse effect of increasing capacity utilization and nominal effort by discouraging vessels from reducing their activity. Thus, maintaining, or increasing the vessel's activity record may

become an objective in itself, as fishermen try to maximize their future opportunities and the associated resale value of their boat, or fishing licence. In fact just such reasoning appears to have been influential on some of the one sixth (15 %) of the skippers interviewed in the FERU survey who said that their primary objective is to take their quota.

Certainly, as with any regulation, regulation of capacity utilization would imply further administrative costs, as well as increased fishing costs due to loss of flexibility. In addition to the more tangible costs, to the extent that a new regulation reduces a fishermen's flexibility of operations, they may also result in significant costs in terms of reducing any non-pecuniary benefits associated with participation in fishing. For example, the vast majority (89 %) of skippers interviewed in the FERU survey said that they enjoyed fishing, with "freedom" and "independence" being amongst the factors most frequently mentioned as particularly enjoyable.

## 3. CONCLUSIONS

Current scientific evidence points to the serious condition of many of the fish stocks in European Community waters and this is a cause of urgent concern. The parlous state of fish stocks is attributed to a mismatch between fleet capacity and fishing opportunities such that there are "too many boats and too few fish".

The current trend in fisheries management is to solve this problem by using structural policies to reduce fleet capacity and effort. Some of the important considerations entailed in such an approach have been highlighted. It is hoped that the exploration presented may contribute to a fuller understanding of the implications of current trends in fisheries management.

However, it ought to be stressed that the considerations highlighted should not by themselves be regarded as implying that the current approach to fisheries management is either especially appropriate, or inappropriate. Such judgements are generally based upon a comparison of alternatives. Such a comparison is outwith the scope of this paper.

# The European Community Decision Making Process : Fisheries with Reference to the Role of the European Parliament

**David I.A. Steel** *

European Parliament Rue Belliard, 97-113 B-1047 Bruxelles, Belgique

ABSTRACT

*Fisheries, although a relatively small industry at the European level is nevertheless a major Community policy. This in itself affects the way in which fisheries decisions are reached at the Community level. The paper focuses on the decision-making process within the E.C. at a time when the Community is undertaking a review of the basic conservation policy, when it is shaping up for the Single Market and when the relationships between the institutions as a whole are under consideration. Given the importance of 1992 to fisheries, the paper first describes the decision - making process with particular reference to the fisheries sector. The paper then goes on to examine the role of the European Parliament in the decision - making process. It will consider both the influences brought to bear on the Parliament and the influence which the Parliament can exert on other Community institutions. The paper also considers how Parliament's influence may be changing over time.*

*The paper draws on a number of case studies which are of interest both from the political standpoint and from the broader socioeconomic view such as changes to conservation legislation, the review of the CFP and the market for salmon. Wherever relevant, the examples are used to show how fisheries policy decisions are taken within a broader strategic framework.*

## 1. INTRODUCTION

1992 is a watershed year for the European Community. It marks the completion of the Single Market. Progress is also under way to extend the scope of the Single Market to the Member States of the European Free Trade Association. EC

* The views are those of the author alone

Member States are now progressing with the ratification of the Maastricht Treaty aimed at achieving economic, monetary and political union. The European Commission has published financial proposals aimed at providing a financial framework for the next five years. Negotiations are to begin shortly on further enlargement of the Community.

After agriculture, fisheries is the industry most subject to Community policy. Together the Community is one of the world's major fisheries powers. It is the world's largest trader in fish. Recent developments in important commodities such as tuna, salmon and herring have important implications for fish trade and policy. The Community has fisheries agreements with over twenty countries. 1992 is the year, too, in which the Common Fisheries Policy is up for a ten-year review provided for in the January 1983 policy agreement[1]. While the immediate policy requirements of this review are limited, the European Commission has taken the opportunity afforded by the review of undertaking a thorough going analysis of the Common Fisheries Policy and has put on the table significant ideas for future policy development.

The purpose of the introduction is twofold. On the one hand, it is to suggest that the major themes which are outlined above - notably the European Economic Space, Enlargement of the Community - not only portend a major increase of Community influence but in certain respects are crucially dependent on fisheries questions and secondly that as other themes such as the current review of Community finances and the review of the Common Fisheries Policy are of major importance to the future of the fishing industry, it is an opportune time to examine the decision making process in the European Community, using the Community's fisheries policy as an example.

The paper will focus on the area of the author's own experience, namely the European Parliament, examine a limited number of subject areas of relevance to Members of IIFET and consider the role of the Parliament in the development of policy on the issues covered.

## 2. THE DECISION MAKING PROCESS : THE COMMUNITY FRAMEWORK

Essentially, it is the European Commission, the administration, which makes legislative proposals. The voice of the industry is heard through a fisheries consultative committee and scientific advice is provided through a scientific and technical committee of national experts. The European Parliament (directly elected since 1979) and the Economic and Social Committee (which represents the two sides of industry) give their opinion and the National Governments, operating as the Council of Ministers takes the final legislative decisions. Council fear of protracted annual haggling over fish quotas initially led to the exclusion of the Parliament from consultation over the implementing legislation flowing from the principal conservation legislation of 1983. However, as the European Parliament has grown in influence so it has fought for greater rights, not just of consultation and being able to bring fisheries matters to public attention but also to increase its Parliamentary powers in other directions such as over the Community budget or in relations with third countries.

The increasing status of Members of the European Parliament (MEPs) has also increased their ability to intervene directly with European Commissioners and to use their contacts to bring national Ministers and Commissioners together. These networks have further developed in recent years with at least two MEPs becoming fisheries Ministers in their own countries (Kent Kirk, Denmark and David Curry, UK). Former Ministers have also become involved with fisheries in the European Parliament (Niels Kofoed, Denmark).

While the principal role of the Parliament is to provide a formal opinion on Commission proposals, Parliament can also produce reports under its own initiative and also has various means of bringing matters to the fore through oral and written questioning of the Commission and Council of Ministers and through the debating of urgent resolutions. While it is always difficult to prove direct cause and effect, it can be shown how ideas developed in the Parliament find there way into Commission documents and often directly into Community legislation.

1. Council Regulation 170/83 of 25/1/83 *establishing a community system for the conservation and management of fishery resources. OJ L24 - 27/1/83.*

## 3. THE MAIN ELEMENTS OF THE COMMON FISHERIES POLICY

The Common Fisheries Policy covers the following areas :

i) *policy for the conservation and management of fishery resources*

fixing total allowable catches (TACs) (not in Mediterranean) ; technical conservation measures ;

ii) *market policy*

marketing standards, management through producer organisations, a withdrawal system, external trade policy ;

iii) *surveillance policy*

inspection and monitoring, Community inspectorate and financial help for national monitoring and inspection costs ;

iv) *policy on fishery agreements with third countries*

competence for international affairs since 1976 ;

v) *structural policy*

monitoring of multi-annual guidance programmes and co-financing measures to adjust capacity, modernise the fleet, develop new fisheries and aquaculture, improve shore based facilities ;

vi) *research policy*

since 1987, Community research programmes in the fisheries and aquaculture sector supported by a budget of 30 m ECU in the period 1988-1992.

## 4. FISHERIES IN THE EUROPEAN PARLIAMENT

Over the decade from the enlargement of the Community to the settlement of January 1983 fisheries policy was a focus of Community disharmony centred on the failure of the Council of Ministers to agree a conservation policy. Naturally, in this period fisheries representatives focused their attention and limited financial means on the Council of Ministers. The appointed European Parliament, which had given its opinion on the Commission proposals in 1977, was of little relevance.

In 1979, however, a new democratically elected Parliament was set up. In November a fisheries working group was established with Robert Battersby, MEP for Humberside in England elected Chairman. Over the Parliament's first five years, the 22 Members of the working group established the Parliament as a forum for public debate on fisheries at the European level and established its credibility as an interlocutor with the Commission with a series of reports on the development of a common policy, control and surveillance, the Mediterranean, social aspects of fisheries policy and the development of aquaculture. The Parliament was successful in achieving a separation between agriculture and fisheries in the Community budget, thus allowing a separate fishing policy to develop. During this period, Parliament can take the credit for establishing a Community fisheries inspectorate - a major step forward in Community competence, in drawing attention to the problems of quota hopping, for ensuring a public debate and understanding of the questions related to the further enlargement of the Community, and for focusing attention on the plight of the Atlantic Salmon - leading to the formation of the international body NASCO. The Parliament also established itself as a voice for the peripheral areas dependent on fishing.

In particular, the Parliament was able to stand back from the day to day management of the policy and point the way forward in several policy areas. Slowly, the Parliament began to show itself as the bridge between the fishing industry at the local level and the Community institutions.

During the second legislature from 1984 to 1989, fisheries became a full sub-committee of the European Parliament's agriculture committee.

The main reports of the Committee covered : the fisheries sector and enlargement, structural policy, research, fisheries agreements with third countries, the estimation and management of fish stocks, the common organisation of the market and the fish processing industry. At the end of the period, the committee produced a report in the name of Parliament's Vice President, Nicole Pery, entitled "Achievements and prospects of Europe's fisheries policy".[2]

The accession of Spain and Portugal in 1986 which doubled the number of Community fishermen and increased the tonnage of the fleet by some 50 percent also increased the political interest in fisheries in the European Parliament with MEPs from the new Member States coming to play an active role on the Fisheries Committee. While the arrival of Spanish and Portuguese Members has created new internal tensions, particularly with regard to access to North East Atlantic waters, it has greatly increased interest in areas such as access to third country waters which is of particular importance to the Spanish distant water-fleet, structural policy and research. Spanish MEP Miguel Arias has played an important role in pursuing fisheries questions through the budgetary procedure.

During the 1984 to 1989 period, the Parliament was probably most influential in the field of structural policy. De Feo notes the extent to which the new legislation agreed at the end of 1986 took up proposals made by Parliament both in an own initiative report prior to the publication of the Commission proposal and in its report on the Commission's legislative proposals which were also largely accepted by the Commission in a revised text to its own proposal.[3] The 1986 legislation provided the Community with substantial funding of 800m ECU for the period 1987/1991, not only for vessel modernisation and new building but also significant sums for aquaculture, exploratory fishing and joint ventures, as well as limited aid for port facilities, market initiatives and other measures. [4]

De Feo also reminds us of the Parliament's budgetary powers in this respect by inscribing a sum of 127m ECU of expenditure in the 1987 budget, allowing the new measures to be financed.

The Pery report of December 1988 was also significant in that it was the first major Community report to sum up the achievements of the CFP and point the way forward to 1992. While confirming the basic principles of relative stability and limitation of access to coastal waters, it is interesting to see how ideas on conservation and management have been taken forward into the Commission's current review exercise as a basis for longer term policy - notably the development of ideas on multispecies, multiannual TACs and the Commission's preparedness to study the possibility of applying a system of individual quotas, with reference to the post-2002 situation.

The current Parliament so far has focused in particular on important technical measures and on the ongoing review of the Common Fisheries Policy. There has also been progress on the budget with the creation in 1990 of separate fisheries guarantee and guidance funds. A significant feature of the current period has been the number of meetings between the fisheries sub-committee and fisheries representative organisations as well as a series of seminars with committee members and senior Commission officials. Recent meetings have ranged from representatives from the Shetland Isles to French and Spanish tuna processors.

There has, too, been a substantial increase in briefing material provided to MEPs on all the Commission proposals and EP reports. All these activities demonstrate not simply the growing influence of the Parliament in policy formulation but of the movement away from Council lobbying towards concentrating on the initial stages of legislation to ensure that relevant interests are taken care of *before* the publication of legislative proposals and throughout the legislative process. Let us look at a few examples.

## 5. FISHERIES AGREEMENTS

Formally, the consultation of Parliament in connection with the conclusion of fishery agreements with non-member countries is based on Article 43 of the Treaty which provides that Parliament is to be consulted before the Council ratifies an agreement. In practice, this means that Parliament merely provides a rubber stamp after agreement has been reached.

2. Nicole Pery *Report on the achievements and prospects of Europe's fisheries policy ("Blue Europe") - DOC A2-0319/88 - EP 1988*
3. Alfredo De Feo *Les progrès de l'Europe bleue et la participation du Parlement européen* - Revue du Marché Commun numéro 309 - 1987
4. Council Regulation 4028/86 of 18/12/86 on *Community measures to improve and adapt structures in the fisheries and aquaculture sector* . OJ L376 - 31/12/86

However, on the one hand Parliament has pressed the Commission consistently on this matter so that there is now much more discussion with Parliament's fisheries sub-committee during the progress of negotiations. Also fisheries agreements are often with countries in particularly sensitive regions and thus the conduct of negotiations or potential negotiations have been influenced not only by the views of Member State Governments which provide the initial mandate to negotiate but also by the public debate engendered by the European Parliament. Namibia is a current example.

Much more significantly, however, has been the use of powers won by the European Parliament under the so-called Single Act which requires Parliament to give its assent to overall agreements with third countries. In the case of Morocco, refusal of the European Parliament in January 1992 to give its assent to a protocol with that country threw negotiations with this major fisheries partner into disarray. Thus, while the formal powers may be weak, the scope for influence is greatly enhanced.

## 6. TECHNICAL MEASURES

In the case of so-called technical measures, the European Parliament would not normally be consulted on those measures required for the implementation of the Conservation Regulation 170/83. However, as Community fish stocks have declined so "technical measures" have assumed a greater political importance and we can see how Parliament has pressed successfully to have its say and how Parliament's opinion has helped to shape Community policy.

In July 1990. for instance, the Commission published proposals to increase substantially the standard mesh size from 90mm to 120mm. [5] As the change was based on regulation 170/83 the European Parliament would not be consulted.

However, at the first meeting of the fisheries sub-committee after the submission of the proposal MEP Paul Howell drew Parliament's attention to the far-reaching effects of the Commission proposal and called for Parliament to be consulted. This was followed by a letter from British MEPs of all parties to President Delors and by a debate in the European Parliament calling again for consultation. Significantly at this debate Commissioner Marin backed Parliaments' call for consultation. [6] The Council of Ministers having failed to reach agreement on the proposals belatedly agreed to consult the Parliament. In October 1991 Parliament adopted its opinion calling inter alia for an increase in mesh size to 100 mm with further increases on a step by step basis.[7] When the Council of Ministers met at the end of the month agreement was reached very much along the lines of the solution proposed by the European Parliament.

## 7. LARGE SCALE DRIFT NETTING FOR TUNA

Back in August 1989 MEP Madron Seligman tabled a parliamentary resolution calling for Community legislation to ban high seas drift netting in its waters and to support international efforts to regulate purse-seine fishing and drift netting.[8] This motion was followed up with reports on both drift netting and purse-seine fishing for tuna.

In a resolution of November 1991 the Parliament called on the Commission to introduce legislation to prohibit imports into the EC of all tuna products harvested by purse-seining on dolphins, together with a ban on tuna imports from other cetacean-endangering fishing methods such as high seas drift nets.[9]

When the European Commission published its proposal to limit drift netting for tuna in Community waters to nets of less than 2.5 km there was little enthusiasm because as well as the French fleet, UK and Irish vessels were conducting experimental voyages. While UK MEPs strongly opposed the fishery on animal welfare grounds and were lobbied by organizations such as Greenpeace and the Worldwide Fund for Nature, it was noticeable that the French authorities drew

9. Minutes of EP 22/11/91

on the "greens" and environmental groups such as Robin des Bois to support French drift net fishing. Nevertheless, Parliament's endorsement of the Commission proposal again helped to smooth the way for agreement in the Council of Ministers - an agreement which would allow traditional fishing to continue after 1993 if it can be proved that other species are not endangered.[10] Parliament also played a part in calling for Community action to protect the Community market against low cost imports caused by trade restrictions elsewhere.

## 8. SALMON

The development of salmon farming in the Community has been of great interest to MEPs as it is a central feature of the aquaculture structural programmes for the UK and Ireland and takes place in some of the most peripheral regions of the Community. It is significant, however, that as the industry developed with Community support the Commission warned of future commercial problems. An October 1987 Commission paper said of the UK programme : "Despite the major potential of aquaculture in the UK and the satisfactory completion of the previous programme, the objective nevertheless appears very ambitious and could come up against, in particular, commercial difficulties which could have negative effects on the profitability of the investments contemplated."

These difficulties became apparent by 1989 when the Scottish and Irish salmon farming industries asked the EC to investigate allegations of dumping by Norwegian salmon exporters. In March 1991 the Commission terminated its anti-dumping proceedings. The Commission had recommended the imposition of an 11 percent tariff against Norwegian salmon but there had been no support from Member States other than the UK and Ireland. The Commission would merely "continue to follow closely the market trend for farmed salmon and the export of salmon to the Community". If further discussions with Norway were unsuccessful the Commission would consider whether to initiate new anti-dumping proceedings. On 8 November 1991, however, the Commission agreed a regulation making imports of Atlantic salmon subject to observance of minimum prices. What role did the European Parliament play in achieving Community action ?

At a seminar with Commission officials at La Toja in Spain, MEPs were told that no other Member States supported the UK and Ireland and even they did not give the matter their full support. This stimulated action by MEPs, in particular, Sir Jack Stewart-Clark who arranged for the salmon growers to meet with Commissioner Andriessen's private office (cabinet), with fisheries officials and with the Parliament's fisheries committee.

The growers expressed their concern to the Parliamentary committee that "political considerations in the EC/EFTA discussions are working against salmon farmers. There is wrangling between Community members and the Norwegians over the Common Fisheries Policy and access to fishing grounds. The impression which we have had is that these talks are seen as more important than our problems, and that no one, and DGI (directorate for external relations) in particular wants that particular boat to be rocked. Our fear is that our problems are being ignored in pursuit of another deal."[11] However action was continuing. According to *Eurofish Report* "External Relations Commissioner Frans Andriessen agreed to the industry-Commission meeting as a result of pressure exerted by the industry, taken up by MEP Sir Jack Stewart-Clark".[12] The MEP was also able to arrange a meeting between the Secretary of State for Scotland and Commissioners during his visit to Strasbourg and to press the British fisheries Minister. He also urged the fisheries Commissioner to raise the matter at the next meeting of fisheries Ministers.

The industry was of the view that it was this concerted effort which galvanised that UK's Ministry of Agriculture into action. On 27 August the Ministry produced a press release entitled "John Gummer takes up salmon farmers' case with EC". In this release the Minister referred to the earlier contacts between himself and the Scottish Secretary and the Commission and stated that he had now written to Commissioner Andriessen "to bring to his attention the evidence submitted by the Scottish industry".[13]

10. Debates of European Parliament 10/10/91
11. Scottish and Irish Salmon Growers Associations' Presentation to EP Fisheries Sub-Committee 27/6/91
12. Eurofish Report 20/6/91
13. MAFF News Release 284/91 27/8/91

During the autumn pressure was kept up on the Commission and the fisheries committee made use of a report prepared on the possibilities of salmon ranching to focus on the market situation for farmed salmon. Thus when the subject was debated in the European Parliament on 22 November MEPs were able to welcome the Commissioner's decision to introduce a minimum price system but also to call for this to continue after February 1992.[14]

## 9. FISHERIES AND FUTURE FINANCING OF THE COMMUNITY

An interesting link between the development of fisheries policy and the development of the Community as a whole is to be found in the current discussions over the future financing of the Community.

The limited structural funding made available in 1983 as a concomitant to the Conservation policy agreed that year provided Community funding for modernisation and new vessel building.

The substantial increase in fisheries structural funding in 1986 led to the exclusion of fisheries from the doubling of structural funds as a whole which was agreed by the European Community in 1988. However, the agreement on regional, social and agricultural spending did provide a precedent for fisheries in that Community structural policy now became five objectives which focused on particular problems in particular types of region ranging from backward industrial regions, so-called objective 1 to problem rural areas known as 5b regions. There had been talk of creating fisheries regions but no objective criteria existed. However, the 1983 conservation regulation pointed a way ahead. Article 8 states "Before 31 December 1991 the Commission shall submit to the Council a report on the fisheries situation in the Community, the economic and social development of the coastal areas and the state of the stocks and their likely evolution."

There was a further development in 1989 when Commissioner Marin took over responsibility for fisheries and third world development because he brought with him his previous experience as Commissioner responsible for social policy.

Social policy as such has been a problem area for fisheries. On the one hand, there is a Community context in safety standards for fishing vessels - an important matter given fishing's poor record - and there has been pressure from within the Parliament for progress on social policy, but on the other there is deep suspicion in certain Member States and in certain fleet sectors of Community attempts to interfere in working practices particularly in an industry which is for the most part family owned in many Community countries and where the scope for enforcing land based measures would be limited. Thus, despite the Commitment to develop social policy under Articles 117 and 118 of the Treaty of Rome, the progress of traditional social policy has been slight.

However, as the degree of overcapacity in the Community fleet has become more acute so the Community has seen a solution in the social policy field. The Pery Report of 1988 stressed the need for policy to take account of the socio-economic dimension of the fisheries sector of the regions concerned.

In November 1990, a group of academics led by the late John Gulland presented a report to the Commission highlighting the degree of over capacity in the Community fleet.

The group believed "the reduction in fleet capacity required for the Community's fisheries as a whole is not less than 40 % on average".[15] Clearly a reduction of anything like this volume of capacity would cause considerable economic and social dislocation.

In its outline paper on the factors to be taken into account in its review of the Common Fisheries Policy due by the end of 1991, the Commission recalled the Gulland figure and indicated that a significant volume of compensation would be required to soften the blow of any major restructuring and to provide alternative employment. The report stated "It would be desirable for accompanying measures to be conceived as an integral part of the reform of the structural funds in order to improve the economic and social cohesion of the Community".[16]

16. *The Common Fisheries Policy.* SEC(90)2244 - European Commission - 6/12/90

The subject was also fully discussed at a two-day seminar with Commission officials and MEPs at Arcachon in September 1990. The Commission's ten-year review of the CFP presented in 1991 further highlights the need for the designation of fishing regions.[17] The review also provides an opportunity to take the matter further because of the requirement for reports on the socio-economic condition of the regions - reports which were being completed in the spring of 1992 and will form the basis for the designation of fisheries dependent regions to benefit from the designation of a so-called objective six which has now been set out in the various documents produced by Commission President Jacques Delors in the aftermath of the Maastricht Summit of December 1991.

The Commission paper "From the Single Act to Maastricht and Beyond" states : "Because of the specific features of areas and regions directly dependent on the fishing industry there might be a case for adding an Objective 6 covering structural programmes for all regions involved in fishing."[18] This has been followed up by the paper *"The Community's Finances between now and 1997* which states that there will be a 58 percent increase in the allocation for the structural funds and that, inter alia this will go towards "structural measures in the fishing industry. This mainly involves :

- improving and adapting fisheries and aquaculture structures ;
- improving processing and marketing conditions for fisheries and aquaculture products ;
- formulating socio-economic flanking measures for the conversion of areas dependent on fishing."

While there will be a battle both in the Community and at Member State level over the volume of resources to be committed to the overall Community budget and while there may also be intense discussion over the definition of socioeconomic dependence on fishing and particularly over any more generalised moves towards a regionally based policy, the concept of support for fishing regions as an accompaniment to fleet restructuring has, with Parliamentary support, become an established part of Community thinking even without any formal legislative proposals.

## 10. CONCLUSION

The purpose of this paper has been to show how the influence of the European Parliament has grown in recent years. The paper has focused on a number of specific examples with which the author is familiar. The paper also shows how fisheries is an element in major Community decisions such as the financing of the Community in the light of the Maastricht agreement. Here too we can see the influence of the Parliament in developing Community policy.

# The Common Fisheries Policy and the Role of Producer Organisations in South West England : Economic Considerations

**John Slaymaker, Aaron Hatcher and Stephen Cunningham**

Centre for Marine Resource Economics, University of Portsmouth,
Locksway Road Portsmouth PO4 8JF United Kingdom

ABSTRACT

*Within the Common Fisheries Policy (CFP), the statutory functions of Producer Organisations (PO's) are relatively limited relating primarily to the common organisation in the market for fishery products. The possibility of a wider role for PO's was referred to in European legislation but not in detail.*

*In the UK, PO's have been given wider responsibilities via the use of the sectoral quota management system. This paper discusses fisheries management in South West England paying particular attention to the emerging role played by PO's and issues arising from such developments.*

*The paper concludes with a brief discussion of possible developments of the CFP on the basis of a more regionalised structure and a more formalised role for PO's.*

## 1. INTRODUCTION

The role of Fish Producers' Organizations (POs) in the United Kingdom has developed substantially since the 1970s. They were originally established as marketing organizations which acquired statutory EC functions relating to the common organisation in the market for fish and fishery products. No statutory function in fisheries management was envisaged for them, although the possibility of a wider role was mentioned in legislation. Since 1984 most UK POs have become centrally involved in fisheries management, assuming responsibility for the management of separate quotas allocated to them by the UK Government under the so-called 'sectoral quota' management arrangements. In addition, a

recent consultation paper by the UK government (MAFF, 1992) clearly envisages a wider role for POs in terms of effort control and decommissioning. The growing importance of POs as a tool of fisheries policy in the UK clearly raises issues for the future of fisheries management, not just in the UK, but throughout the European Community.

This paper, based on exploratory research undertaken at the Centre of Marine Resource Economics at the University of Portsmouth (eg Hatcher, 1991), discusses the developing management role of POs based in the South West of England, in particular the South Western Fish Producers Organisation (SWFPO). The aim is to identify the issues arising and to evaluate their significance. In addition, the paper briefly addresses the possible future role of POs within the broader European context in the light of the recently published review of the Common Fisheries Policy (Commission of the European Communities, 1991).

## 2. THE UK SECTORAL QUOTA MANAGEMENT SYSTEM

The Shetland FPO was the first UK PO to be given a 'sectoral allocation' (for Area IV & VI haddock) in 1984. The system was subsequently extended to other POs and other stocks (including pelagics) in Areas IV & VI and soon became central to UK quota management in these areas. Sectoral management of Area VII stocks began in 1990 when the Irish Sea POs (the Anglo-North Irish, Northern Ireland and Fleetwood FPOs) took sectoral quotas for VIIa cod, whiting, plaice and sole in order to protect their fishing from Scottish vessels. Government Fisheries Departments (GFD) extended sectoral quota management to the rest of Area VII during 1991. 1992 is the first full year of sectoral quota management for the south west of England POs.

The operation of the UK sectoral quota management system may be explained by reference to the figure 1.

*Under 10m vessels* have a separate allocation, regardless of whether they are members of POs or not, and this is managed directly by GFD. In the case of such vessels, fishing is simply either unrestricted or prohibited.

The *over 10m fleet* is divided into the 'sector' and the 'non-sector' for the purposes of quota management.

The *sector* is defined as vessels in membership of a PO for which a sectoral allocation has been made for a particular stock. For example, the SWFPO has taken a sectoral quota for Area VII megrim in 1992 - SWFPO members are therefore defined as being "in the sector" for Area VII megrim.

The *non-sector* comprises vessels not in membership of a PO or those in membership of a PO for which no sectoral allocation has been made for a particular stock. For example, the SWFPO has not taken a sectoral quota for Area VII saithe in 1992 - SWFPO members are therefore in the non-sector for Area VII saithe.

It is therefore apparent that the same vessel can be in the sector for some stocks and in the non-sector for others.

*Non-sector allocations* are managed directly by GFD through 'licence variations'. These list restrictions for appropriate stocks and are issued as required, according to the pattern of quota uptake. For example : 'no restriction', 'x tonnes per vessel per calendar month' (either flat rate or according to length or horsepower band or whether vessel is a beam trawler or non-beam trawler), 'suspension' (when it is considered necessary to reserve allocation for later in the year) or 'closure' (when the non-sector allocation is exhausted). The basic aim of management is to 'share out' quota between vessels and throughout the year, while neither under-utilising nor overshooting the total quota.

*Sectoral allocations* are managed by the POs themselves through the imposition of restrictions similar to those used GFD, but clearly they may be operated in a manner better suited to the particular local requirements of the PO membership (in terms of fishing methods, sizes of vessel, seasonality of fisheries and market demand, weather etc). Sectoral allocations are offered and granted by GFD in response to requests from POs. Allocations are calculated as a percentage of the total UK quota on the basis of the landings track record of the PO's licensed membership (ie vessels over 10m) over the preceding 3 years (2 years for pelagic stocks). The track record itself is calculated as a percentage of the total UK quota *uptake* in those preceding years for the stock in question. Allocations are usually made at the beginning of the year but POs can and do make requests at other times.

The decision to apply for and to accept a sectoral allocation by a PO depends on a number of factors. Essentially, it is worth while the PO taking a sectoral allocation if as a result its members are likely to be better off in terms of fishing opportunities for the particular stock than they would be in the non-sector. This point is discussed further in section 4.

*Withdrawal from the sector* is allowed by GFD provided that the PO's management during the year in question has not been less restrictive than that applied to the non-sector. For example, in April 1992 the SWFPO moved into the non-sector for Area VII hake after provisional sectoral allocations for this stock (together with Area VII anglers and megrim) were revised downwards by GFD to increase the non-sector's allocation because of the re-registration and licensing of formerly excluded 'Anglo-Spanish' ('quota-hopping') vessels.

The sectoral quota may change during the year for a number of reasons, which may also have a knock-on effect on subsequent years' allocation. For instance, *swaps* are allowed between POs provided they are ratified by GFD. At present all swaps must balance. Where different species are involved, transactions are calculated on the basis of cod equivalents. Since allocations are always made on the previous three years' track record, any net change in landings at the end of the year as a result of swaps will affect subsequent years' allocations accordingly. *Increases in allocation* can otherwise only be achieved by a PO through new membership at present.

*Reallocations of quota* by GFD are often necessary in the autumn. GFD reserve the right to reallocate part of a PO's quota to the non-sector if the PO looks likely to underutilise its allocation. The underlying principle is "if you don't use it, you lose it."

*Closure of a fishery* may also be imposed by GFD even if some POs have allocation left on paper for the year. If uptake by the non-sector or the =10m fleet (or indeed by other POs) were to overshoot their allocation so that the total UK quota were exhausted before the end of the year, then GFD would have no option but to close the fishery to all vessels. Compensation adjustments may, however, be agreed to by GFD in allocating quotas for the subsequent year.

If a PO is left with *unused quota* at the end of the year it inevitably loses a part of its quota for the following year since allocations are always based on the immediately preceding three years' track record. Once again, the "if you don't use, it you lose it" principle applies.

If a PO *overshoots its quota*, it will only be penalised in the following year if another PO or the non-sector has been prejudiced as a result (ie. has lost fishing opportunities that would otherwise have been available). Excesses are always discounted from the PO's track record.

## 3. POS IN THE UNITED KINGDOM

There are currently 14 officially recognised POs in the UK. These are classified by the EC as representing predominantly 'high-seas', 'offshore' or 'local inshore' fishing vessels :

High-sea fishing :

The Fish Producers' Organisation (Grimsby)

Grimsby FPO

Offshore fishing :

Aberdeen FPO

Anglo-Scottish FPO (Berwick)

Fleetwood FPO

NE of Scotland Fishermen's Organisation (Peterhead)

Scottish Fishermen's Organisation (Edinburgh)

Local inshore fishing :

Anglo-North Irish FPO (Kilkeel, Co Down)

Cornish FPO (Newlyn)

Fife FPO Northern Ireland FPO (Portavogie, Co Down)

Shetland FPO (Lerwick)

South Western FPO (Plymouth)

Yorkshire and Anglia FPO (Bridlington)

## 4. PRODUCER ORGANISATIONS IN SOUTH-WEST ENGLAND

The two POs in the South West of England are the Cornish Fish Producers' Organisation (CFPO) and the South Western Fish Producers' Organisation (SWFPO). In terms of gross earnings, roughly 70 % of the Cornish fleet belongs to the CFPO and 80 % of the Devon fleet to the SWFPO. The main areas of operation for member vessels are primarily in ICES Area VII where a wide range of species are caught, but the emphasis is on high unit value species such as sole, monkfish, hake, lemon sole and plaice. Many of these species are subject to "pressure stock management"[1]. A high proportion of landings are exported to other EC countries, notably France, Spain and the Netherlands.

Historically, both POs operated market support for a narrow range of species, primarily mackerel and pilchard. However, in recent years the POs have successfully encouraged members not to target pelagic species in the absence of viable markets so that the withdrawal system now operates only rarely. Significantly, market support arrangements have never operated for prime demersal species. South West fisheries witnessed a major development in 1991 when both POs took sectoral quotas for the first time.

The South Western FPO Ltd was established in 1974 and was the first PO in UK to be recognised by the EC. The SWFPO currently has 161 members, based mainly in Brixham and Looe, but including vessels from elsewhere in the south and southeast (eg Shoreham) and the Channel Islands. The common link for membership is increasingly the areas and species fished rather than the base port. During 1991 the SWFPO took sectoral quotas for 4 stocks in Area VII (anglers, megrim, hake and VIId sole). In 1992, its first full year of sectoral management, the SWFPO took sectoral allocations of 18 stocks, but this was later reduced to 17 when it moved back into the non-sector for Western hake. These 17 stocks are : Sole VIIa, VIId, VIIe, VIIfg, VIIhjk ; Plaice VIIa, VIId, VIIe, VIIfg, VIIhjk ; Whiting VIIa, VIIb-k, IV, VI ; Anglers VII, Megrim VII, Pollack VII, and Western mackerel.

## 5. ISSUES ARISING FROM SECTORAL QUOTA MANAGEMENT IN SOUTH WEST ENGLAND

Preliminary research concentrating on the emerging management role of the SWFPO in particular led to the identification of a number of issues relating to decision making by PO managers and to the sectoral quota management system as a whole.

A fundamental issue for POs is the decision whether or not to take a sectoral allocation. Two possible kinds of benefit may flow from an allocation, and these might be termed 'catch increase' and 'catch insurance'.

**Catch increase** will occur if, as a result of a sectoral allocation, PO vessels are able to land more of a given stock than they would be able to if they remained in the non-sector. This would arise if the average catches of PO members over the track-record period were higher than the average for the non-sector (although in practice this is difficult to know with certainty). The PO needs to have a good track record of catches over the three years prior to taking an allocation. Because sectoral quotas are allocated as a *percentage* of the total UK quota uptake, it is more important that the PO's track record is good relative to total landings than as an absolute amount. In 1991 the SWFPO, for example, decided to wait before applying for an allocation for Area VII whiting as catches were still increasing from the new pair trawling fleet in Looe.

**Catch insurance** may arise in the sense that, even if fishing opportunities are expected to be no better than in the non-sector, it might be wise to take a sectoral allocation if it is considered likely that a reallocation or early closure might

1. Pressure stocks are those (effectively all quota stocks) for which unrestricted fishing is considered by UK government to be inappropriate. Vessels wishing to exploit such stocks must be licensed and must observe periodic restrictions attached to such licences.

result in fishing opportunities in the non-sector being 'unexpectedly' prejudiced. This would not only harm members in the short term but there would be the prospect of a bad year in the track record. It may be wise for a PO to opt for a sectoral allocation lower than it might ideally have sought if the need for 'insurance' is perceived. This was the reasoning behind the SWFPO's request for VIId sole in July 1991 and its late decision (contradicting its own position of just a month previously) to opt for anglerfish, megrim and hake as well in September of that year. Interestingly, for opposite reasons, the SWFPO moved out of the sector for hake in April 1992, as discussed above.

There is always the possibility that something may reduce the expected take up by the non-sector, so that later in the year more is available to those vessels than to PO boats. This happened to the Scottish Fishermens' Organisation (SFO) in 1990, when in December non-sector boats were on unrestricted fishing for North Sea cod and haddock, while SFO vessels had no cod left and only 2t pcm of haddock.

Nevertheless, the general arguments in favour of the sectoral quota system are reasonably well rehearsed, for example in the paper by Goodlad (1992). The major advantage of the system is that day to day decisions on quota management can be taken at a more appropriate level, that is at the level of the PO membership, and that there will inevitably be more flexibility and responsiveness to changing requirements. It is argued that local fishermen are better placed than GFD to decide how to allocate the quota between boats and over the fishing year, according to the many relevant factors, including market demand. In this way, POs are able in theory to 'maximise potential profitability' of their members. It is also reported that fishermen are likely to pay far greater respect to management measures imposed by their own PO than to those imposed from higher up. This has important implications for the success of quota management and enforcement.

The manner in which a PO manages its sectoral allocation will depend on the particular characteristics of its membership in terms of target species, sizes of vessel etc. The SWFPO, for example, has so far only used flat rate monthly restrictions (ie. the same for all member vessels). The Shetland FPO allocates quota on a bi-monthly basis according to vessel size (measured in terms of both length and horsepower) while the Anglo-Scottish PO imposes monthly restrictions according to crew size. Some POs with pelagic quotas (eg. Shetland) make annual allocations to individual vessels.

The immediate advantages of a sectoral allocation to PO members are often stark. For example, in May 1992 the following restrictions were applied by GFD to non-sector vessels fishing in Area VII :

| | |
|---|---|
| Plaice VIIa | 5 tonnes/vessel/month |
| Whiting VIIb-k | 5 tonnes/vessel/month |
| Anglers | 8 tonnes/vessel/month |

Whereas SWFPO members at the same time were on the following restrictions imposed by their own PO :

| | |
|---|---|
| Plaice VIIa | Unrestricted |
| Whiting VIIb-k | 10 tonnes/vessel/month |
| Anglers | Unrestricted |

The existence of two separate groups (sector and non-sector) is understandably potentially divisive, and there are already signs of conflict between the two groups, as the following examples illustrate.

In 1990 there was controversy over misreporting of whitefish catches in Area VII. A number of Scottish vessels were accused of taking North Sea fish (particularly cod and haddock), for which as PO members they had sectoral quotas, and reporting these catches as coming from the Irish Sea where they were part of the non-sector, so dishonestly saving their own sectoral allocations for later in the year. Because the catches were counted against the non-sector for Area VII, this led to severe early restrictions on fishermen in South West England, including a closure of the non-sector cod fishery in VIIa. Although the argument was never completely resolved, for 1991 and 1992 GFD automatically issued allocations (based on track records) for all three areas VI, VI and VII when POs took allocations of cod, haddock, whiting or saithe in any one or more of these areas. The 1990 figures for cod, haddock and saithe in Area VII have been ignored in calculating the appropriate track records. Consequently, in 1991 and 1992 some northern POs holding sectoral quotas in Areas IV and VI were given unrequested Area VII allocations for the same species of a few tonnes or in some cases zero (ie. no fishing allowed at all).

Another area of controversy has been the recent reallocation of quota from the sector to the non-sector in Area VII by GFD to compensate for the re-instatement of the so-called 'quota hoppers' to the UK Register, as mentioned previously. At the same time, a number of former 'quota hoppers' are now in the process of setting up their own 'Anglo-Spanish PO' to be based in Milford Haven, a move which is not welcomed by other fishermen in the south west.

In the south west, to some extent sectoral quotas have been seen as a refuge from pressure on the non-sector from the Anglo-Spanish 'flagships' and a possible repeat of the sort of problems arising from the 1990 VIIa misreporting scandal.

A fundamental issue relating to the sectoral quota management system as a whole, and one which may well become problematic before too long, is the relative size and constitution of the sector and the non-sector.

POs have a legal duty not to discriminate against applicants (for example, on grounds of race or sex), but nevertheless retain the right to refuse applicants membership. This is significant, for there is no advantage to a PO with sectoral quotas in accepting a new member whose track record for the relevant stocks is less than the corresponding average for the existing membership. The increase in the SWFPO's membership from 1991 to 1992, for example, comprised boats with good track records of sole and plaice.

If POs are striving for a quality of membership based upon track records and they are permitted to do so, then it is possible that one might witness the emergence of elite clubs only open to the most successful fishermen, where any benefits accrue. While efficiency gains and rent generation might be facilitated as a result, there will also be distributional consequences and equity issues.

The benefits of PO membership therefore arguably depend on a proportion of the fleet remaining outside the sector. It also follows logically that if all vessels were in POs with sectoral allocations, then the problems of management with a fleet that is significantly over capacity would simply be transferred from GFD to the POs. This has led to sectoral management being viewed by some fishermen in the south west as a case of GFD trying to 'pass the buck'.

Expanding the size of existing POs or forming new ones may therefore not be desirable for improved resource management. There is no evidence that problems between POs or between POs and the non-sector will disappear, and until fleet capacity moves into line with the available catches, conflict about equitable treatment will always remain. The UK government's proposals (MAFF, 1992) on the increased role for POs in fleet capacity reduction appear to be an acknowledgement of the problems, and could be interpreted as a recognition that purely relying on sectoral quota management as the single role for POs is inadequate.

The consultation paper issued by GFD on effort control and decommissioning in April 1992 contains the following suggested changes to the role of POs in fisheries management :

> i) *Free trading* of quota between POs : Swaps need no longer balance and quota could be sold by one PO to another. Quota could in theory be swapped with non-sector, but not bought or sold.
>
> ii) POs could *buy* the track record of a member vessel wishing to exit from the fleet (but only as an alternative to decommissioning funded by Government). Sectoral allocation would then be calculated as if the vessel had stayed in the PO but had not fished : its track record would be absorbed by the remaining members so that at the end of three years its track record would have expired but those of the other vessels in the PO would be enhanced accordingly.
>
> iii) While licensing is to be extended to under 10m vessels from 1993, these licences will be simple permits and there are no plans at present to change the way in which the under 10m allocations are managed by GFD.

## 6. CONCLUSION

In the mid-term review of the Common Fisheries Policy (Commission of the European Communities, 1991), the European Commission hints that POs might play a more significant role in fisheries management throughout the EC. One of the objectives proposed for the revised policy is as follows :

> "distribution of responsibility at all levels, in accordance with the subsidiarity principle, conferring responsibility on the parties concerned, in particular the fishermen's organisations which could be given the task of implementing the management measures at the appropriate level." (page v)

It is also stated that :

> "The principle of subsidiarity requires appropriate sharing of responsibility among the Community, the Member States, the regions and the fishery professionals.
>
> The hierarchy of rules (clarified and simplified rules, national implementing measures, administrative provisions and Community intervention) must allow much of the work of implementation to be delegated to the various parties concerned (national, regional and professional authorities), giving them sufficient scope to choose the means and the methods used. Here the rule must be to optimize the degree of flexibility allowed to the various partners" (page 66)

We actually know relatively little about the way in which fisheries management by POs might develop, and as economists we need to use our conceptual frameworks and techniques to further understanding of POs in order to help identify their most appropriate role in the future of fisheries policy in Europe.

# Evaluating Socio-Economic Impact of EEC Fishery Policy Using a Social Accounting Matrices Approach

**G. Cella, V. Placenti and M. Spagnolo ***

I.R.E.P.A. Istituto Ricerche Economiche per la Pesca E l'Acquacoltura, via B. Croce, 35, 84100 Salerno, Italy

ABSTRACT

*Aim of the paper is to suggest and apply a methodological scheme for the evaluation of socio-economic impacts of EC fishery policy at sub-regional level within a general planning framework, when variations in the scheme of fishing are also introduced. The proposed evaluation approach considers the direct effects of the activity and the effects variations will have on the rest of the economic system through the interdependencies of sectors - the indirect effects. The impact of the overall effects of a reduction in fisheries and related sectors considers the role of production, intermediate and final consumption and investment. Effects are estimated using the Social Accounting Matrix (SAM) which approach make use of existing interdependencies in the economic system. The analysis has been applied to five administrative italian regions. Results are reported and expressed in terms of four indicators : the value of gross output, value added, incomes earned by employees and employment.*

## 1. THE IDENTIFICATION AND CHARACTERISTICS OF ZONES HIGHLY DEPENDENT ON FISHERIES AND ANCILLARY SECTORS

### *1.1 Identification of the zones through the measurement of relative dependence : a traditional approach*

#### 1.1.1 Introduction

The investigated area is comprised of five administrative regions containing 26 administrative provinces (of which 18 are on the coast) (fig. 1). It has four administratively distinct coastlines, which in turn are subdivided up into 16 maritime

* This research is part of a larger work commissioned by EC, Directorate for Fisheries, Direction of Structures, within a series of socio-economic studies in the Community.

districts each with autonomous maritime control and powers of jurisdiction. Each of these districts has its own particular geographical and social characteristics. The existence of around 300 landing-points with the consequent dispersion of the fleet and employment along the 2,000 km of coast is the dominant characteristic of fishing activities.

In the area under study there are no "real" centres of fisheries. In fact, to the distribution of resources and the consequent dispersion of the fleet along the entire coast, should be added the structural characteristics of fishing methods and supporting activities. The entire area is, therefore, characterised by dissagregated and disaggregating fishing activities whether in physical, economic or social terms.

To summarise, fishing activities in the area under consideration are the sum of a series of highly localised situations which, determined by the widely varying characteristics of the local sea's ecosystem, have given rise to a multiplicity of locally specific methods of production. **Thus, one cannot assert that there exist "geographical zones highly dependent upon fisheries" which go beyond the confines of the local administrative unit (comune) in which fishing is carried out.**

Looking at the situation from the overall point of view, the degree of concentration of the fleet and the landing places and, therefore, employment is so low that fishing activities in the area in question appear as a continuum along the length of the coast.

**Thus, it is important to stress that the relative importance attributed to fishing will be highly sensitive to choice of the level of geographical dissagregation to which the suggested socioeconomic indicators relate. The evaluation of socioeconomic indicators changes radically when one passes from the regional to the provincial level. Furthermore, it is only at the level of the local administrative unit (comune) that the role and relative importance of fishing in the local economy (principally as regards employment) can be identified with clarity and precision.**

With regard to the question of employment, it should be pointed out that, in the context of the territorial subdivision for the purposes of economic analysis, and, in particular, labour economics, the "local labour systems" and the "functional labour regions" in Italy are territorially correlated entities, both of which are designed to identify local labour markets and are therefore a point of reference in the design and management of active labour market policy.

The model of the territorial repartition of Italy represents a development of the "Standard Metropolitan Areas (SMSA)" (USA- 1960), the "Functional Economic Areas (FEA)" (USA-1970), the "Standard Metropolitan Labour Areas (SMLA)" (GB-1978), the "Travel to Work Areas (TTWA)" (GB-1974), the "Daily Urban Systems (DUS)" (GB-1979), as well as the "Regionale Arbeitsmarkte" (RDF) and the "Zones d'Etude de l'Emploi (ZEE)" (FR-1985).

The territorial dimensions of "local labour markets" in Italy do not go much beyond communal boundaries, and, more or less, coincide with the said comunes. Furthermore, according the ISERS model [1]of the functional repartition of the territory (IT-1990), Italian comunes have, on average, a degree of occupational autonomy (self contained employment) of over 90 %, or, in other words, almost all employment opportunities are contained in the comune of residence of the workers. This is all the more true in areas in which the local economy is heavily dependent on fisheries and ancillary activities. In other words, this implies the penalisation of geographical labour mobility with the consequent rigidity in employment in productive areas (administrative comunes or provinces).

To this rigidity, is added the intersectoral rigidity, whether at a regional, comunal or local level, which characterises productive activity in the area in question. If one adds the specialised character and the emargination of fisheries, one can only emphasise the meaninglessness of the identification of specific geographical zones which are highly dependent on fisheries and ancillary activities. **It is not unreasonable to suggest that, in the area under study, there are as many zones which are highly dependent on fisheries as there are landing-places.**

Unfortunately, this suggestion cannot be verified by a quantitative analysis. In fact, in Italy, the absense of a data on the relevant variables at a communal (local administrative unit) level and the implicit difficulties of estimation impede the precise identification, or rather ordering, of the degree of relative dependence of comunes on fisheries.

We report, however, results obtained at the level of the administrative region and at that of the province (tables 1 and 2). The latter provide the basis for the identification of the "zones highly dependent on fisheries" (even if the concept is not really applicable in the present case). The relative dependence being assessed in primarly and secondly terms on employment and in economic terms (tables 3 and figure 1).

1. A. Erba *et al.*, *Partizioni funzionali del territorio: il modello*, Franco Angeli, 1990.

The statistics relating to employment in, and the value added of, fishing employed for the classification of administrative regions are the official ISTAT figures, whilst for related activities the statistics are the result of our estimates produced on the basis of the classification of the individual economic activities related to fishing (of which there are more than 250) drawn from the sectoral interrelationships between branches and sectors of economic activity at the national level, grouped into the 17 branches of economic activity (SEC classification) at the regional level which were constructed for each individual administrative region under consideration.

### 1.1.2 Relative dependence at the level of administrative regions and provinces

The population present in the investigated area represents 32 % of the national total and comes to 18,200 million people, of whom 40 % are in the labour force. The high rate of unemployment (roughly 17 % compared to the national average of 12 %) in the area, however, brings total employment down to around 6,200 or 29 % of national employment. A consequence of this is the lower per capita gross output of the area equal to 11,100 ECU compared to the national average of 12,200 ECU.

Employment in fisheries represents just 0.27 % of total employment in the area and produces just 0.10 % of total wealth. If one considers also activities related to fisheries the degree of relative dependence increases to 0.44 % in terms of employment and 0.24 % in terms of economic value.

There are substantial regional disparities in the area under consideration and it is rather difficult to classify one in particular as the administrative region which is highly dependent on fishing, even though Liguria has the highest values of the relevant statistics. Such a classification would ignore 80 % of employment in, and 70 % of valued added produced by, fisheries and ancillary activites in the area.

Rather, there is a balance between the relative degree of dependence in economic and occupational terms both for fishing and for all the activities connected to it. This is the consequence of the specific productive structures and the relative weight that local economies have within the individual administrative regions and/or the geographical area under study.

One may thus identify the existence of "zones highly dependent on fisheries" distributed in patches across the entire area. This distribution is even more clearly identified when one considers the individual provinces (see table 2).

This demonstrates the difficulty of application and the limited usefulness of economic measures applied to individual regions or provinces in the area.

Nevertheless, four "zones highly dependent on fisheries and ancillary activities" have been identified in area. On the basis of the relative importance of fisheries, in economic and occupational terms, the zones are : the provinces of Livorno and Grosseto in Tuscany ; the province of Latina in Latium ; and, the Imperia province in Liguria (see table 3). It is important to stress that the identification is highly dependent on the specific criteria adopted. Indeed, the results for the above provinces are not so far away from those for other provinces in the area. It may be noted that the adoption of the above criteria immediately leads one to the consideration of just three of the five administrative regions in the area, excluding precisely the regions in which employment opportunities outside fishing are much more limited with respect to the other three.

For the regions with weaker economies, being penalised in this way, would only aggravate the already existing problems in terms of the productivity of labour and capital.

These considerations lead one to suggest the use of alternative criteria for identifying zones highly dependent on fisheries, leaving aside measures which only take account of the direct effects of fisheries on employment and production.

## 2. IDENTIFICATION OF THE ZONES USING THE SOCIAL ACCOUNTING MATRIX (SAM) APPROACH

### *2.1 Criteria employed for the identification of geographical areas which are highly dependent on fisheries*

A consideration of the economic and social importance of variations in the scale of fishing should take account, not just of the direct effects of the activity under consideration, but also the effects variations will have on the rest of the economic system through the interdependencies of sectors - the indirect effects.

The analysis of direct and indirect effects through the economic analysis of productive interdependencies have helped to resolve similar problems to the one under consideration here. One thinks of the example of the report prepared by M.I.T. economists regarding the dispute between Canada and the United States concerning fishing rights in the George Bank area, which came before the Aja High Court of Justice [2].

The evaluation of the overall (direct and indirect) effects of a reduction in fisheries and ancillary activities takes into account the roles of production, intermediate and final consumption and investment.

As regards the roles of production and consumption, a reduction in the level of activity in any sector in a particular area will have immediate repercussions for the level of income generated and distributed in the area through that activity. In the absence of specific (e.g. legislative) constraints, almost immediately one witnesses a reduction in the demand for labour in the activity, probably affecting the weaker segment of the labour force disproportionately. These are the direct effects, to which are added a series of indirect effects on incomes and employment depending on the interdependencies in production and consumption.

With regard to interdependencies in consumption, the initial reduction in the fishing activity gives rise to a reduction in incomes and therefore a reduction in expenditure financed by those incomes. In as much as part of local incomes are spent on local products, there will be a further reduction in local production with its consequent effects on incomes and so on. At this point, it is clear that the true overall effects comprise not only those considered above, but also include a series of spillover or indirect effects resulting from interdependencies in the local economy. For reasons of brevity, in the literature on the subject all overall effects (including direct and indirect effects) are called multipliers of second type.

As regards the role of investment, a reduction in the activity of interest also gives rise, to a certain extent, to a variation in investment flows, apart from that necessary to cover the replacement of equipment. Also in this case, the reduction in demand will give rise to a series of secondary effects as described above.

### *2.2 Methodological issues : a quasi-SAM approach*

The quantification of the effects outlined above can be undertaken using Social Accounting Matrices (SAM) which delineate existing interrelationships in the economic system. These interrelationships are captured not just as concerns production but also with regard to the generation, distribution, redistribution and expenditure of incomes. With the purpose of taking into account of the most important interrelationships, tables were constructed which may be thought of as a "half-way house" between the traditional Input-Output model and a typical SAM with a complete structure. This "half-way house" is termed a quasi-SAM, which, on the one hand takes account of interdependencies in production, whilst on the other, although including the generation and distribution of incomes, does not take into account all the aspects of these flows (ignoring, for example, the redistribution of incomes, effects on different social groups and so on) which, although interesting, in our case, appear to be of secondary importance.

### *2.3 Results : overall effects*

Table 2.6 reports the overall results for the administrative regions in the area. The results are expressed in terms of four indicators of a socioeconomic character. These indicators are : the value of gross output ; value added ( in other words the sum of distributed incomes) ; incomes earned by employees (salaries and wages) and, employment.

The impact on each indicator is considered for each region of a given reduction (one billion lire, roughly equivalent to 650 thousand ECU) in the value of produce of the fishing sector of that region. On the basis of data on production and value added for each segment of the fleet, it is straightforward to derive the corresponding figures in terms of the reduction in tonnage and productive units (see tables 5 and 6).

**It should be stressed that having reported the effects of a specific reduction, one may immediately evaluate the effects of any given change in the scale of fishing in the region under consideration (see tables 6, 7 and the appendix).**

2. P.G. Jordan, K.R. Polenske, *Multiplier impacts of fishing activities in New England and Nova Scotia,* 1988.

For every reduction in fishing of one billion lire, the area under consideration will witness, on average, a reduction in gross output of two billion lire (around 1.3 million ECU) in each region, with small variations between administrative regions (see the first column of table 6). The gross income of the area considered would fall by 1.3 billion lire (equal to 850 thousand ECU) on average (see column 2) with the consequent average reduction in employees' incomes of 700 million lire (equal to 450 thousand ECU) in the area (see column 3).

**The most worrying results encountered in the study relate to employment.** In this regard, one finds that a reduction of one billion lire (650 thousand ECU) reduces unemployment by 70 thousand working units (see column 4). Finally, column 5 gives the reduction in annual employment in the region arising out of a unit reduction in employment in fishing which, on average, comes to around 1.38.

It should be remembered that the reductions in employment are expressed in terms of the full-time annual manhours. Thus, the concept of a working unit does not necessarily correspond to actual employees whose actual working hours will vary between types of work. In other words, the figures refer to the volume of work in productive activities.

**In practice, the results obtained concerning the effects of a unit reduction in gross output (see tables 6, 7 and appendix) allow the calculation of the overall variation in any of the relevant quantities.** Specifically, GRT, KW, number of boats, volume of produce, or prices both by geographical area or fishing method.

Once the structural parameters concerning fishing activities in specific regions have been derived (for example : GROSS OUTPUT/GRT, GROSS OUTPUT/KW, GROSS OUTPUT/HOURS, GROSS OUTPUT/WORKING UNITS, GROSS OUTPUT/EQUIPMENT etc.,), in order to analyse any conceivable scenario, it is sufficient to define the amount (in terms of value) by which the output of the region falls. Multiplying this by the relevant indicator(s) given for the specific region gives the overall impact of the reduction on the quantity of interest.

In the case of the administrative regions in the area, and more generally, the case of Italy, the structural parameters of fishing activities (by type of boats, fishing method and geographical area) have been derived by IREPA [3]on behalf of the Ministry for the Merchant Navy and European Commission. Tables 4 and 5 reproduce some of these parameters which underly the calculation of overall impact, in this case concerned with the reduction in tonnage.

In practice, once the proportionate reduction in tonnage of the regional fishing fleet has been established, the overall effect is calculated on the basis of the gross tonnage of boats in the area. Through the use of the parameter GROSS OUTPUT/GRT the equivalent reduction in gross output (in value terms) is then derived. This figure is reported in unitary terms and the ratio is applied to the regional socioeconomic indicators. Finally, given the ratio of annual full-time equivalent manhours to regional employment, the overall effect in terms of the actual number of people employed is determined.

As regards overall employment effects, the reduction of 650 thousand ECU results in the loss of around 50 jobs, 40 of which in fishing sector.

To summarise, for every reduction of one billion lire (equal to 650 thousand ECU) in fisheries, there are, more or less, 40 fewer seamen employed in fisheries and ten fewer employees in ancillary activities.

**This may be translated into a reduction in the loss of 300 jobs in area I.1, following the reduction of 2 % in gross tonnage required by the Commission's for the period 1991-1996.**

### 2.3.1 Impact of the direct and indirect effects

From the overall indicators, it is possible to derive some general indications.

On Gross Output

Gross output is the indicator which varies the least between regions.

The differences that do exist, with Tuscany first followed by Campania with the other three administrative regions in the area bringing up the rear, depend fundamentally on two type of interaction in production : the interaction between fishing and other activities ; and, interactions within the latter.

3. IREPA, *Sistema di rilevazione sistematica ed organica degli indicatori economici della pesca in Italia,* 1991; *Le interelazioni settoriali nella pesca italiana: un' analisi input-output,* Dec. C (85) 2223/7, 1986; *Standardizzazione dei parametri tecnici ed economici della pesca italiana,* Dec. C (85) 2223/6, 1986.

The indicator under consideration is predominantly affected by the interactions between fisheries and other related activities and is less influenced by factors which are internal to the sector, such as, for example, the productivity of labour and capital. This gives an idea of the level of interdependence which links the fishing sector with the rest of the regional economy. This level is moderately intense and is fairly uniform across different regions (although there are some important differences which distinguish Tuscany and Campania from the other regions probably due to the greater interdependence between the sector and the rest of the economy).

**These considerations underline the fact that, in the case of the regions under consideration, fishing is a "pervasive" activity.** Even if it is adequately integrated with other activities, fishing has not given rise in any of the regions to particular territorial concentrations of fishing itself, nor of related industries. Fishing is an activity with a long tradition, and has not given rise, apart from in some particular cases, to the range of activities that produce a vertically integrated industrial complex.

On investment

The relative uniformity of the low level of investment flows confirms, indirectly, the absense of vertical integration in the productive process, or rather, the non-existence of a geographical area in which there is sufficient vertical integration of production to assert the existence of multi-sector productive processes, and, in the last instance, of "zones highly dependent on fishing". The low level of flows does not only depend on the low rate of substitution of equipment in all of the regions considered, but also on the fact that there is no concentration of boat building or of the construction of other fishing equipment in the area.

On value added and incomes

The indicator on value added shows the same lack of interregional variability as gross output. However, there are significant regional differences in labour productivity in the sectors bearing the brunt of the secondary effects. This reflects differences in the relative weight of labour and capital between regions.

The same is true of the impact on incomes, which is both of significant proportions and uniform across regions, as are the effects on employees' incomes (salaries and wages).

On employment

The impact on employment varies greatly from region to region which is due to the substantial differences in labour productivity across sectors. **As regards employment in the fisheries sector and induced employment, one notes that the direct and indirect effects are roughly proportional. Where the direct impact on employment in fishing is relatively small, so too is the fall in employment in other activities and vice versa.**

**Of the greatest importance to the present study, there is a tendency for the sizes of the direct and indirect effects to vary in opposite directions across regions, thereby dampening regional differences.**

This tendency is particularly pronounced in the case of gross output and value added, slightly less so in the case of employees' incomes, but, as indicated above, is entirely absent in the case of employment. This demonstrates the degree of complementarity that exists between the fisheries sector and ancillary activities. In other words, this shows the relative importance of the indirect effects in determining the dependence of geographical areas on the fisheries sector. The results obtained, with the aid of the construction of regional quasi- SAM's (which for the the sake of simplicity are not all given here, see final report), demonstrate, in general, that where the direct effects are small, the indirect effects are large and vice versa.

This tendency of compensatory movements in the two types of effects modifies, or rather, overturns the results obtained by the analysis above of the direct effects by themselves (see point 1), giving an entirely different picture of the "relative dependence of geographical zones on fisheries", as well as providing further evidence of the pervasive nature of this activity. Furthermore, it allows one to assert definitively the similarity of the regions in the area in terms of their relative dependence on fisheries.

### 2.3.2 Some considerations on the direct and indirect effects

The analysis up to here has been based on the assumption that a reduction in the scale of fishing will induce a more or less proportional contraction in employment.

In reality, the decrease in employment may well be more than proportional if a reduction in output is accompanied by a rationalisation of productive processes aimed at sustaining profit levels in the face of lower output.

Above all, if supported by incentives, the tendency to sustain stable profit levels becomes a serious likelihood. If, on the one hand, this leads to an increase in the indirect effects felt by ancilliary industries, such as boat building (indirect effects which, however, need not necessarily be felt in the inland areas of the region), on the other, they will also have a more than proportionate direct effect on the number of people involved in fisheries.

Unlike the indirect effects on investment, which do not necessarily occur in the same region and will tend to affect skilled industrial manpower, the direct effects on fisheries will be felt by the weakest segment of the workforce, for whom the transfer to another occupation is extremely problematic. This is true because the affected segments are the weakest in the work force, but also because the habits and traditions of fishermen do not adapt well to the rhythym required in other productive processes.

Regional differences in the effects on employment, which in Campania is almost twice the size of the effect in Liguria and Tuscany (see table 7), may be explained by the greater intensity of employment with respect to output in these two regions compared with the other three. This is particularly true of service sectors, which are the sectors which feel the indirect effects to the greatest extent.

One last consideration regards the significance of the indirect effects arising from the failure to substitute equipment in the fishing sector. This is an important aspect, given the insufficiency of available funds for the modernisation of boats. Indeed, it is well known that the large number of boats of an advanced age require a substantial financial undertaking, in the absense of which boat owners tend to postpone their decision to modernise from their own funds. In the absence of a substantial transfer intervention through capital loans as opposed to capital grants, it is extremely likely that things will remain the way they are.

The effects of the lack of investment are of a purely indirect character, whilst the overall effects have both direct and indirect consequences. In order to gain a clearer picture of the importance of the former, one needs to compare them, not with the overall impact, but with the indirect effects. The results of this comparison, which for simplicity of exposition are laid out just in the final report, confirm the limited role of these effects, which are however, substantial. It is worth noting that, at least in Liguria, Tuscany, Latium and Campania, these effects represent about 10 % of the indirect effects.

If accompanied by a policy providing incentives, concentrated on contributions on capital loans, a demand for investment aimed at replacing existing capital equipment in order to improve efficiency could be created. In this case, the effects under consideration would be positive and substantial and would counteract the negative trends in the economic and social indicators considered.

### *2.4 Results : sectorial and regional analysis*

A sectorial and regional analysis allows the evaluation and comparison of the impact on the socioeconomic indicators considered at the level of the 17 sectors for each region. With the aid of these results, it is possible to consider in detail the effects of different ways of reducing fishing in each of the regions under study.

The fundamental results emerging from these dissagregated data (which are given in appendix) is that, apart from those already noted, there are no substantial regionally specific effects. On the contrary, **the most important finding is that the indirect effects reach significant levels, not through a concentration in regional sub-systems, but in their pervasive presence of a large impact throughout all the sectors,** albeit with different levels of incidence. The greatest sectoral concentration in indirect effects is no more than 15 % (reached in very few cases). Furthermore, these relatively high levels of concentration occur in the service sectors (trade, lodging and catering). This demonstrates that these more concentrated effects are due to changes in the distribution of income expenditure rather than to specific cases of productive integration between fishing and other sectors.

## 3. CONCLUDING COMMENTS AND PROPOSALS

The identification of geographical zones which are highly dependent on fisheries and ancillary activities on the basis of the analysis of relative dependence (considered in section 1), can only give an indication of the direct effects on the local

economy, thus indicating the zones at immediate risk. The analysis using the SAM approach has demonstrated, on the other hand, that direct and indirect effects compensate each other, thus equalising relative dependence across individual areas and regions.

In general terms, a reduction in fishing activities in the Tyrrhenian regions in Italy would produce substantial socioeconomic effects, both direct and indirect. The latter, even if some caution must be used in giving excessive weight to the precision of estimates, appear to almost double the consequences on the socioeconomic indicators. Whether one considers total income, employees' incomes or employment, the secondary effects are always substantial. Their presence and the way in which they are induced, provides useful information for the refinement of policies aimed at compensating the negative effects under consideration.

It is clear that these policies must be altered according to whether they are intended to counteract direct or indirect effects.

In the case of direct effects, policies should be concentrated territorially, and aimed at supply. Territorial concentration is necessary because the direct reduction in incomes and employment will occur in coastal areas. The concentration on supply is important because it is necessary to identify alternative productive activities able to provide adequate incomes. The principal problem is not so much incomes, as that of transfering workers who, as members of fishing boats' crew, have acquired very specific traditions and working habits, to other forms of work with very different working rhythms and organisation. This is an extremely difficult problem, as has been shown by a study carried out by the New England Institute for Employment Policy in 1982 regarding the possibility of transfering the fishermen of the area to other activities, and by the experience of the various attempts that have been made in Italy over the last ten years to bring about such transfers.

As regards the indirect effects, on the other hand, their pervasive nature and the varied routes which they follow suggest that the appropriate action would be a policy aimed at sustaining the level of regional demand. Obviously, such policies could be coordinated with those aimed directly at the fisheries sector, however, without the need for a particular territorial concentration since it has been shown that the secondary effects have the peculiarity to be widely diffused amongst all the regions' activities.

It is important to remember that, as is noted above, the demand for investment could play an important role in counteracting negative indirect effects. Thus, alongside a policy on supply aimed at aiding the re-absorbtion of the labour force leaving the fishing sector, a policy encouraging the substitution of capital equipment would be useful. Unfortunately, however, such a policy will only be beneficial in regions which are able to satisfy this investment demand in significant measure.

In the absense of this capability, the positive effects will be felt by different regions to those suffering the damage. Thus, in regions which do not produce a substantial quantity of capital goods, the only remaining alternative is a policy aimed at sustaining final demand.

## 4. APPENDIX : METHODOLOGICAL NOTES

1. The application of Input-Output analysis to the evaluation of the effects (at a regional level) of different possible scenarios regarding the evolution of fisheries in our country requires the availability of intersectoral tables with two basic characteristics. On the one hand, the sectoral breakdown must be sufficient to allow the identification of fisheries as a sector separate from other primary activities. On the other, a territorial breakdown is also necessary to allow the differentiation of the socio-economic effects at a regional level.

These two requirements are not satisfied by available sources of official statistics.

On the one hand, national tables are available in which the degree of sectoral breakdown is sufficient, but these neglect the territorial aspect (ISTAT, "Tavole settoriali dell'economia italiana a 92 branche produttive per l'anno 1985"). On the other, there are tables constructed at the regional level (Progetto FORMEZ-ISTAT, "Tavole delle interdipendenze settoriale delle regioni italiane al 1986). The latter, however, contain a lower degree of sectoral disaggregation, considering just 17 productive sectors in which fisheries appear as part of the "Agriculture, forestry and fishery products" category and not as a separate sector.

This implies that the first step in the analysis consisted in the breakdown of the regional tables to separate fisheries from the other activities with which it was aggregated. In order to undertake this disaggregation, a method was employed based on the indirect information of fisheries at the national level (contained in the Italian tables), and direct information on production, value added, net taxes on production and total intermediate costs of fisheries for each region in the analysis (see Table A1).

The national table was first aggregated from 92 to 18 sectors, which included, on the one hand, fisheries (sector 1) and on the other, the 17 sectors included in the regional tables. Thus, the "disaggregated" regional table (in which the fisheries sector is separated from other activities) for region j takes the form :

$TR_j =$

| | Fishery | Agriculture | Other activities |
|---|---|---|---|
| Fishery | $bgg\ C_n^j\ F^j$ | $bg_1 (x_1^j - F^j)$ | $bg.x_{.n-1}$ |
| Agricult. | $b_1g\ C_r^j\ F^j$ | $a_{11}\, x_1^j - (b_1g\ C_r^j\ F^j + bg_1\, x_1^j)$ | $(a_1 - b_1)\, x_{n-T1}$ |
| Other activities | $b.g\ C_r^j\ F^j$ | $a_{.1}x_1^j - b.g\ C_r^j\ F^j$ | $a_{n-1}\, x_{n-1}$ |
| Value added | $V_g^j$ | $V_1^j - V_g^j$ | $V_{n-1}$ |
| GRT at factor c. | $F^j$ | $x_1^j - F^j$ | $x_{.n-1}$ |

where scalars (with a double subscript), vectors (with a subscript and a superscript) and matrices (with a single superscript) indicated by the letters a, x and V, are derived from the following decomposition of the original regional matrix (with 17 sectors) of input coefficients, the vector of gross sectoral output (x) and the vector of sectoral value added (V) :

| | Agriculture and fishery | Other activities |
|---|---|---|
| Agr. and fishery | $a_{11}$ | $a_1$ |
| Other activities | $a_{.1}$ | $a_{n-1}$ |
| G.R.T. at f.c. | $X_1^J$ | $x_{n-1}$ |
| Value added at f.c | $V_1^j$ | $V_{.n-1}$ |

Subsequently, scalars and vectors indicated by the letter b are derived from the following decomposition of the national matrix with 18 sectors (fisheries plus the 17 sectors contained in the regional tables) :

| | Fishery | Agriculture | Other activities |
|---|---|---|---|
| Fishery | $bgg$ | $bg_1$ | $bg.$ |
| Agricult. | $b_1g$ | ..... | ..... |
| Other activities | $b.g$ | ..... | ..... |

The circumflex accent indicates vectors transformed into diagonal matrices, $F^j$ and $Vg^j$ indicate gross output and value added (both at factor cost) of fisheries in region j.

Finally, $Cr^j$ is a correction coefficient included to take account of differences between cost structures at the regional and national levels.

In the procedure outlined above, both at the regional and national levels, total intermediate transactions are considered, that is to say, including both internal production and imports. This was necessary because the regional tables provide information on total transactions. It goes without saying that this implies a further adjustment to derive the effects at a regional level. Appropriate coefficients are required which take account of spacial limits in the propagation of the effects. Following current practice, the following coefficient was employed :

$$t_i^r = \frac{X_i^r}{X_i^r + M_i^r}$$

where $Xi^r$ is gross regional output of good i and $Mi^r$ represents imports of good i in the same region. The coefficients thus derived allow the construction of the diagonal matrix t employed in the procedure outlined below.

2. Once eighteen sector regional tables had been constructed (with fisheries included separately as the first sector) multipliers were estimated according to the following procedure. For the sake of notational simplicity, given that the procedure is applied to each individual region, we omit the regional superscipt from hereon. Thus, we have :

a (18x18 matrix) = matrix of total regional input coefficients

$\hat{t}$ (18x18 matrix) = matrix of adjustment coefficients to derive the regional specific demand for inputs.

x (18x1 vector) = gross regional output of each sector

m (18x1 vector) = imports iof the eighteen types of good

f (18x1 vector) = final regional demand comprising consumption (public and private), investment (opublic and private), and (gross) exports

q (18x1 vector) = indicates the composition of goods required for the annual substitution of capital equipment in the fisheries sector (measured in terms of units of gross output of the sector)

From which we may write the following identity :

$$x = \hat{t}ax + f - m \tag{1}$$

rearranging terms, this may be expressed as :

$$\begin{pmatrix} 1 & -ts_1 a_1 \\ 0 & 1 - \hat{t}_{n-1} a_{n-1} \end{pmatrix} \begin{pmatrix} m_1 \\ x_{n-1} \end{pmatrix} = \begin{pmatrix} t_1 a_{11} - 1 \\ \hat{t}_{n-1} a_1 \end{pmatrix} x_1 + \delta - \begin{pmatrix} 0 \\ m_{gg-1} \end{pmatrix} \tag{2}$$

in which fisheries is separated from other activities. The level of production is also considered as exogenous, whilst imports of fish products are considered endogenous. The vectors $x_{n-1}$and $m_{n-1}$ represent the vectors x and m without their first element. The vectors a . 1 and $a_1$ . indicate respectively the input coefficients for fisheries and the intermediate demand for fish products by other sectors. $m_1$ and $x_1$ are imports and output of fish products and the $a_{n-1}$ is the matrix excluding the first row and column (corresponding to fisheries). From (2) :

$$\begin{pmatrix} m_1 \\ x_{n-1} \end{pmatrix} = \begin{pmatrix} 1 & -t_1 a_1 \\ 0 & 1 - \hat{t}_{n-1} a_{n-1} \end{pmatrix}^{-1} \left( \begin{pmatrix} t_1 a_{11} - 1 \\ \hat{t}_{n-1} a_1 \end{pmatrix} x_1 + \delta - \begin{pmatrix} 0 \\ m_{n-1} \end{pmatrix} \right) \tag{3}$$

Equation (3) allows the evaluation of the indirect regional effects arising from a reduction $\Delta x_1$ in the output of the fisheries sector in the region under consideration. If one makes the plausible assumption that the substitution of capital equipment is proportional to annual sales, then the reduction $\Delta x_1$ will lead to a corresponding reduction $\delta \Delta x_1$ in the regional demand for investment.

Thus :

$$\begin{pmatrix} \Delta m_1 \\ \Delta x_{n-1} \end{pmatrix} = \begin{pmatrix} 1 & -t_1 a_1 \\ 0 & 1 - t_{n-1} a_{n-1} \end{pmatrix}^{-1} \begin{pmatrix} t_1 a_{11} - 1 \\ t_{n-1} a_1 \end{pmatrix} \Delta x_1 + \begin{pmatrix} 1 & -t_1 a_1 \\ 0 & 1 - t_{n-1} a_{n-1} \end{pmatrix}^{-1} tq \, \delta \Delta x_1 \tag{4}$$

where the first part of the right hand side represents the indirect effects due to the reduction in fishing activities, whilst the second part indicates the indirect effects of the reduction in the substitution of capital equipment.

The sum of direct and indirect effects is given by :

$$ET = \Delta x_1 + \Delta x_{n-1} \tag{5}$$

where $\Delta x_{n-1}$ is derived from (4).

3. The multipliers calculated above are different from normal demand multipliers. However, from these the indirect consequences of different hypothetical reductions in output may be calculated. This formulation, however, only takes account of the effects employed for the calculation of the first type of multiplier, that is, effects transmitted exclusively through productive interdependencies. It is well known that this type of methodology is unsatisfactory because it does not take account of the effects of the distribution of expenditure of incomes. Thus, one needs to have recourse to the second type of multiplier which also takes account of these effects. In order to introduce these additional effects it is necessary to rewrite (4) as :

$$\begin{pmatrix} \Delta m_1 \\ \Delta x_{n-1} \\ \Delta v \end{pmatrix} = \begin{pmatrix} 1 & -t_1 a_{1.} & -\gamma_1 \\ 0 & 1 - \hat{t}_{n-1} a_{n-1} & -\gamma_{n-1} \\ 0 & -v_{1.} & 1 \end{pmatrix}^{-1} \left\{ \begin{pmatrix} ta_{11} - 1 \\ \hat{t}a_{.1} \\ v_1 \end{pmatrix} \Delta x_1 + \begin{pmatrix} t_1 q_1 \\ \hat{t}_n q_{n-1} \\ 0 \end{pmatrix} \delta \Delta x_1 \right\} \tag{6}$$

where v represents regional value added, $v_1$ is the (marginal) coefficient of value added of fisheries, $v_{1.}$ is the (marginal) coefficient of value added in other sectors. The $\gamma$ terms represent the marginal propensity to consume for individual goods. If one assumes that consumers have Cobb-Douglas utility functions (and therefore spend the same proportion of income on each good), $\gamma$ may be estimated by :

$$\gamma i = t_i' \alpha_i C (1 - \tau) \tag{7}$$

where C is the total marginal propensity to consume, $\tau$ is the marginal tax-rate and $\alpha_1$ is the exponent on $C_1$ in the utility function (Regarding the technical coefficients it is assumed, a la Leontief, that marginal and average coefficients are equal. The same consideration applies to the coefficients on value added).

As before, the indirect effects may be subdivided into those due to a reduction in fishing activity and those due to the reduction in the substitution of capital equipment.

4. In section 2. the direct and indirect effects were measured in terms of gross output. In section 3. they were measured in terms of gross output and aggregate value added. They may also be expressed in terms of sectoral value added and as well as in terms of incomes and employment. These latter indicators allow a consideration of the effects not just in economic terms but also in terms of the social impact. If v, w and e are the diagonal matrices of value added, income (per unit of output) and employment (per unit of output) coefficients respectively, it follows that the vectors :

$$\hat{v} \begin{pmatrix} \Delta \chi 1 \\ \Delta \chi_{n-1} \end{pmatrix}; \quad \hat{w} \begin{pmatrix} \Delta \chi 1 \\ \Delta \chi_{n-1} \end{pmatrix}; \quad \hat{e} \begin{pmatrix} \Delta \chi 1 \\ \Delta \chi_{n-1} \end{pmatrix}$$

measure the direct (the first element in each vector) and indirect (the remaining 17 elements) effects in terms of value added, employees' incomes and employment.

In the present study, notwithstanding the problems of estimation and the need to not overstress the precision of the estimates produced when interpreting the results, we believe, considering the literature in this area, that the more useful conclusions are to be drawn from the second type of multipliers.

(*) The reported values refer to 18 coastal provinces alone, not to all of 26 provinces of the corresponding administrative regions, therefore total amounts of area I.1 do not correspond to the sum of columns. Work-force and job totals by province may be inconsistent with the regional total or zone total, due to a systematic defect in the ISTAT work-force survey sampling pattern.

**AREA I.1: ZONES HIGHLY DEPENDENT ON FISHERIES AND ANCILLARY ACTIVITIES**

# Aquaculture, sectoral dynamics by M. Antona and D. Bailly

L'aquaculture a deux visages : d'une part, il s'agit d'activités traditionnelles qui ont géré depuis plusieurs siècles leur propre développement avec une intervention publique très limitée ; d'autre part, ce sont des productions résultant du volontarisme public, produit direct des laboratoires de recherche. Toutes les communications présentées dans cette session font référence à ce second type d'aquaculture, dans lequel on trouve deux types de filières :

- celles dont le succès est de courte durée et les réalisations en deçà de l'investissement public et privé consenti,
- celles qui connaissent un développement majeur et posent tous les problèmes de la recherche d'autonomie envers l'aide publique.

Dans ce contexte, émanent plusieurs questions économiques dont l'intensité et l'actualité dépendent souvent du stade de développement des filières aquacoles. Les recherches économiques réalisées sont encore loin d'être à la mesure de l'investissement public technique et technologique en aquaculture. L'économie de l'aquaculture semble rester, à tort, une discipline marginale de l'économie des pêches. Les communications de cette session présentent donc l'intérêt d'être représentatives des contraintes et des enjeux de ce développement aquacole. Elles illustrent autant la diversité des questions de recherche que la difficulté pour les économistes à les traiter dans le cas de l'aquaculture.

Si l'on analyse l'aquaculture sous l'angle de la dynamique des filières, la réponse reste à construire pour une interrogation majeure. Existe-t-il aujourd'hui possibilité *d'émergence* d'une filière aquacole sans soutien public massif en terme d'investissement comme de recherche ou transfert ? Cette nécessité du soutien est constatée par tous mais peu explicitée. La communication de

There are two aspects to aquaculture : on the one hand there are traditional activities which have developed over several centuries with very limited public intervention, and on the other productive activities which are a direct result of public will, a direct product of research. All the papers presented in this session refer to the second type of aquaculture where two different kinds can be distinguished :

- those with only short-lasting success and where the public and private investments made exceed the results obtained
- those achieving a major development which then pose all the usual problems of the search for autonomy from government support.

In this context, many economic questions which arise depend for their intensity and their relevance on the stage of development of the aquaculture system. Economic research is far from matching technical and technological public investment in aquaculture. Wrongly, aquaculture seems to remain a marginal discipline in fisheries economics. The papers in this session are interesting because they demonstrate the stakes and constraints in aquaculture development. They show that research topics are both varied and difficult for economists in the case of aquaculture.

If the dynamics of the whole chain of aquaculture activities are considered, it is clear that the following major question remains to be answered: is it possible today to have an aquaculture sector without massive public support in terms of investment, research or transfer? This need for support is noted by all but seldom explained. The paper of J. Ungson is concerned with the role of research in innovation transfer in the initial phase of an aquaculture activity. Does this mean that aquaculture can be compared to a high technology sector in

J. Ungson aborde à ce propos le rôle de la recherche pour le transfert de l'innovation au stade du démarrage d'une activité d'aquaculture. Cela signifie-t-il que l'aquaculture peut être assimilée à un secteur à haute technologie, pour lequel on constate le même recours à l'investissement public en recherche-développement ? Au contraire, est-ce le caractère familial et la production de nature artisanale qui rend impossible toute mise au point de nouvelle filière de manière endogène, comme en agriculture ? La question du calcul économique du coût public est aussi abordée dans la communication de J. Ungson qui montre, au moyen d'une analyse coûts-bénéfices que le sea-ranching de la daurade japonaise au Japon ne peut être envisagé sans un soutien à l'activité et surtout des bonifications de taux d'intérêts qui influent sur le coût d'opportunité du capital.

Une fois prise l'initiative de démarrage d'une activité d'aquaculture, les options retenues par la recherche définissent les premiers pas de la *" période infantile "* des filières de production, selon les termes employés par S. Shaw et M. Gabbott.

Même si la viabilité des filières reste encore fortement liée à l'intervention publique pour la protection du secteur, les questions à aborder concernent plus le relais du soutien public par un secteur privé ou encore l'identification des facteurs-clés du développement. Dans la protection du secteur, interviennent alors les aides à la production ou à la commercialisation. En référence au cas de l'industrie de la mytiliculture en Ecosse et en Irlande, S. Shaw et M. Gabbott relèvent comme facteur-clé de développement l'existence d'une demande nationale, relayée éventuellement dans un second temps par une demande à l'exportation. De ce fait, la coopération entre entreprises du secteur permet d'atteindre la taille critique pour fournir des marchés d'aquaculture en croissance et pour lesquels la différenciation des produits joue encore très peu.

Le stade de *croissance* est marqué par les questions qui concernent la viabilité des types d'entreprises (artisanal versus industriel, intensif versus extensif, a forte composante main-d'œuvre versus capital-intensif) ou encore l'enjeu des gains de productivité. Rainer Cedrins aborde ainsi le choix de la taille « optimale » et celui du système technique dans le cas de l'aquaculture du saumon en Scandinavie. L'innovation comme facteur de réduction de l'incertitude et de gain de productivité est traitée par K. Hansen. L'auteur présente une analyse fine des paramètres qui jouent sur la diffusion de l'innovation informatique dans les fermes d'aquaculture. Le rôle de l'innovation sur la dynamique économique d'une filière constitue une voie de recherche prometteuse en aquaculture pour laquelle le même appel à l'investissement public en recherche-développement est fait ? Ou au contraire, est-ce le caractère familial et la production de nature artisanale qui rend impossible toute mise au point de nouvelle filière de manière endogène, comme en agriculture ? La question du calcul économique du coût public est aussi abordée dans la communication de J. Ungson qui montre, au moyen d'une analyse coûts-bénéfices que le sea-ranching de la daurade japonaise au Japon ne peut être envisagé sans un soutien à l'activité et surtout des bonifications de taux d'intérêts qui influent sur le coût d'opportunité du capital.

Once the decision has been taken to start an aquaculture activity, the options developed through research define the first steps of the infant period of the production line according to the terms used by S. Shaw and M. Gabott.

Even if the viability of activities remains strongly linked to public intervention providing protection for the sector, the questions to be considered are more concerned with replacing public support by the private sector or else with identifying the key factors in development. Subsidies to production and to marketing also intervene in the protection of the sector. When referring to the case of mussel culture in Scotland and in Ireland, S. Shaw and M. Gabott note that a key factor in development is the existence of national demand supported at a later stage by export demand. Thus, cooperation between businesses in the sector allows for a critical size to be reached in growing aquaculture markets in which product differentiation has still only a small part to play.

The stage of growth is marked by questions concerned with the viability of certain types of businesses (artisanal vs industrial; intensive vs extensive; labour vs capital-intensive) or with the importance of productivity gains. Rainer Cedrins deals with the choice of an "optimal" size and that of the technical system in the case of salmon aquaculture in Scandinavia. Innovation as a factor of uncertainty reduction and productivity gain is dealt with by K. Hansen. The author presents a precise analysis of the parameters which have an impact on the diffusion of computing innovation in aquaculture farms. The role that innovation plays in the economic dynamics of a sector is a promising research area in aquaculture where innovations are developing especially in biotechnology, genetics and quality definition.

At the stage of maturity the market becomes the major question and the object of most research. In the papers presented, the case of salmon markets is discussed from the viewpoints of price formation and market development. The Norwegian syndrome shows very well how difficult it is to foresee market evolution in aquaculture products. It also shows how difficult it is to evaluate interactions between markets of different fisheries products and aquaculture.

ture où les innovations se développent notamment en matière de biotechnologie et génétique, ou encore de définition de la qualité.

Le marché devient l'interrogation majeure et l'objet de la quasi-totalité des recherches au stade de la *maturité des filières*. Dans les communications présentées, le seul cas du marché du saumon est discuté sous l'angle de la formation des prix et de l'évolution des marchés. Le syndrome norvégien est révélateur de l'incapacité de prévoir l'évolution des marchés des produits d'aquaculture. Il illustre également les difficultés que pose l'évaluation des interactions entre marchés des différents produits de pêche et d'aquaculture.

Plusieurs constats en guise de conclusion...

(i) Les communications présentées font souvent référence à l'économie des productions industrielles, avec des analyses en terme de pôle de croissance, de stratégie d'innovation privée, qui parfois, semblent éloignées de la réalité des secteurs. A l'opposé, il est peu fait mention des travaux en économie de l'agriculture qui abordent l'entreprise en terme de flexibilité, de gestion de la variabilité annuelle, de savoir-faire ou de transmission de patrimoine.

(ii) Il est à noter que la filière de la crevette est peu étudiée, alors qu'elle fournit matière à des questionnaires intéressants en terme de dynamique sectorielle, en terme de marchés ou en terme d'impact sur l'environnement comme nouveau facteur-clé de développement.

(iii) L'approche économique de l'aquaculture révèle un bon niveau d'expertise sur les secteurs mais aussi plus de constats *a posteriori* que de capacité d'anticipation. L'on rejoint ici le problème souvent abordé du manque de données fiables, durables et de l'absence de méthodes adaptées à une approche construite de l'économie de ce secteur.

Several statements to conclude:

(i) The papers presented are often concerned with the economics of industrial production with analyses in terms of economic growth, of private innovation strategies sometimes distant from the reality of the sectors. On the other hand, work in agricultural economics dealing with businesses in terms of flexibility, management of natural variability, know-how or inheritance transfer is little mentioned.

(ii) We note that the prawn sector is little studied even though it provides interesting questions in terms of sectoral dynamics, markets or in the impact on the environment as a new key factor in development.

(iii) The economic approach to aquaculture shows a good level of expertise concerning the sectors although more statements *a posteriori* than in anticipation. Here again we meet with the problem of reliable, lasting data and the lack of methods adapted to a constructed approach of this sector's economics.

# A Comparative Study of the Development of Mussel Farming in Scotland and Ireland with Emphasis on the Development of Marketing

ABSTRACT

*This paper reports a study of the comparative development of mussel farming in Scotland and Ireland. It suggests that key factors in development are the incentives to adopt suitable marketing structures and in particular the incentive for industry members to co-operate to achieve a critical mass. When government support is of a sufficient volume and in harmony with the objectives of individual growers this also acts as a stimulus to development.*

## 1. INTRODUCTION

The ability of an industry to successfully take advantage of the opportunities which are available will depend, among other factors, on the way in which it is organised, the activity of industry members and the activity of support agencies. This paper examines two industries which display significant differences as well as similarities in the manner in which growth has been pursued. It is hoped that this analysis will make some contribution toward the identification and understanding of critical success factors for aquaculture development.

The industries used in this analysis are the mussel farming industries of Scotland and Ireland. Both industries are comprised mainly of small businesses with similar problems in terms of finance, marketing and industry organisation. The paper starts with a review of the key factors identified in existing literature which encourage industry development. It then describes the pertinent features of the two chosen industries before presenting some general conclusions applicable for policy makers.

The words growth and development are often used interchangeably and in most circumstances the distinction is not important. However, in considering a particular industrial sector there is a need to distinguish simple unidimensional growth (such as growth in output) from the more permanent and pervasive development which implies both growth and changes to the technical and institutional arrangement in an industry. It is with both development and growth that this paper is concerned and with the factors which need to be considered when understanding development in aquaculture.

## 2. FACTORS ENCOURAGING DEVELOPMENT

### *2.1 Scale*

A number of different disciplines have contributed towards the identification of key criteria associated with industry development. While the evidence is equivocal some broad themes can be identified which will aid the comparative analysis. The first of these is scale.

The scale or size of an industry is important in determining the extent to which the industry or company has access to economies of scale in production or in marketing. Some authors have pointed to the role of size in predicting profitability of industrial companies and upon the observation that larger companies appear to be more profitable (Buzzell et al 1975). This would suggest a linear relationship between size and profitability. With this model the imperative from a development perspective would be to ensure sufficient scale among individual industry members. Other writers have pointed to the existence of a U shaped profitability curve with both large and small firms being profitable. The larger firms are profitable due to differentiation and/or cost advantage, the smaller due to niche marketing. This is consistent with the view of development writers such as Meier (1989) who writes that there is a critical number or size of business necessary to develop a market and secure profitable growth. The issue of numbers is different from size and is discussed further in Section 2.4 below but the role of size is also consistent with the 'big push' model presented by Rosenstein-Rodan (1943). Others such as Peters (1987) and Howard (1990) challenge the merits of size for its own sake and point toward the role of organisation and structural parameters in determining success including the extent to which businesses are driven by customer needs and are efficient implementers of appropriate strategies rather than simply questions of scale.

### *2.2 Method of Organisation*

While the foregoing suggests that many factors influence competitive success, often this literature is orientated towards situations where there is potential for the differentiation of products and services. This is not always the case as in agricultural markets and the agricultural marketing literature tends to take a different focus. While accepting the existence of niche markets for primary and value added products in aquaculture (see Shaw 1990 and Barker 1981) most products are largely undifferentiated and have to be sold in major markets where small scale operations are at a disadvantage. The small high cost producer with options to sell locally directly to final consumers, retailers or the food service sector can do so due to easy access to markets via short distribution channels offering opportunities for higher margins. By contrast the larger producer can take advantage of larger orders and access to a wider variety of customers and markets. The knowledge and skills necessary to service the larger market successfully are likely to be much greater than those in supplying local markets. Where the size discrepancy is greatest ie in a situation where there are a large number of small producers but a smaller number of purchasers or where the scope for sale in local markets is limited, there are benefits in co-operation (Barker 1981). This co-operation can take many forms but has a number of advantages such as cost savings, competitiveness and the delivery of consistent customer benefits (Shaw 1990).

### *2.3 Orientation of Development*

A third factor identified by Little (1970), Bhagwati (1978) and Kreuger (1978) is the debate concerning the orientation of development. This relates to whether the industry is orientated toward serving internal markets and pursuing an import substitution or internal market development role or whether there is an export orientation, serving international markets.

The World Bank (1991) suggests that import substitution polices as a development engine have been notably unsuccessful while polices which use an export or outward orientation have produced sustained growth and productivity by virtue of wider competitive experience and a larger market. The presence of a domestic market for the product will undoubtedly dominate the first stages of industry development. The extent to which domestic orientation can support continued growth will depend upon the size of the market and upon the activities of competitors and government.

### *2.4 The Role of Externalities*

Samuelson (1976) points to the existence of external economies or diseconomies which accrue to members of an industry. External economies consist of favourable effects upon the firm which emanate from the activity of other firms or people. Externalities can have a considerable impact upon the development path of a particular industry. Social capital such as roads, communications and general infrastructure have effects upon access to resources and access to markets. Wherever there are externalities a strong case can be made for limiting or reducing individual freedom to act in favour of a collective or collaborative approach.

One of the externalities associated with development is the role of government both in setting macro economic conditions conducive to growth and specific policies aimed at the development of particular industries. In terms of ensuring even development but development based upon sustainable growth, governments have used a development strategy based upon the protection of 'infant industries'. It is argued that a young industry faced with foreign competition will be unable to cope with the early stages of experimentation and financial pressure. As a result comparative advantage cannot be capitalised upon. However industries could be given some protection in the early phase of development and thereby achieve sufficient scale to break out of protection and compete effectively both nationally and internationally. Protection is only one form of intervention in respect of infant industry. Others may include subsidy of production, technology or marketing as well as help with investment in people or capital.

A common model used to explain the patterns of development on this basis and to identify potential industries or projects is to identify 'growth points', 'growth poles' or 'poles de croissance' (see Perroux 1950, Boudeville 1957 and Zarka 1958, see also a critique by Gravier 1958 in favour of 'forces motrices'). These growth poles or growth points have a high potential for development because their effects are felt in a wide area both geographic and economically. These growth points are associated with labour skills (or human capital), high income elasticity of demand or more importantly consist of industries with complex interrelations of intermediate goods, buying supplies from many suppliers and selling products onward to many markets. These growth points within an industry could be identified as processing capacity, marketing arrangements or co-operatives which offer primary markets to a small fragmented producer group but of sufficient combined scale to undertake specialised marketing and take advantage of available economies. This links to both the "big-push" model and to the agricultural marketing tradition described above.

## 3. RESEARCH METHODOLOGY

The themes which emerge from the literature therefore suggest that the issues of market orientation, size of individual operations, size of collective organisation and the role of government agencies are relevant to the success of industry development. In the second part of this paper we consider these factors in relation to the Scottish and Irish mussel industries. This is based upon a comparative analysis of the findings of two studies of these industries in 1991 (Shaw et al 1991 and Gabbott et al 1991). Both industries can be regarded as relatively new industries which wish to grow and both operate in broadly similar climatic conditions. The studies consisted of a series of interviews and meetings with influential parties in each industry as well as use of secondary data sources. Normal qualitative research techniques such as data triangulation were used to check the consistency of findings. Following Van Maanen (1983) we sought to come to terms with the meaning, not the frequency of phenomena. The issues involved were complex since they involved not only an analysis of events but also an understanding of the reasons why actors behaved in particular ways. This paper presents a synthesis of these results and, due to the nature of the material, conclusions are tentative at this stage.

## 4. DEVELOPMENT OF THE SCOTTISH AND IRISH MUSSEL INDUSTRIES

In Scotland production of cultivated mussels has grown from 200 tonnes in 1985 to 457 tonnes in 1990 to 1,024 tonnes in 1991. There is also a single large producer using wild stocks who produced approximately 1,100 tonnes in 1991. The development of the Scottish industry has been slow with forecast increases in output often not materialising. Production has reached a plateau with little sign of continuing growth until 1991. The majority of producers harvest less than 10 tonnes per year. These small producers are mainly part-time and enter and leave production based upon market prices.

The Irish industry by contrast has shown consistent underlying growth in production of both cultured and dredged mussels over the last five years. Output of cultured mussels has improved from 1,636 tonnes in 1985 to 3,700 tonnes in 1990 to an estimated 4,000 tonnes in 1991. There is also a strong industry based upon dredged mussels from wild or managed beds which has grown from 10,358 tonnes in 1985 to an estimated 15,000 tonnes in 1991. There are also a large number of small cultivated producers often part-time.

## 5. ANALYSIS

### *5.1 Common Development Issues*

There are a number of similarities between the two selected industries in Scotland and Ireland which provide a common set of development criteria :

i) a wide range of managerial skills and capabilities within each industry with varying degrees of understanding of marketing.

ii) a wide range of objectives between companies based upon location and size.

iii) a reluctance of major producers to become involved in cooperative ventures thereby supporting others.

iv) supportive development agencies providing advice and technical and scientific support as well as capital grants.

v) encouragement to co-operate by state agencies.

The wide variety of managerial skills and capabilities is a function of the secondary nature of mussel production for some farmers, providing additional income on a part-time basis, with little interest in encouraging growth in order to support full-time activity. Individual business growth may not be feasible in some cases due to resource constraints but discussions with industry experts in both countries suggested that this was not generally a major issue. At the same time in each industry there are larger businesses which, while still relatively small require full-time incomes and normal profit criteria. These businesses are often owned and run by individuals, not necessarily local to the area and often with considerable previous business experience. The problems of integrating a part-time approach with the objectives of the larger producers needs to be recognised. The second main theme of this section is the role of the support agencies. Both industries have government and trade support agencies. In the case of government agencies these are a channel for European Community finance as well as technical and marketing advice. The trade agencies are similar in function although there are different links to producers and to government and other agencies. The final theme of the similarities between the two industries is a recognition of the benefits of co-operation but difficulties in implementing co-operative schemes due to location factors, differing objectives of producers and the type of capital investment necessary.

### *5.2 Differences in approach*

In addition to a number of similarities between the industries there are also a number of differences :

(i) Markets and Marketing Channels

A key difference between the two industries is in access to markets and access to different types of distribution channel. This factor emerged from the research as being probably the most critical issue in the differential rates of progress in the two countries. Scotland has a domestic orientation based upon accessible intermediaries and large domestic markets. This has two features. First, there are local markets for output to local retail outlets and restaurants. Secondly, there is a widespread network of wholesalers and traders within Scotland and in the wider British market who are able to take product from growers. In turn the mussels are destined either for the British retail or catering sector or for export markets, particularly in France. Many of these wholesalers trade in a variety of fish products, often landed in adjacent areas of Scotland and are willing to deal with discontinuous quantities of variable quality. In addition in most cases, particularly on the mainland, transport is readily available to customers. Thus there is not a problem in securing outlets, nor is great skill required to supply them.

The problem faced is one of low prices as a result of variable, discontinuous quantities and limited bargaining power. This has hindered the development of a premium image for the product. The output was also not sold or promoted through the major growth outlets in multiple retailing because of image and lack of consistency of quality. This has ensured continuing low profitability in the industry which in itself acted as a disincentive to expansion. However, because these options were available, even if they were not optimal for the development of the industry, this muted the incentive to forego independence through co-operative types of organisation.

By contrast, Ireland has virtually no domestic market for its produce and does not have the same infrastructure of local wholesale intermediaries as is the case in Scotland. The industry has been dependent upon international export markets for significant development. The production areas of Bantry and Kenmare were dependent originally upon the presence of a local processor who provided a market for local produce. In the early stages the processing capacity was sufficient to encourage investment by some producers, as the processor provided a local or regional growth point allowing local development to occur. The situation changed dramatically after the failure of the processor in Bantry and corresponding fall in local prices. This left formerly dependent producers of relatively large scale in need of markets for their produce. The solution was to re-direct production to the wholesale markets of France. Initially a short term solution, favourable market conditions at the time led producers to co-operate informally in the provision of capital equipment, transport arrangements and market information to enable the placing of large volumes of Irish rope grown mussels. Subsequently a more formal co-operative structure emerged based upon shared local interests which overcame initial reluctance to co-operate. This organisation provides some central administrative support as well as marketing expertise but members are not obliged to participate. In many ways the arrangement can still be classified as informal.

This experience highlights the importance of localised growth points in providing a development path from small scale fragmented production to larger scale production formats. While the adjustment from local to international orientation disrupted Irish production in the short term, the necessary scale of production was present to allow an orderly re-orientation and provide the basis for long term growth.

In order to secure a place in the international market the Irish producers have recognised the need to develop marketing skills aimed primarily at providing consistent quality, volume and prompt delivery. French wholesalers were used to the Irish dredged mussel which was of poor quality and irregular delivery. As a result the growing cultured sector had to change perceptions in order to achieve market share. Thus the imperative for structural change to secure development was much greater in the Irish than in the Scottish case. New marketing structures, formal and informal became a prerequisite for development.

(ii) Location

A further issue is the locational factor. The Scottish industry is widely dispersed geographically, with producers in particular regions not necessarily seeing a communality of interest with their more distant counterparts elsewhere in Scotland. This was probably exacerbated by differences in grant structures in different areas with island areas typically being treated more favourably than the mainland. This has reduced the incentive for processors to locate in any one of these areas because of supply limitations. The lack of processors willing to take product and work with producers has in turn dulled the incentive for individual producers to expand. This has probably tended to reinforce the link with wholesalers rather than other growers. By contrast, Irish mussel producers are geographically clustered in the two main areas of Bantry and Kenmare. The proximity of a large number of producers operating under similar constraints has engendered a significant local identity. Individual producers have recognised shared interests especially in the provision of infrastructure and capital equipment that contrasts markedly with the Scottish experience. This 'local effect' has provided the necessary impetus to overcome traditional reluctance to co-operate and has been recognised as a major strength of the Irish industry.

(iii) Structure

The problems of size in determining the development of an industry have already been discussed. Both the Scottish and Irish industry have a range of producer sizes. In Scotland there are a smaller number of large producers with output of over 50 tonnes per year than is the case in Ireland, with the majority of Scottish farms producing less than 10 tonnes per year (Table 2). The objectives of these producers vary according to the markets which they serve and the competitive position that they hold. Nevertheless, in Scotland larger producers have been reluctant to join with their smaller counterparts in co-operative groups. Discussions with individual companies suggest that this is primarily associated with a view that the gains in such a relationship are disproportionately linked to the smaller rather than the larger member. Larger companies have developed markets, often international ones. They see future development as being less risky when under their own control. In particular they are concerned about variable quality standards among smaller producers and lack of reliability of delivery. Larger companies have developed and expanded their businesses at the same time that smaller producers have failed and left the industry. This fear of co-operation has been exacerbated by the reluctance of smaller producers themselves to join such groups. Some discussions to form regional co-operatives are still underway but currently are making little progress.

A judgement of the current situation is that the future development of the Scottish industry is most likely to come through larger companies and their satellites. A recent trend is for larger growers to develop contractual arrangements with their smaller counterparts so that the smaller producer grows and harvests to the dictates of the larger business. This is attractive to the larger growers because they have the necessary marketing expertise. They also urgently need increased production volume if they are to be able to sell to the major multiple retailers. The smaller producers are more responsive than before because of the saturation of local markets. Recent more favourable prices, coupled with grants have encouraged the entry of new producers into the industry, often people seeking full-time as opposed to part-time earnings from the sector. This has had the effect of depressing local prices and thus the small grower can no longer rely on the traditional easy marketing option. The responsiveness of smaller producers may also have increased due to the campaigns, conducted both by the trade association and the state agency, to persuade them that they are too small for successful marketing. However, the incentive for co-operation in the traditional sense has been dulled because of the rise of the larger businesses. Contract sales offer an easier marketing solution for them.

However in Ireland there have been significant steps forwards in encouraging co-operation which are of much earlier origin than those in Scotland. Much of the impetus toward co-operation has been borne of geographic proximity and the facing of similar production and marketing problems. This has produced an environment characterised by the sharing of capital equipment, in some cases the parcelling of production to ensure transportation economies and common marketing activity. This co-operation has been used to lobby government for specific funding, investment in infrastructure and to generally promote local interests. However, as in Scotland there is still reluctance to join the main trade association, the Irish Shellfish Association. Set up initially with help from BIM under the auspices of the Irish Salmon Growers Association there has been some lack of interest especially among the larger growers who would be under-represented in terms of voting power and whose local interests are already being served through the activities of the co-operatives in Bantry and Kenmare. Future development is likely to come from the activities of the larger producers in Ireland who have been able through internal organisation and marketing expertise to successfully manage the re-orientation of their industry from serving local wholesale markets to serving international markets directly.

(iv) Externalities

The similarities between the countries in relation to the activity of government have already been identified. Both governments operate through two channels, the administrative department of the civil service and a specialised agency concerned with fisheries. Both countries pursue policies to improve technical efficiency in production, provide training for staff and undertake the funding of feasibility and marketing reports. Both countries have been agents in the administration of the grants awarded to the industries by the European Commission. However, there have been differences in the extent of support, its apparent success, and in approach to the two industries.

In Ireland EC support is considered to have been crucial to the development of individual projects and for the industry as a whole (Shaw et al 1990). The two Irish development agencies, BIM and UNG worked very closely with the industry in the submission of grant applications and most applications were for a reasonably substantial scale of operations. This is linked to support for marketing and the co-operation described above. By contrast, in Scotland while many small growers also received very substantial support, particularly on the outer isles, many did not survive. Badly located and lacking the support of the organisation in marketing, they never achieved the critical volumes necessary for sustainable development.

The Irish agency has a specific aquaculture development plan of which the shellfish industry forms a part. It provides a strategic role in identifying the direction of development. The power to pursue these strategic objectives is vested in the Irish agency by virtue of its responsibility for development grants and loans which it can use to encourage or discourage development. This is either geographically through the selective aiding of facilities, sectorally through grant aiding of certain projects or on the basis of scale via the distinction in funding between pilot and commercial scale developments. BIM provides funding under an aquaculture grants scheme directed at two main production phases, pilot development and commercial development. Pilot development funding is the first stage of financial assistance. If successful the applicant can then access the comercial development scheme which in turn gives access to European Commission funds. Over the last ten years BIM has invested IR£6.7m as part of a total private investment in aquaculture valued at IR£45m. In 1989 BIM paid a total of £287,901 in grants to mussel projects alone.

The Scottish Regional Development Agency, Highlands and Islands Enterprise (formerly the Highlands and Islands Development Board) is also involved in the development of its industry. Marketing funds have been made available for the development of the industry trade association and the industry has been strongly encouraged by the agency to re-structure itself. In 1989 HIE invested a total of £410,000 in the Scottish shellfish industry ; £370,000 in the form of capital grants and £40,000 for generic promotion. However, a number of difficulties can be cited.

First, marketing funding has been primarily associated with the trade association in their attempts to develop generic promotion and higher quality standards. However, this activity has been built on an industry structure which has discouraged co-operation. The trade association has faced the problem that it could not develop a quality scheme because of a lack of consensus among farmers, due to fragmentation. The fragmentation and low levels of output further made financing the scheme very difficult. In any case, the fragmented structure of the industry and the generally poor standards of marketing limit the effectiveness of the trade association. Higher quality standards are more likely to come in a piecemeal fashion through the larger growers and their business with multiple retailers.

## 6. CONCLUSIONS

This paper has been a study of two emerging industries in the early stages of development. Conclusions can only be tentative, given that the development process is still underway. Findings are also tentative because of the difficulty in identifying the impact of different causal variables. However, from the evidence it appears that to understand the development process the roles of existing and new marketing channels must be understood with a recognition that existing institutional arrangements can inhibit as well as enable development. Co-operation to achieve development is likely when there is convergence among industry members, in their objectives, in their characteristics and in their location. Finally, state agencies can play an enabling role in development when sufficient resources are available, when their objectives are in harmony with those of the industry and where their activities are part of a strategic approach to growth and development.

# Economic Evaluation of the Red Sea Bream Ranching in Kagoshima, Japan

**Julita R. Ungson[a], Hachiro Hirata[b] and Yoshiaki Matsuda[b]**

[a]Mariano Marcos State University, Batac, Ilocos Norte, Phillippines

[b]Kagoshima University, 4-50-20 Shimoarata, Kagoshima City, Japan

ABSTRACT

*The purpose of this paper is to demonstrate the usefulness of simple economic data in assessing the economic status of sea ranching activity in preparation to any decission facing fishery policy makers, to analyze the productivity, cost structure and profitability of the major activities of sea ranching.*

*This paper considers different approaches in dealing with the cost components of sea ranching (fingerling production, fingerling release and the whole sea ranching). A total of 150 cases were examined with annual cost treated with and without depreciation, opportunity cost ranging from 0-8 % basing from the present value of investment and subsidy rates of 0 %, 25 %, 50 %, 75 % and 100 % with its effects on profit, breakeven price and production.*

## 1. INTRODUCTION

Red sea bream is considered as a prime fish in Japan because of its high demand and market value. The high price of red sea bream and wide distribution in the coastal waters of Japan will cause problems on resource depletion, if not controlled. Thus, the government has encouraged coastal enhancement or sea ranching of primary species like red sea bream.

Sea ranching activities in Japan have been initiated by the government by establishing sea ranching centers and other facilities. At present, red sea bream ranching in Japan is already in an experimental stage where the government is in the process of gradually transferring the responsibility to the private sector such as sea ranching associations and fisheries cooperatives.

Red sea bream ranching in Japan started at the Kanagawa Prefecture and followed by other prefectures. In Kagoshima Prefecture, red sea bream ranching begun in 1974. There had been numerous studies conducted regarding the sea ranching activity but focussed mainly on the technical and biological aspects. Until now very few studies, if any, had been conducted to investigate the economics of the activity.

In order to understand the present economic status of the red sea bream ranching in Kagoshima and its potential to operate in a long range term including privatization, the goal of this study is to collect and analyze economic information from different agencies involved in sea ranching.

The objective of this paper is to determine the amount of capital investment needed in sea ranching and its present value and to analyze the productivity, cost structure and profitability of the sea ranching activity.

## 2. METHODOLOGY

Data collection was conducted through surveys and interviews with different agencies directly involved in sea ranching such as fisheries cooperatives, Kagoshima Prefecture Fisheries Experiment Station, Kagoshima Prefecture Mariculture Center and the Kagoshima Prefecture Marine Ranching Association. Ideally, a long time-series costs and earnings are needed to calculate the economic performance of the activity and its changes over time. Unluckily, the available data do not allow the construction of the necessary time-series for establishing a reliable trends. Thus, the analysis focussed mainly on the 1990 financial data. The data were analyzed by conventional cost-return and break-even analyses, using profit as an economic indicator. Comparisons were made among 150 different combinations of depreciation (with and without), five opportunity costs (0, 3, 6, 7 and 8 % of investment capital) and five subsidy rates (0, 25, 50, 75 and 100 % of operating cost). Subsidy was assumed to be given equal percentage to fixed and variable costs. Throughout the analyses, economic concepts and depreciation, present value, opportunity cost and subsidy were included.

The red sea bream ranching activity is composed of two major activities of fingerling production and fingerling release, the analysis treated them seperately and as a whole. The 1990 financial data of the red sea bream ranching program was provided by the Kagoshima Prefecture Marine Ranching Association. These data were utilized in making the balance sheet of the two activities of sea ranching and also the two activities were combined together in order to see the economic performance of the whole activity.

## 3. COST-RETURN ANALYSIS

The Kagoshima Prefecture Marine Ranching Association is designated by the government as in-charge in the whole implementation of the sea ranching activity. The association considered only the out of pocket expense incurred during the conduct of the said activity as its cost components. Economic factors like the present value of the capital invested, opportunity cost, depreciation, subsidy and harvesting cost were not considered. In this analysis, these economic factors were thourougly considered at different levels except for harvesting costs and its corresponding effects on the economic performance of the activity.

## 4. FINGERLING PRODUCTION

Table 1 presents the summary of the economic performance of the red sea bream fingerling production. It shows the different approaches in dealing with the cost components specifically on depreciation (with and without), opportunity cost (0 %, 3 %, 6 %,7 %, 8 % investment) and subsidy rates (0 %, 25 %, 50 %, 75 %, 100 %). It could be noted that all possible alternatives (50 cases) in dealing with cost was dealt with from the highest case (with depreciation, with interest rate (8 %) and without subsidy) representing a typical private investment at perfect free market to the lowest case (without depreciation, without interest and with 100 % subsidy). Results showed that out of the 25 cases only six cases will generate profit and the 19 cases show a big loss where the cost component includes depreciation of the facilities used in the production of red sea bream fingerlings. Annual cost with depreciation, without opportunity cost, with subsidy rates of 25 %, 50 %, 75 % and 100 % exhibited a positive return (profit) on the investment of Y3,978,000, Y26,274,000, Y48,569,000 and Y70,864,000 respectively. Moreover, 2 cases where the annual cost includes depreciation with 3 % opportunity cost at 75 % and 100 % subsidy rates also give profits of Y7,794,000 and Y30,089,000.

Twenty five cases were also considered where the annual cost did not include depreciation cost. Results showed that only 8 cases will generate profit despite the fact that depreciatiom was not included in the annual cost. Profits are observed where the out of pocket expense, without depreciation, without opportunity cost and with subsidy rates of 0 %, 25 %, 50 %, 75 %, and 100 %.

The findings show that even depreciation is fully counted, the fingerling production becomes profitable with over 25 % subsidy rates if opportunity cost is negligible or over 75 % subsidy rate if less than 3 % opportunity cost is adopted. If depreciation is not counted, fingerling production becomes profitable without subsidy if opportunity cost is negligible or with over 50 % subsidy rates with minimal opportunity cost of 3 %. Fingerling production is highly capital intensive and it needs a lot of subsidy from the government. This implies that a great amount of money should be pumped into the activity for it to survive. Otherwise, the amount of fingerling production or the price of fingerling should be increased. However, an increase in fingerling production would entail additional expenses in terms of additional capital investment like an expansion of hatchery facilities and additional variable cost like labor cost. On the othe hand, increasing the price per fingerling should be checked by demand and supply conditions for the fingerlings. At present, mariculturists in Japan is no longer interested in fingerlings raised at mariculture centers, the major interest of which is sea ranching. This is because fingerlings from mariculture centers are inferior to fingerlings produced from private hatcheries dealing with improved varieties for mariculture. Thus, this approach is not also optimistic.

## 5. FINGERLING RELEASE

The second phase is the fingerling release activity. The same approach in the analysis of cost for fingerling production was done. A total of 50 cases, 25 cases for the annual cost with depreciation and 25 cases without depreciation as shown in Table 2. Opportunity costs also ranges from 0 to 8 % and subsidy rates from 0 to 100 %. All cases shows profits even in the highest case (with depreciation, with 8 % opportunity cost and without subsidy which exhibited a profit of Y75,719,000). It should be noted that the revenue from fingerling release was just an estimation based on the available data on the number of fingerling released which was provided by the Kagoshima Prefecture Marine Ranching Association and the recapture rate of 14 %, average weight of a 2 year old red sea bream which is 0.34 kg provided by the Kagoshima Prefecture Fisheries Experiment Station and the price per kilogram of red sea bream less than 1 kilogram at Y2,000 - Y4,000/kilogram (Ichikawa, 1990). However, a conservative estimate of Y2,000/kg was used in the computation. Further, any harvesting cost was not included in the analysis.

## 6. WHOLE SEA RANCHING

Another approach in the economic analysis was to combine the costs incurred in fingerling production and fingerling release activities as shown in Table 3. The results show that the whole activity is fairly profitable.

The 25 cases where the annual cost includes depreciation, 14 cases show positive returns (profits) while 11 cases will incur losses. The whole red sea bream ranching activity becomes profitable in the case where the annual cost includes depreciation, if opportunity cost does not exceed 3 % regardless of the amount of subsidy given and also the case where the opportunity cost is 6 % with subsidy rates of 50 % and above, likewise at 7 % opportunity cost with 100 % subsidy rates are adopted.

The other 25 cases where the annual cost without depreciation were considered, 16 cases will generate profits while 9 cases will experience losses. If depreciation is not accounted, the whole red sea bream ranching is profitable with opportunity cost not to exceed 3 % even without subsidy. Further, profitable cases of 6 % opportunity cost with subsidy rates of 25 % and above or 7 % opportunity cost with subsidy rates of 75 % and above.

## 7. BREAKEVEN ANALYSIS

The breakeven price and production of fingerling production activity are shown in Table 4. The breakeven prices of fingerlings where the annual cost includes depreciation ranged from Y0 to Y74/pc while in cases where the annual cost without depreciation, the breakeven price per fingerling ranged from Y0 to Y63.

The present situation of Y18/pc on the average is a case where the annual cost includes depreciation at 0 % opportunity cost and 25 % subsidy rate or a case where the annual cost does not include depreciation at 3 % opportunity cost and 50 % subsidy rate.

The breakeven production was also computed at Y12/pc and Y32/pc. Breakeven production at Y12/pc ranged from 0 to 23,813,583 pieces where the annual cost includes depreciation. However, if depreciation is not included on the annual

cost the breakeven production ranged from 0 to 20,357,583 pieces. Nevertheless, if the price per fingerling is Y32/pc breakeven production ranged from 0 to 8,930,094 pieces if the annual cost includes depreciation but if it did not include depreciation, it ranged from 0 to 7,634,094 pieces.

Table 5 shows the breakeven analyis of the red sea bream fingerling release activity in Kagoshima, 1990. The analysis was also done using the same approach in fingerling production. The case where the annual cost with depreciation the breakeven price ranged from Y0 to Y674 per kilogram. The breakeven production with depreciation at Y2,000 per kilogram ranged from 0 to 19,261 kilograms. However, in the case without depreciation it ranged from 0 to 18,806 kilograms.

Table 6 presents the breakeven analysis of the combined activity of the red sea bream ranching. With depreciation, the breakeven prices ranged from Y0 to Y5,677 per kilogram while the breakeven prices without depreciation ranged from Y0 to Y4,935 per kilogram. These ranges are plausible at current market condition.

The breakeven production with depreciation at Y2,000 per kilogram ranged from 0 to 162,142 kg. While 0 to 140,952 kg for the production without depreciation. The upper sides of the production are 2.4 to 2.8 times higher than the present total production of 57,120 kilograms. However, this is impossible unless a great improvement occurs in the recovery rates.

Even assuming 20 % increase in recovery rates, the upper limit of target production is 68,544 kg. This implies that the sea ranching operations are economically viable at 3 % opportunity cost and 25 % subsidy rate, at 0 % opportunity cost and subsidy rate or at 6 % opportunity cost and 100 % subsidy rate with depreciation whereas viable at 3 % opportunity cost and 0 % subsidy or at 6 % opportunity cost and 100 % subsidy when depreciation is excluded.

Depreciation is the cost for continuity of the operation and opportunity cost can be regarded as the interest on capital investment whereas subsidy is a transfer payment from government to public activities in terms of price support etc. thus reducing costs or increasing the revenue associated with economic activities. The fingerling production was more capital intensive than fingerling release activity while the former's economic alternatives were less than the latter's that is excluding harvesting costs. The result is more desirable when both fingerling production and release activities were combined.

Although the harvesting cost was excluded due to the fact that it varied widely among commercial and recreational fishermen, the result implies that many economically viable alternatives for red sea bream ranching in Kagoshima exist. This means that the current sea ranching activity in Kagoshima is sound as a non-profit economic activity. The current performance represents that the operation is vital at 100 % subsidy on operating cost even if 6 % interest on investment capital were charged, opportunity cost with depreciation at over 25 % subsidy on operating cost without borrowed capital investment or without depreciation at over 25 % subsidy on operating cost with less than 3 % interest on capital investment.

In summary, the breakeven analysis is simple and vital to consider public or quasi-governmental or non-profit organization on economic activity such as sea ranching as well as profit maximizing private enterprise's activities. Any economic activity involves costs and revenue. If the revenue exceeds total costs, any economic activity could be justified in particular for the non-profit and economic activity. Conditions for justification, however, changes widely according to political as well as economic environment. These environmental differences are treated as plausible variations in depreciation, opportunity cost and subsidy in the analysis.

## 8. CONCLUSION

In order to realize the idea of privatization of the sea ranching activity, it is imperative to reduce the cost of fingerling production. This could be materialized by increasing the survival rate of fingerlings. Thus, researches on sea ranching should now focus on this aspect like genetic improvement of brooders that will yield high survival rate of fingerlings. Also, a research on how to improve the recapture rate by exploring on the optimum release size of fingerlings that would minimize rearing cost during the intermediate culture, high survival rate after release and high recapture rate.

# Adoption of Innovations in the Norwegian Aquaculture Industry - Perceived Attributes

**Kåre Hansen**

Norwegian Institute of Fisheries and Aquaculture, P.O. Box 2511, N-9002 Tromsoe, Norway

ABSTRACT

*The paper discusses which attributes of innovations are perceived by aquaculture farms as important in the adoption process. When one peruses the adoption research literature, one may be surprised at how little effort has been devoted to analyzing "innovation" differences (that is, in investigating how the properties of an innovation affect its rate of adoption). This type of research can be of great value to change agents seeking to predict the reactions of their clients to an innovation, and perhaps to modify certain of these reactions by the way they name and position an innovation and relate the new idea to existing beliefs.*

*The paper discusses empirical findings from a study of Norwegian salmon farms who have adopted a unique external marketing information system. The Norwegian aquaculture industry consists of about 700 small farms located along the Norwegian coast. To provide the farmers with market information, a farmer-owned company has developed a computerized market information system.*

*We have carried out a study on the early adopters of the system to explore which attributes of the innovation are perceived by the farms as important in the adoption process.*

*The data is gathered from a questionnaire sent to early adopters of the system. We have used the factor analysis approach which is a common approach to the interpretation of scaling type instruments. This technique explicitly addresses the question of what distinct factors are being recorded for the sample unit.*

## 1. INTRODUCTION

This paper discusses the attributes of innovations that are perceived by Norwegian aquaculture farmers as important in the adoption process. When one peruses the adoption research literature, one may be surprised with how little effort has been devoted to analyzing "innovation" differences (that is, in investigating how the properties of an innovation affect

its rate of adoption). This type of research can be of great value to change agents seeking to predict the reactions of their clients to an innovation, and to modify certain of these reactions by the way they name and position an innovation and relate the new idea to existing beliefs.

In organizational innovativeness studies, a highly quantitative approach to data set is used. The dependent variable of adoption behaviour is typically measured as a composite score, composed of the adoption of from ten to twenty innovations. The innovation process for each such innovation is thus submerged through aggregation into an overall innovativeness score for each organization. As a result, differences among the innovations are lost (Rogers, 1983).

Our approach, as suggested by Downs & Mohr (1976), is a single-innovation study. The innovation we have studied is an information technology innovation ; "Marinet".

This innovation consists of two parts. The first part is an external marketing information system which provide the farmers with different kinds of marketing information. Via a telephone connection, they can log on to the system from their personal computer in search for marketing information from a database updated by an organization owned by the farmers.

The second part is a management information system. This system makes it possible to the users to improve their control of the production process and provides the farmers with information for management decisions.

This innovation was chosen as an example of information technology (IT). In our context IT is interesting because it has an affect on both the external contacts and relationships of the organizations and on different levels within the organizations (Rousseau, 1985).

The innovative Norwegian aquaculture industry are adopting a lot of new technologies as a mean to sustain their competitive advantages. Knowledge about factors which inhibit or facilitate innovations are therefore crucial in that process.

## 2. THEORY

While a great deal of research has been concerned with the determination of differences between adopter categories, there has been relatively little research conducted in relation to the differences between innovations. The characteristics or attributes of innovations can have a pronounced effect on their rate of adoption, and consequently this is an important area of research. We will stress that it is the potential adopters perception of the attributes of an innovation which is the most important dimension in relation to the rate of adoption. It is not the perception of attributes by experts in the particular field or by the innovating organization itself that is important.

It can be assumed that perception of the attributes of an innovation will vary between different groups or organizations as their situations change. It is therefore generally accepted that perception is, partially, situationally determined. An additional reason for interest in perceived attributes of innovations is as a basis for a standard classification scheme for types of innovations on which they could be compared, and which would provide a stronger basis from which to generalize on the results of particular studies.

Wilkening (1954) in the United States, and Emery, Oeser and Tully (1958) in Australia made some of the earliest attempt to determine which attributes of innovations affect the rate of adoption. These studies examined the diffusion of various agricultural innovations within particular communities. By mapping the differential rates and patterns of acceptance the authors determined which attributes affected diffusion most. Mort and Cornell (1941) undertook the first study on educational innovations where this approach was adopted.

It was mainly attributes that where economic in nature that where focused on in these three studies, for example expected profitability, expenditure required and risk associated with adoption.

Barnett (1953) extended the research and suggested that material innovation would have a higher rate of adoption than non-material innovation because they are more easily communicated and their utility is more demonstrable. Menzl (1960) ranked medical innovations on the basis of his estimates of their communicability, risk and persuasiveness.

Studies from research traditions like sociology, medical and rural sociology, anthropology, education, geography and marketing have, to date, examined a large number of attributes of innovations. These have ranged from those which are

highly specific to those that have highly generalised attributes (Lancaster & Taylor, 1986). Clearly as the rationale for the study of attributes of innovation lies in the desire to develop a standard of classification scheme for innovations, the more generalised and more universally applicable attributes are of greatest interest.

Rogers (1983) has, to this end, proposed five innovation attributes which, he believed, were as comprehensive, mutually exclusive and universally relevant as possible. The selection of these five characteristics was based on past writings and research. The attributes are :

- *Relative advantage*
- *Compatibility*
- *Complexibility*
- *Trialability*
- *Observability*

Each attribute is discussed in detail in the following section.

### *2.1 Relative advantage*

Relative advantage is the degree to which an innovation is perceived as being better than the idea it supersedes. The nature of the innovation largely determines what specific type of relative advantage (often expressed in economic or social terms) is important to the adopters, although the characteristics of the potential adopters also effect which dimensions of relative advantage are most important.

The adoption and diffusion of an innovation is an uncertainty-reduction process. When organizations pass through the innovation-decision process, they are motivated to seek information in order to decrease uncertainty about the relative advantage of an innovation. They want to know the degree to which a new idea is better than an existing practice. In the search for innovation-evaluation information, relative advantage is therefore often the most important element.

### *2.2 Compatibility*

Compatibility is the degree to which an innovation is perceived as consistent with the existing values, past experiences, and needs of potential adopters. An innovation that is more compatible is less uncertain to the potential adopters.

An innovation that is incompatible with the organizations values and beliefs will often blocks its adoption. Many change agents face difficult assignments in promoting innovations that run counter to strongly held values.

An innovation may be compatible also with previously adopted ideas. Previous ideas or practice is a familiar standard against which the innovation can be interpreted, thus decreasing uncertainty. The rate of adoption of an innovation is effected by the old idea that is supersedes. However, if the innovation was completely congruent with existing practice, there would not be an innovation for the adopting organization. Such a very highly compatible innovation is still useful if it is seen as the first step in a series of innovations that are to be introduced sequentially.

The compatibility of an innovation is also indicated by the perceived needs that it meets by the clients. Change agents need to determine the needs of their clients, and then recommend innovations that fulfil these needs. The difficulty then lies in how to reveal these needs. Clients may not recognize that they have needs for an innovation until they are aware of the new idea or of its consequences.

### *2.3 Complexibility*

Complexibility is the degree of difficulty involved in undertaking and using a particular innovation. Potential adopters will perceive an innovation at some point on a complexity-simplicity continuum. The complexity associated with an greater innovation the lower, it is hypothesized, will be the rate of adoption of the innovation.

### *2.4 Trialability*

Trialability is the degree of which an innovation can be used on a trial basis before adoption needs to be confirmed. An innovation that is trialable is less uncertain for the adopter. The early adopters can not rely on others evaluation and experience in their adoption-process. The trialability is therefore perceived as more important for relatively early adopters.

### *2.5 Observability*

Observability is the degree to which the benefits (relative advantage) and other attributes of an innovation are apparent to non-adopters. The results of some ideas are easily observed and communicated to others, whereas some innovations are difficult to describe to others. It is suggested that observability will be positively related to rate of adoption.

Technological innovations consists of two components. The hardware aspect is the technology as materials or physical objects. The software aspect is the information base for the tool which enable the adopter to use the innovation as a problem solver. There is, in other words, an interaction between the tool and the way it is used.

Usually the software component of a technological innovation is not so apparent to observation, so innovations in which the software aspect is dominant possess less observability, and usually have relatively slower rates of adoption. A higher degree of trialability can compensate for less degree of observability. New technology as information technology will have a dominant software aspect. Knowledge about the relationship described above is therefore essential to change agents.

## 3. METHOD

The selling firm of "Marinet" provided us with a list of addresses of aquaculture farms that had adopted the system until march 1991. At this stage of the diffusion process, 68 farms has adopted the system. A questionnaire and introductory letter was sent to the adopters and it was given one week deadline for answering. As a respondent "teaser", a lottery ticket and pre-paid envelope was enclosed the questionnaire. This resulted in 59 % respondent rate without any reminder, which we consider as an outstanding rate given normal rate in postal questionnaires to be 20 to 30 % (Wärneryd *et.al.*, 1990). To our repeated reminders the respondent rate increased to 74 %. Table 1 explains the population and return rate of the questionnaire.

Through contact with the adopters who was not willing to answer the questionnaire, it was our impression that they do not differ significantly from the respondents in any aspects of rate of adoption, adoption behaviour or perception of innovation attributes. On that ground we have no reason to suspect systematic errors in the data.

### *3.1 Dependent variables*

The rate of adoption or adoption behaviour is generally measured as the number of organizations or individuals who adopt a new idea in a specified period. We have developed two measures on adoption behaviour which we have used in the questionnaire :

- *time when the innovation was adopted (year and month).*
- *to which degree new technology is perceived as an opportunity for improved efficiency in the production process.*

### *3.2 Independent variables*

Perceptions or concepts typically cannot be measured directly, but may be approached via a set of tests, scales, and other measures (Kleinbaum *et.al.*, 1987). This set of measures will be interrelated and contribute in varying proportions to the perception or concept itself. Based on the five innovation attributes ; relative advantage,

compatibility, complexibility, trialability and observability, we developed a set of 12 statements in an attempt to measure these characteristics. The statements are reproduced in table 2.

The respondent was asked to indicate the extent of their agreement or disagreement by writing the number that best described their reaction to the statements [strongly agree (1), agree (2), neither agree nor disagree (3), disagree (4), strongly disagree (5)].

The most common approach to the interpretation of this Likert summated scaling instrument is that of factor analysis (Green *et.al.*, 1988 ; Baron, 1990). This technique explicitly addresses the question of what distinct characteristics (factors) are being recorded for each sample unit. It specifically avoids the danger of presuming the relationship between scales and factors, and even avoids presumptions about the number of factors perceived by respondents. Factor analysis seeks sequentially, linear combinations of the original variables which explain as much variation in the original data set as possible, and yet are constrained to be independent of each other factor.

After the factor analysis, it is necessary to examine the contributions of each of the factors to the rate of adoption and adoption behaviour. This relationship is explored by using multiple regression.

## 4. RESULTS

We have indicated that one important type of variable in explaining the rate of adoption of an innovation is its perceived attributes. In Rogers (1983) there is a summary of investigations of perceived attributes of innovations and their rate of adoption. Almost every one of these studies reports a positive relationship between attributes (relative attributes, compatibility, complexibility, trialability, and observability) and rate of adoption.

In addition to these perceived attributes of an innovation, other variables such as (1) the extent of change agents promotion efforts in diffusing the innovation, (2) the nature of the social system, (3) the nature of communication channels diffusing the innovation at various stages in the innovation-decision process, and (4) the type of innovation-decision process, effect an innovation's rate of adoption. In this paper we are concerned about the perceived attributes of the innovation. These attributes are derived from a factor analysis of a set of statements (table 2).

Mathematically there are as many factors as original variables or statements. The selection procedure is, however, based on the criteria of maximizing variation explained. Thus, if there are only few real dimensions in the variable set, the first few factors will explain most of the variability. At the other extreme, if each original variable was independent, then all factors would be required to explain their variability.

The resultant factors are each linear combinations of all variables. To assist in interpretation of the meaning of each factor a further mathematical procedure is added to the analysis. This is known as "rotation", and involves a mathematical transformation so that each factor lies as close as possible to a distinct set of original variables. In the two-dimensional case this is equivalent to rotating the conventional vertical and horizontal axes about the origin ; hence the name.

It seemed appropriate to examine the data set with this kind of technique to establish how many real dimensions of perception exists in the respondents minds, and select rationally the appropriate variables and their relative contribution to each revealed factor. The specific method used was a principal components extraction with orthogonal (Varimax) rotation.

The number of factors extracted is chosen on the basis of the Kaiser criterion and by means of the Scree test (Hair et.al., 1990 ; Norusis, 1990 ; Stewart, 1981). The Kaiser criterion argues that any factor which explains more than 1 % of total variation should be retained since it performs better than an original (standardized) variable. In this data set, the Kaiser criterion suggested 5 factors. The number of factors excluded the use of Scree test which would have been an appropriate statistic if the Kaiser criterion had suggested an excessive numbers of factors.

The next stage of the analysis was to rotate the original factor solution to a configuration in which each factors loads heavily on as few variables as possible. The Varimax rotation achieved this while preserving orthogonality of the factors and is reproduced in Table 2.

In this table each factor is identified by enclosure of significant loadings in a box, terminated by a horizontal line which is drawn across the table to delimit the scales contributing to that factor (loadings scores 0,3 are supressed in the table). Each block of scales appears in a numerical sequence from Factor 1 through to Factor 5.

Naming or identification of the five factors remains subjective and is based on the scales contributing to the factor in question.

It is apparent that a "cost-benefit orientation" factor is substantially reproduced in Factor 1. This is confirmed when an inspection is made of scale descriptions in the matrix of rotated factor scores shown in table 2. The factor makes the largest contribution (25 %) to explaining the total variation in the data set.

It appears that "Complexibility" is reproduced in Factor 2. The factor correlates to which degree the innovation was perceived as difficult to use in the beginning, to which degree an introductory course was necessary or not, and valuation of uncertainty how the innovation was anticipated to effect on the working procedures. The factor explains 10 % of total variation in the data set.

By examining the contributory scales, Factor 3 might be labelled "Knowledge of consequences" since the scales are mainly about valuation of economic consequences and felt scepticism to the innovation in the early adoption phase. The factor contribute in explaining 12 % of total variation in the data set.

Factor 4 contains scales of to which extent information technology (IT) is used to other functions in the firm and to which degree the users have positive experience in using IT previous to the adoption of "Marinet". Factor 4 might, therefore, be named "Previous experiences" and explains 15 % of the total variation.

By inspecting the scale descriptions on the fifth factor, it might be labelled "Trialability" since the scale mainly correlates to the degree the innovation was seen in use within other firms previous to adoption and how decisive the opportunity to test the system in advance effected the adoption decision. The factor explains 9 % of the total variation in the data set.

The five factors above explain a total of 71 % of the variation in the data set.

### *4.1 Juxtaposition with Rogers framework*

In table 3 we have compared the factors derived from the data set with the attributes outlined by Rogers (1983). The juxtaposition shows that the perceived attributes of the innovation "Marinet" to a great extend are dimensions of Rogers universally attributes.

The "Cost-benefit orientation" factor is a subdimension of relative advantage. It is hypothesized in the research literature that the higher the perceived relative advantage of an innovation is, the higher is the rate of adoption of that innovation (Grønhaug, 1991).

The factor "Previous experiences" is sorting under the attribute of compatibility. The degree of compatibility of an innovation can both inhibit and facilitate adoption. If the new idea is completely compatible with previous practice we are no longer facing an innovation. Such a very highly compatible innovation is still useful if it is seen as the first step in a series of innovations that are to be introduced sequentially.

"Knowledge of consequences" is a dimension of the attribute observability. Some innovations are easily communicated to others, whereas others are difficult to describe and communicate to non-adopters. It is, however, suggested in the literature that the innovation's trialability is able to compensate for some of the negative relation which is inherent in less observable innovations. The factors "Trialability" and "Complexibility" are labelled the same as Rogers attributes. Therefore they are not further discussed.

### *4.2 The influence of attributes on adoption behaviour*

We will now examine the contribution of each of the five factors to the adoption behaviour. Because there are five explanatory factors, a single graphical exposition is not possible. We are using multiple regression to explore the relationship.

Table 4 presents the regression results with explanatory variables listed in order of entry to the regression. The factor "Knowledge of consequences" is the only factor that explains time of adoption. The explanatory power is 19 %. No other factors are significant and contribute nothing to explanatory power. The regression shows, in other words, that the perceived observability of an innovation leads to less uncertainty and facilitate adoption of the innovation in question.

An another measure on adoption behaviour is to which extent new technology is perceived as an opportunity for improved efficiency in the production process. Table 5 shows that in this case the factor "Previous experiences" contribute to the explanatory power ($R^2 = 0,18$). We can therefore conclude that if the perception of new technology as an opportunity leads to actual innovative behaviour, compatibility with previous experiences plays a crucial role in that process.

## 5. CONCLUSIONS

In this study we have revealed those perceived attributes of a information technology innovation which facilitate its rate of adoption. The study of perceived attributes are important because it is the receivers'perceptions of the attributes of innovations, not the attributes as classified by experts or change agents, that affect their rate of adoption. Like beauty, innovations exists only in the eye of the adopter. And it is the adopter's perceptions that influence the adopter's behaviour.

The analysis extracted 5 factors in our data set. The five perceived factors are :

- "Cost-benefit orientation"
- "Complexibility"
- "Knowledge of consequences"
- "Previous experiences"
- "Trialability"

A juxtaposition with Rogers framework suggested that these factors to a great extend are dimensions of his universally attributes.

In the subsequent analysis we have examined the contribution of each of the factors to rate of adoption and adoption behaviour. This analysis revealed that "Knowledge of consequences" was the only factor that explained time of adoption. The factor "Previous experiences" contributes to the explanatory power of adoption behaviour.

In most of the reported studies in Rogers (1983), perceived relative advantage was the single most important attribute that facilitate adoption. Surprisingly, perception of this factor is not significant and contribute nothing to explanatory power of innovative behaviour in our data set. On the other hand, dimensions of relative advantages are inherent in the factor "Knowledge of consequences".

When organizations pass through the innovation-decision process, they seek information in order to decrease uncertainty. This research shows that perceived attributes affect an innovation's rate of adoption. New technology as the information technology innovation studied here, tends to have a dominant software aspect. Perceived compatibility with past experiences and needs and perceived observability tends to be important for the organizations adopting information technology innovations.

This knowledge is essential to the change agents promotion efforts in diffusing innovations.

# Scandinavian Aquaculture in a Global Perspective. A Study Concerning Structural and Marketing aspects

**Rainis Cedrins**

Swedish University of Agricultural Sciences. Department of Economics. Box 7013. S-750 07 Uppsala. Sweden

ABSTRACT

*Researchers at the Swedish University of Agricultural Sciences have been engaged since 1977 in research concerning economy and marketing in aquaculture. Consequently a lot of empirical materials have been presented and an immense network of personal contacts has been built up. This is the base for a three-year research project that will start in 1992. The purpose of the project is to analyse the behaviour of aquaculture firms in Nordic countries outside the different models in economic theory.*

*A special stress will be put on Porters and Ohmaes models concerning competition analysis, Mc Carthys and Kotlers marketing management models and different models concerning entrepreneurship, creativity, the innovation process and theories about personal networks.*

*The study will result in a normative model on how Scandinavian actors in aquaculture should act in the future market that is characterized by turbulence and change.*

## 1. BACKGROUND

A research project is established at the Swedish University of Agricultural Sciences, Department of Economics, concerning Scandinavian aquaculture in a global perspective. The stress is put on structural and marketing aspects.

The aim with the project is to explain how the different aquacultural firms in the nordic countries have acted or presented lack of activity concerning economic models in business development, marketing and competition strategies. Important concepts in the study are innovation, entrepreneurship and creativity. The main question will be what these concepts have mattered for the aquaculture in the different nordic countries.

It must be noticed that the study is not finished. However some interesting aspects that have been observed in the first stage will be discussed in this paper.

## 2. AQUACULTURE IN SCANDINAVIA

The Scandinavian countries are the first in the world regarding farmed production of salmonid fish weighing more than one kilogram. The produced quantity can be regarded in table 1.

Of Norways total produced amount 135 000 tons were exported 1991. As a comparison can be mentioned that the total catch of salmon in the Baltic sea is annually about 4 000 metric tons. The Norwegian aquaculture is dominating in Scandinavia and the other Nordic countries are to a high degree affected of the development in Norway. The production development in Norway is very remarkable as can be seen in table 2.

The primary production turnover was 5 milliard norwegian kronor 1991. The development has been affected of natural advantages as the golfstream and a long coast with sheltered fiords. Also an existing infrastructure is an important factor.

The primary production is nearly totally based on the family firm. About 1 000 such firms today account for most of the production. The technique is rather simple and the investmentcosts are low. The Norwegian regional policy is so formulated that only the local inhabitants have been able to receive permission to establish net cage cultivation at the coast.

However table 2 shows a significant break1991. Until 1991 the Norwegian aquaculture developed new markets and found selling possibilities for all the increasing production. Mainly it was due to the marketing efforts. These efforts were financed by producers and exporters who together put 3 percent of their total turnover in a market fund. About 90 percent of the farmed fish is exported to about 20 countries.

However the world supply of salmonide fish increased rapidly in 1989 and 1990. The catch of pacific salmon was very big and several countries increased their production of farmed fish. The profitable export market for Norwegian salmon in USA was closed due to new american import fees and duties. Consequently the Norwegian Fish Farmers' Sales Organization (FOS) had to freeze a large amount of the farmed fish. However this "frozen salmon mountain" increased drastically. It was 37 000 metric tons in autumn 1991 and cost a lot of money. In November 1991 FOS was facing bankruptcy. Today the Norwegian farmers situation is rather chaotic and they have to build up a new market organization.

## 3. CAGE CULTIVATION AND LANDBASED CULTIVATION

Although the situation in Norway today the fact is that Scandinavian fish farming has been very successful during the last ten years. In Denmark about 460 farms cultivate 35 000 metric tons of portionsized rainbowtrout (0,2-0,3 kg) in ponds. Most of the salmon and big rainbowtrout is however produced in net cages by family farms. However it is astonishing that a great amount of the resources concerning research development and education is concentrated on the so called landbased forms of cultivation today. The landbased forms of cultivation are largescale and dominated by big firms. In a theoretical sense the landbased forms have advantages compared with net cage technique. However the former have not commercially been successful in Scandinavia.

In Sweden big plants have faced bankruptcy and at last been sold symbolically for one Swedish krona. All the four Swedish nuclear power plants have ran fish farms or have had fargoing plans to do that, in order to get use of the hot waste water. But today all this kind of production is liquidated.

In Iceland a lot of big land based plants were established during 1985-1990. Today all these have gone in bankruptcy and nearly one milliard american dollars is lost. These plants were judged to death already from beginning because the financial and running costs were to high in relation to production.

In Norway some people today speak about the third generation of landbased plants and that these will be successful contrary to the earlier generations that have not shown any success. Part of the explanation why the landbased plants have not shown any success is due to the fact that the technique has failed when the production has been performed on a commercial scale.

However there are also reasons to assume that the failure is depending on imperfections concerning entrepreneurship, marketing analysis and competition strategies. These aspects will here be discussed.

## 4. THE ENTREPRENEURIAL CONCEPTION

Entrepreneurship still is a concept that lacks a general definition. The differences in opinion mainly have reference to the abilities and functions concerning the entrepreneurial concept. If entrepreneurship is a production factor or if it is at all a need for such a concept. The Austrian school does not regard the entrepreneur as a production factor but a "positive function". The market economy could not work without that function (Shand 1988).

Kirzner (1978) emphasize that the entrepreneur is not only a product of a market economy, but only the market economy with its profit mechanisms can create entrepreneurs. He means that the entrepreneurship is a kind of arbitrage. Profit opportunities arise when the prices at the product market are not adapted to the prices at the resource market. Something is sold to different prices at different markets due to lacking information between these markets. The entrepreneur takes advantage of this situation and redistributes the resources towards new balance. Kirzner means that the chance to get profit results in the entrepreneur's activity.

Also Schumpeter (1961) consider that it is the profit that stimulates entrepreneurship. Profit is, however, the result of an innovation. New technology and new products create imbalance on the market. Kirzner on the other hand stress the balance in action of the entrepreneur.

Gilder (1984) considers that the entrepreneur is both an discoverer of opportunities and a creator of opportunities. The entrepreneur not only use capital but is also a capital creator. Gilder means that the real entrepreneur does not begin with the objections but concentrates on activity. However, the activity must be performed in the right time. "Timing" is a very important concept for Gilder.

Bjerke (1989) has a definition that entrepreneurship is to force an idea or an investigation towards a new business project. It does not matter how splendid a business idea is, if nobody is able to conduct this idea through difficulties and traditions towards realization.

Johannisson (1984) stresses that creativity is a vital component in the concept of entrepreneurship. He means that entrepreneurship just like artistic activities is a question of breaking established patterns. It is to understand a new or revised pattern.

Hammarkvist, Håkansson and Mattsson (1982) stress the cooperation. They consider that "Entrepreneurs" act to get interplay between market and society, break standards and build up new things. This is often performed through creating and developing personal networks. Relations and network positions are often very important for a firm.

Hubendick, Johannisson and Josefsson (1982) discern three stages in the development of a firm. An innovative stage, a growth stage and an administrative stage. The innovative stage is characterized of creating ideas. It is in this stage that the creative investigations are found. The actors are more interested in technological aspects than marketing aspects.

In the growth stage the product idea is transformed to the business idea. The interest will change towards marketing aspects and the aim is to develop the firm. It is in this stage that the entrepreneur will be most useful.

In the administrative stage the firm has reached stability. Effectiveness, coordination and regulations are the main conceptions in this stage.

Hubendick, Johannisson and Josefsson mean that the entrepreneur is no friend of regulations. He must not necessarily be a good administrator, planner and delegator. Regarding those aspects Drucker (1985) has another opinion. Drucker speaks about "entrepreneurial management" as a most important conception. Without a management the new firm will not survive. Then it does not matter how successful the products are or how easy the firm acquires capital.

To manage a new established firm the following aspects are required in Druckers opinion :

i) Concentration on market.

ii) Liquidity and capital planning.

iii) A based management before the real business has started.

iv) That the entrepreneur makes decisions concerning his branch, his own role and his relations.

Drucker means that an entrepreneur who establish a firm shall not primarily concentrate upon profit. Cashflow, capital and control are more important conceptions. The new firm need liquidity analysis and liquidity prognosis. The circumstances that the new established firms in USA have got better on during the last years than before can be explained by the fact that they put more stress upon the above described aspects. A significant exception is the high technological firms.

Drucker means to sum up that the organizational aspects must be involved in the entrepreneurial concept.

Casson (1982) takes a further step and defines the entrepreneur as a person who is a specialist in making decisions concerning scarce resources during uncertain conditions. Casson means that the entrepreneur is a clever negotiator and activ planner. The organizational aspect in the entrepreneurship is of the same importance as the technical or marketing aspect.

The ability to combine is a quality that many authors emphasize concerning entrepreneurship.

Siropolis (1982) means that entrepreneurship is the available capacity for innovations, investments and expansion on new markets, new products and new forms of technology.

Hubendick, Johannisson and Josefsson consider that the entrepreneur often works with technology as well as economy and marketing unlike the investigator who put the main importance on the technological qualities of the product and often make a wrong estimation concerning the marketing aspects.

Concerning the risk, most authors consider that the entrepreneur is a risktaker but not a gambler or a speculator.

Bjerke means that the entrepreneur works with calculated risks. He is aware of what he has to lose but at the same time he takes the responsibility for a mission that seems impossible for others.

Nyström (1990) has formulated the situation in the following way :

"Our research indicates that entrepreneurship is a balancing act between strong risk creation and strong risk elimination. It is in the timing and balancing of risk that the successful innovative entrepreneur excels".

## 5. ENTREPRENEURSHIP AND AQUACULTURE. SOME INDICATIONS.

Cultivation of salmon in net cages in Norway is an example of successful entrepreneurship. A totally new activity is built up based on biological and infrastructural advantages. The technique did not exist before 1970. In terms of theory of innovation and entrepreneurship this form of aquaculture has become a profitable business.

To some extent it has been a question of "shooting for the moon" in Gilders terminology. This can be exemplified by the Norwegian establishment on the American salmon market 12 years ago. Probably it is a question of the "impossible" because USA is the leading nation in the world concerning pacific salmon fisheries. Pacific salmon is a competitor to the farmed atlantic salmon and big rainbow trout in Scandinavia. 1990 the global catch of atlantic salmon was about 800 000 metric tons. The american part was more than half of this amount.

Now the salmon fishing in America is performed mainly during the period April - November. During the other months there is no supply of fresh salmon. The Norwegian and partly Swedish fish farmers have taken advantage of this situation. The farmed fish can be slaughtered and transported fresh by air to USA during the whole year. The Norwegian farmers' marketing organizations have succeeded to profile the product. "Norwegian Salmon" today is a concept that the American consumer associate to "high mountains and deep fiords". Another effect is that many American restaurants have been forced to take up Norwegian salmon on the meny also during the period April - November when there is a supply of fresh pacific salmon because of consumers desire. These kind of export efforts have however been performed with a tendency of risk elimination to cite Nyström.

The risk elimination means that the Norwegian fish farmers try to develop markets in several countries. This fact is very important today when the American lobby of Pacific salmon interests have managed to restrict the Norwegian export. The Norwegian fish farmers were accused with dumping and the US auhorities determined in February 1991 to charge the Norwegian fishfarmers with a 24 percent dumping fee and a 2,27 percent subsidizing custom. The last word is not said in this affair. The Norwegian government has made a protest in GATT. GATT is now performing an investigation. Today only a few 100 kg of Norwegain salmon is exported to USA. Before 1991 the annual export was about 10 000 metric tons. Today France, Germany and Denmark are the largest importers of Norwegian salmon. All the successful Norwegian export have been realized through cooperation between small producers, the marketing organizations and the society. All this is entrepreneurial concepts to cite Hammarqvist and Johannisson. New markets with new requirements have been developed but all the "critical factors" that Drucker mentions have been solved.

The last two years however the production increase of farmed salmon has been so enormous that the farmers have been forced to "check". The smolt production and foddering have been limited. Part of the ready production has been freezed. These actions have however not been enough and in November 1991 the Norwegian Fish Farmers Sales Organization (FOS) went in bankruptcy due to a bad liquidity. Perhaps it has also been a tendency that the administration concerning regulations and restrictions has grown too much at the expense of marketing and product development in Norwegian fish farming. That is a tendency that Drucker warns against. Today however a new organization is built up with less regulations.

The fact that the land based plants have not succeeded in spite of big investments can partly be explained by the fact that the actors' have remained in the "innovative stage" in Hubendick's - Johannisson's - Josefsson's model. The actors became fascinated by the new technique and neglected to perform analysis concerning the marketing process. One of the landbased Norwegian fish farms now try to introduce the product on the American market described as "organic salmon". This product is guaranteed to be without artificial additions, disease and remains of medicine. But the traditional net cage farmers in Norway hardly will leave a product on market that is characterized of disease or remains of medicine. The farmers have a sophisticated quality control. Cage farmers and salmon fishermen could in their turn emphasize the high fish density in land based farms. High fish density is a precondition for profit in the land based farms but is hardly a selling argument because the food consumer today is target for an intensive debate concerning ethics in animal management.

In Iceland it is very difficult to manage net cage cultivation because it is hard to find sheltered locations. The established land based fish farms have demanded big capital investments that to a great extent have been financed by foreign capital. Due to the large global catch of pacific salmon 1989 - 1990 and the big Norwegian supply of farmed salmon the salmon prices drastically decreased.

This fact together with increased rate of interests, exceeding of calculated investments and problems concerning the technical operations caused a serious liquidity situation for the farmers in Iceland. In Druckers terminology it has been a question of bad "entrepreneurial management". An important fact is however that the costs for administration increased very rapidly. To a great extent this was due to the compensation for the external consultants. Their efforts could not save the companies. Deficient entrepreneurship cannot be replaced by consultancy. Drucker means that in USA the most hightechnological companies are most deficient concerning "entrepreneurial management". Perhaps this can also be significant for the Scandinavian aquaculture.

## 6. MODELS FOR COMPETITIVE ANALYSIS

Competitive analysis is a basic concept in business planning. One of the models that perhaps has received most attention is developed by Michael Porter. Porter (1980) emphasizes five competitive forces in a sector :

i) rivalry among present competitors

ii) the consumers' force of negotiation

iii) the suppliers' force of negotiation

iv) threats concerning new establishments

v) threats concerning substitutes

To control these forces there are three strategies

i) cost superiority

ii) differentiation

iii) focusing (market segmentation)

"Cost superiority" means that the company tries to look after all possibilities to get cost advantages. "Differentiation" means that the company tries to develop the products in a way that seems to be unique for the consumer in some sense. "Focusing" means that the company concentrates its resources toward a special market or target group and tries to satisfy its demands more successfully than the competitors do.

Porter emphasizes that the company only has ability to manage one of the strategies at the same time. But is is a question concerning how to choose the right strategy.

Kenichi Ohmae (1985) has developed a model where he points out four different ways how a firm can strenghten its position in relation to the competitors :

i) Key factors for success. If the firm change its resources to the keyfactors for success, it can reach competitive advantages even if the competitors have the same resources.

ii) Relative superiority. A firm is able to utilize its differences in relation to the competitors or take advantage of the competitors weak abilities. It can deal about technique, marketing organizations or something else that is less developed by the competitors.

iii) Offensive initiatives. Concentration on unconventional efforts to disturb the competitors positions. For instance to disturb the keyfactors for success for the competitors.

iv) Strategic freedom. The firm has the possibility to develop new markets by innovations. Innovations often include market segmentations in order to examine new demands and consuming patterns.

## 7. COMPETITION ANALYSIS AND AQUACULTURE

The net cage farmers in Norway have mainly taken advantage of "focusing" to control the competitors in Porters terminology. Competitors are mainly the global supply of pacific salmon, recently established cage farms in especially Chile and Canada and finally the landbased plants. In USA the target group is the first class restaurants in the big cities at the east coast. In the EC-countries the main customers of norwegian salmon are the big fish smoking companies.

The net cage farmers in Sweden and Finland have due to biological conditions mainly concentrated on big rainbow trout instead of salmon. The Finnish farmers have a superiority on their home market in relation to the competitors because the latter are confrontated with far reaching import quotas.

Also Swedish farmers use "focusing" as strategy and the target segment is the Japanese market. Japan representate the highest consumtion in world of fish and fish products in relation to its number of inhabitants.

The Japanese consumers demand a salmonide fish that is very red in the flesh. It is more easy to get red colour through additives in the fodder for rainbow trout compared with atlantic salmon. This fact the Swedish farmers have taken advantage to in the product development (strategic freedom in Ohmaes terminology). Especially bad in this connection is the caught salmon in the Baltic Sea that has a very pale flesh.

The fish farmers in Denmark mainly concentrate on portion sized (0,2-0,3 kg) rainbowtrout that is cultivated in ponds. In this sector the Danes possess a relative superiority in relation to ohter countries due to long time experience, technique and marketorganisation. 90 percent of the final product is exported to Germany.

To some extent also the Norwegian fish farmers have concentrated on "differentiation" and "strategic freedom" during the last years.

Among other things by introducing farmed cod. Today there is a shortage of cod during certain periods of the year. Then the market pay more for cod than salmon. 1990 about 2000 metric tons of cod were produced in net cages in Norway. Big research resources is also applied to halibut farming.

The land based farms have concentrated on cost superiority and partly of differentiation as competitive strategies. There is however a risk that the technique can be imitated of fish farmers in other countries. Landbased fish farming can be established at all coast areas if the deep of the water is more than 30 meters. Consequently it would be possible to establish such plants in the EC countries where the demand for salmon is very high. The traditional cage farming in Norway however has advantages that cannot be imitated in other countries. Firstly effects of the golfstream and big coast area with sheltered localities. An important fact is also that people are living along the total coast and that service and communications are available.

Porter mentions a lot of risk moments with cost superiority as competitive strategy. This strategy cause a constant pressure to the firm to keep its position. Consequently the firm is forced to constant investments in modern equipment and openness for technical improvements. All this demands large capital resources and stable marketprices. Stable marketprices are not existing in such a turbulent sector as aquaculture. Another risk with concentration on cost superiority is that necessary product developments and marketing efforts will not be recogniced in time due to the attention on the production costs.

The landbased Norwegian farms also try to use "differentiation" in their strategy. Because deep water is pumped up to the cultivation system, a water without algae and less diseasebringing bacteria is guaranteed. This will decrease the production costs. Representatives for the landbased farms will however use this fact as an argument that their fish is better than the net cage cultivated. This is an example of "offensive initiatives" in Ohmaes terminology. The representatives for landbased systems tries to disturb the traditional fish farmers key factor, the quality profiling.

## 8. COMPETITIVENESS ON NATIONAL LEVEL

In a later work from 1990 "The Competitive Advantage of Nations", Porter tries to explain, "Why does a nation achieve international success in a particular industry ?"

Porter uses four attributes in his so called "diamond model" :

i) Factor conditions. Human, physical, knowledge and capital resources. Infrastructure.

ii) Demand conditions. The nature of home demand for the industries product or service.

iii) Related and supporting industries. The presence of supplier industries and related industries.

iv) Firm strategy, structure and rivalry. The conditions concerning how companies are created, organized and managed. The nature of domestic rivalry.

Regarding the Norwegian aquaculture the success of the sector is mainly due to the "factor conditions" that have been discussed earlier, but also "related and supporting industries". Norway is one of the leading nations in the world fisheries. This "Know how" concerning all parts of fish, fisheries and fish processing has been very useful in the development of aquaculture.

The obstacle for Norwegian aquaculture out from Porters terminology is "demand conditions". Norway has only four million inhabitants and the home market is too small for the salmon supply. Consequently the dependence of a foreign market is total. The farmers organisations have solved the market problems rather well. However they have not been strong enough regarding negotiations in foreign countries. Therefore lobby interests managed to spoil the American market one year ago.

# What is the "Right" Price of Norwegian Salmon?

**Rögnvaldur Hannesson** *

Centre for Fisheries Economics, the Norwegian School of Economics and Business Administration, Helleveien 30, N-5035 Bergen-Sandviken, Norway

ABSTRACT

*A Stackelberg model for farmed salmon, with Norway as a price leader and the rest of the world as a competitive fringe, is discussed. The optimal price of salmon is shown to be between 30-40 NOK per kg., depending on the elasticity of demand and the fringe suppliers' elasticity of supply. Changes in the level of the competitors' marginal cost has relatively little effect on the price and affects mainly the quantity sold by the price leader versus the fringe suppliers.*

## 1. INTRODUCTION

The market for farmed salmon has changed radically over the last decade. In 1980 the average price of exported Norwegian salmon was about 57 "kroner", or 122 "kroner" at 1991 prices, and the quantity exported was 4,300 tonnes. By 1991 the price had fallen to 37 "kroner", while the quantity exported had increased to 134,700 tonnes.

The story is familiar. New products fetch a high price immediately after they are put on the market, while they are still in limited supply. High profits attract new suppliers, and after some time competition has pressed the price to a level that only allows the most efficient suppliers to survive. The fact that fish farmers have been going broke by the dozen indicates that this level has now been attained or possibly surpassed.

This development has taken place despite the fact that Norway has had a high market share. A high market share is not, however, sufficient to wield some control over the market price, in addition the industry must be so organized as to permit effective control over the quantity produced. The Norwegian salmon farming industry is quite fragmented, both on the production and the export side, and it is perhaps doubtful whether it would be at all possible to control the production

* I am grateful to Kjell Salvanes, Norwegian School of Economics and Business Administration, for valuable comments and assistance.

unless the ownership of farms becomes much more concentrated. That notwithstanding, the question what the optimal level of Norwegian salmon exports might be is interesting in its own right. Here an attempt will be made to answer that question with respect to the export of salmon to the European Community.

The Norwegian market share of farmed salmon in the European Community is about 60 per cent. There is some reason to believe that this share will remain high, despite the rapid development of salmon farming in other countries. The cost of salmon production in other European countries appears to be higher, and the scope of expanding production further at suitable sites in these countries is somewhat limited. The competition from overseas growers like Chile and Canada is likely to be limited by high freight costs of fresh salmon. These costs increase substantially once the freight exceeds volumes that can be accommodated by the freight capacity of passenger airplanes. A high and sustained market share will not suffice, however, to confer any market power unless there are no perfect substitutes for farmed salmon or these substitutes are themselves in limited supply. The latter appears a reasonable assumption; even if wild salmon is a near-perfect substitute to farmed salmon its supply is not likely to increase in the long term, while it is known to fluctuate substantially over time and hence to shift the demand curve for farmed salmon back and forth. An increase in the supply of near-perfect substitutes for salmon is most likely to be due to increased production of other farmed high quality fish, such as turbot and sea bass.

The way the problem is dealt with here is as follows. A a downward sloping demand curve is assumed for farmed salmon, characterized by a constant price elasticity. Changes over time are ignored. Norway is regarded as a market leader facing competition from competitive producers who adjust their production so that their marginal cost is equal to the market price. Norway as a market leader is supposed to maximize its salmon rent (difference between export income and production costs), taking into account how the competitive fringe adjusts to price changes. This leads to a traditional, static Stackelberg model of price leadership.

## 2. THE MODEL

Let the demand function be specified as

$$Q = AP^{-b}, \tag{1}$$

where Q is quantity demanded, P is the market price, and A and b are parameters, with b expressing the (constant) price elasticity of demand.

The marginal cost function is specified as

$$X = B \exp(gS), \tag{2}$$

where X denotes marginal cost, S is the quantity supplied, and B and g are parameters. These will not be the same for Norway and her competitors. The subscripts n and c will be used to distinguish between these two.

The parameter g is related to the elasticity of supply. It can be shown that the elasticity of supply is $(gS)^{-1}$

Following the traditional price leadership model, Norway is assumed to maximize her salmon rent (profits from exporting salmon), taking into account how the competitors will react to a change in the market price. Denoting the salmon rent by R, this entails

$$\max R = P(S_n + S_c) S_n - C(S_n), \tag{3}$$

where market clearance implies $Q = S_n + S_c$ and

$$C = \int_0^{S_n} X dS = B_n[\exp(g_n S_n) - 1]/g_n, \tag{4}$$

assuming there are no fixed costs.
The first order condition of maximizing (3) is

$$dR/dS_n = P - P[1 + dS_c/dS_n]S_n/b(S_n + S_c) - X_n = 0. \quad (5)$$

To evaluate the term $dS_c/dS_n$, differentiate (1) and (2) for the competitors:

$$dP = -P(dS_n + dS_c)/b(S_n + S_c),$$

$$dX_c = g_c B_c \exp(g_g S_c) dS_c$$

By assumption, $dP = dX_c$, from this we get

$$dS_c/dS_n = -P[b(S_n + S_c)g_c B_c \exp(g_c S_c) + P]^{-1}, \quad (6)$$

which, inserted in (5), makes it possible to solve for the optimal value of, given the value of the parameters, using Equations (1) and (2) to determine P and $S_c$.

## 3. NORWAY AS A MONOPOLIST

We will solve the above model under varying assumptions of its parameters which appear consistent with reality. On the demand side (Equation 1) we must specify the parameters A and b. Salvanes et al. (1991) reports various investigations of the markets for farmed salmon in Europe. The estimates of the price elasticity of demand in these investigations range from 1 to 2.9. Here we shall use four alternative values, 1.5, 2, 2.5 and 3. The parameter A will be calibrated so that the price is 37 for a demand of 170,000 tonnes, as this is close to the price and volume of farmed salmon in the EC market in 1991. Lacking an exact figure on this, we have estimated the volume on the basis of Norwegian exports and the production of farmed salmon in other European countries. The exports from Norway were 103,000 tonnes, and the production by the main competitors (Scotland, Ireland and the Faroe Islands) was 69,000, which corresponds to 63,000 tonnes of gutted fish head on. The price refers to the average Norwegian fob export price.

As a reference point, let us consider what the optimum price and quantity of farmed salmon in the EC market would be for Norway as a monopolist. Recent investigations into the profitability of Norwegian salmon farms report a production cost of 24.08 "kroner" per kg. live weight (figures from 1989) [1]. Allowing for a 10 per cent weight reduction for gutted fish gives a cost of 26.48 "kroner" per kg. Actual production cost for the 15 most efficient farms in 1987-1989 was 20 "kroner" per kg. live weight, according to investigations carried out by the Directorate of Fisheries. Adjusting for gutting and adding 3 "kroner" for freight and packing brings this up to 25 "kroner". Assuming a rising marginal cost curve from 25 "kroner", reaching 30 "kroner" at the 1991 supplies to the EC market (100,000 tonnes) appears reasonable and not likely to err on the low side. Maximizing the monopoly rent of Norway under this assumption gives the following result:

| Price elasticity of demand | Market price "kroner" | Norwegian supply 1000 tonnes |
|---|---|---|
| 1.5 | 60.65 | 81 |
| 2.0 | 51.43 | 88 |
| 2.5 | 46.50 | 96 |
| 3.0 | 43.59 | 104 |

According to these results, the world could be a lot happier place for Norwegian fish farmers if they were sole suppliers of farmed fish to the EC and took full advantage of this through monopolizing exports. The optimum market price and

1. Figure provided by "Kontali A/S" and based on production costs in 41 Norwegian fish farms which the EC inspected due to dumping accusations.

quantity are sensitive, however, to the price elasticity of demand. In particular it may be noted that with an elasticity of 3 the market price is not very much above the recent "cut-throat" [2] price of 37 "kroner" per kg., and the quantity supplied is identical to the actual supply in 1990 and 1991.

Given a high but not unreasonable price elasticity of demand (3 or more) it is thus not at all clear that the present prices and volumes are much different from what they would be under a perfect Norwegian monopoly in the supply of farmed salmon. What, then, are the implications of the presence of price-taking competitors in this market?

## 4. NORWAY AS A PRICE LEADER

If a large Norwegian market share for farmed salmon in the EC is at all sustainable, the long term marginal cost of Norwegian farms must be below that of her competitors, except perhaps for relatively low production volumes of the competitors. There is some evidence that this is the case. Recent investigations into the production costs of Scottish farms report a production cost per kg. live weight of 37.48 "kroner" for 1989 [3]. This translates into 41.23 "kroner" per kg. gutted fish, which is well above the figure reported for Norwegian farms (26.48, cf. above).

Below we shall report some results from maximizing the Norwegian salmon rent, for alternative values of the parameters of Equation (2) which all imply a cost advantage for Norway. These results and the assumptions are summarized in an Appendix.

Suppose, first, that the marginal cost curves of Norway and the competitors both start at 25 "kroner" per kg., which is close to the actual cost in the 15 most efficient Norwegian farms in 1987-89, as reported above. Assume that the marginal cost rises to 30 "kroner" for Norway at 100,000 tonnes and to 40 "kroner" at 60,000 tonnes for the competitors, both of which are close to the actual volumes supplied in 1991 and broadly consistent with the figures quoted above. Figure 1 shows the marginal cost curves. The results obtained show optimum Norwegian supplies ranging from 93,000 to 113,000 tonnes, competitors' supplies ranging from 59,000 to 51,000 tonnes, and price ranging from 39.87 to 37.45, when varying the price elasticity of demand from 1.5 to 3. Thus the optimum price is not much higher than the actual price in 1991 and is not very sensitive to the elasticity of demand. Even if the competitors are high cost producers they set an effective limit to how high the market price can be. The optimum Norwegian supply is more sensitive to the assumed price elasticity of demand, but nevertheless not very different from the actual Norwegian supply in 1991. Figures 2 and 3 show the optimum supply, price and the value of the Norwegian exports and salmon rent, for different assumptions of the price elasticity of demand.

The fact that the competitors supply less than they did in 1991, even if the market price is slightly higher, indicates that we may have set their marginal cost too high. Changing the parameter g in Equation (2) so that the marginal cost of the competitors is 35 "kroner" for a production of 60,000 tonnes produces the following results. The optimum supply ranges from 93.000 to 113.000 for Norway and 73.000 to 67.000 tonnes for the competitors, as the price elasticity of demand increases from 1.5 to 3. The optimum market price is also very similar to the price prevailing in 1991; it falls from 37.60 to 36.30 "kroner" as the price elasticity of demand increases from 1.5 to 3.

Lowering the marginal cost of the competitors further still, so that it becomes 30 "kroner" at a production volume of 60,000 tonnes, results in an optimum Norwegian supply in the range of 88,000 to 109,000 tonnes, with a supply from the competitors of 104,000 to 105,000 tonnes, and a price of 34.12 to 34.27 "kroner" per kg., for the said variations in the price elasticity of demand. This would reduce the Norwegian market share appreciably, or to about 50 per cent at a price elasticity of demand of 2.5.

The marginal cost curves so far assumed give Norway very little cost advantage for low volumes of production. What if the Norwegian farmers have a cost advantage at all levels of production? In this case Norwegian price leadership could have a quite dramatic effect on the competitors' supply. Figure 4 shows marginal cost curves with the same supply

2. This corresponds approximately to the average fob unit value of Norwegian exports of farmed salmon in 1990 and 1991, and covers various quality grades, sizes, etc.
3. This figure is reported by "Kontali A/S", and is based on "Costs and returns from farm salmon production in Scotland", published by the Agricultural and Rural Economics Department, The North of Scotland College of Agriculture.

elasticity for Norway and the competitors, where the competitors' curve is everywhere above the Norwegian curve. The parameters are adjusted so that the marginal cost is 30 "kroner" for Norway at a production volume of 100,000, and 35 "kroner" for the competitors at a production volume of 60,000 tonnes. Figure 5 shows the optimum supply, which ranges from 115,000 to 127,000 tonnes for Norway, and is practically constant at 66,000 tonnes for the competitors, as the price elasticity of demand increases from 1.5 to 3. This is a slightly greater supply than provided by Norway in 1991 (104,000 tonnes), and about the same for the competitors. However, if the marginal cost of the competitors is raised, the effect on their supply and market share is dramatic. Increasing the competitors' marginal cost to 43.45 "kroner" per kg. at a production level of 60,000 tonnes would virtually eliminate the competitors from the market. In this case it would be optimal for Norway to supply a quantity resulting in a price of about 39 "kroner" per kg., which would be below the competitors' marginal cost at all production levels.

## 5. CONCLUSION

The main conclusion to be drawn from this analysis is that the market price of salmon which would result from Norway taking advantage of its position as a price leader in the EC market for farmed salmon would not be much different from the price we have observed in the last couple of years, by some considered to be catastrophically low. The prices we have come up with under various, in our view reasonable, assumptions about the price elasticity of demand, the competitors' marginal cost of production and their supply elasticity, are all in the range 33 to 40 "kroner" per kg. The sensitive variables are the total quantity supplied and its division between Norway and its competitors. Only a slightly unrealistic assumption about the competitors' marginal cost of production (45 "kroner" at 60,000 tonnes) and their supply elasticity (the marginal cost is as high as 39 "kroner" even at virtually zero production) is sufficient to eliminate the competitors from the market, as a consequence of Norwegian price leadership. The most important variables for a presumptive Norwegian export cartel to know in order to exercise a successful price leadership thus is the production cost of its competitors and their elasticity of supply. These are also the variables on which information is least likely to be forthcoming.

# Why 1991 Alaskan Salmon Prices Crashed

**Mark Herrmann[a] and Joshua A. Greenberg[b]**

[a]Department of Economics University of Alaska, Fairbanks, Alaska 99775

ABSTRACT

*The 1991 Alaskan salmon season was a disaster. Fishermen's strikes and the dumping of salmon has brought a great deal of focus on what went wrong. This paper examines some possible factors that resulted in the lowest salmon prices in many years. The conclusion is that increased world supplies, coupled with tremendous Alaskan harvests, have brought pressures on Alaska that the salmon industry was ill prepared to handle.*

## 1. INTRODUCTION

The 1991 Alaskan salmon season was marked by tremendous turmoil. Two situations symbolized the stress that nearly everyone involved in the salmon industry felt. In Bristol Bay, the largest harvest area for sockeye salmon, the opening offer of $0.47 per pound was declined and a strike of 2,500 fishermen began. The end result was a settlement of $0.70 per pound, which was substantially lower than the 1990 price of $1.04, the 1989 price of $1.24, and the 1988 price of $2.25.

The situation was even worse for pink salmon. The price offered for humpies fell below the fishermen's breakeven point and millions of pounds of Prince William Sound pinks were harvested only to be dumped back into the ocean, given away to local citizens, or canned and given away in a much publicized airlift, funded by Exxon Oil, to the Soviet Union for humanitarian purposes. In addition, pink and chum salmon were given away in food lines and to local food charities. The price for pinks settled at $0.12 a pound, when processors were buying them at all, which meant that an average boat needed to catch a million pounds just to make boat payments (Fitzgerald, 1991). Frozen pink salmon retailed for as low as $0.99 per pound in the United States. (See figure 1 for all Alaskan exvessel prices).

* This publication has been prepared for **session 2** in the sixth annual meeting of ther IIFET in Paris, France July 1992. This publication is the result of research sponsored by Alaska Sea Grant with funds from the National Oceanic and Atmospheric Administration, Office of Sea Grant, Department of Commerce, under grant no. NA90AA-D-SG066, project #M/81-01, and from the University of Alaska with funds appropriated by the state.

Since the 1991 season, there has been much speculation about what or who was to blame for the low prices. Suspicion has generally fallen into five areas (not necessarily in order of importance) : too much farmed salmon supply, unfair Japanese trading practices, poor quality of Alaskan fish, unfair U.S. wholesale pricing practices, and oversupply of wild stock.

A tremendous amount of effort has been devoted to solving the problem of low salmon prices. The governor of Alaska created a special Governor's Salmon Strategy Task Force to study the issue. The Alaska state legislature is reviewing the entire salmon enhancement program from a cost/benefit point of view. The Alaska Seafood Marketing Institute is spending more money on salmon advertising. Researchers are trying to find new markets for existing products and developing new products.

This paper will review some of these issues and offer the results of a model that attempts to explain the various factors that have been causing rapid salmon price decreases. The results discussed in this paper are tentative, as the core of the modelling research is presently under way.

## 2. IDENTIFICATION OF POSSIBLE CAUSES

Early blame for the depressed Alaskan salmon prices fell on the Japanese, and cases of Japanese bashing in Alaska were, unfortunately, all too common. Although this theory has since lost favor among most industry participants, the head of Alaska's antitrust office has recently claimed that there is evidence of Japanese market manipulation.

The quality of Alaskan salmon remains a concern. Not only is Alaskan salmon reputed to be of variable quality, but it is well documented that wild salmon is reputed to be of lesser quality than farmed salmon. In 1991, there were additional problems with the pink salmon harvest. First, there was a late run and the fish were turning sooner than expected. The Alaska Department of Fish and Game did not open pink salmon fishing in the straits where the fish are of excellent quality because of the danger of overharvesting the wild stock, which had not yet returned in sufficiently high numbers. In the hatchery bays, Prince William Sound Aquaculture Cooperative, a non-profit hatchery association, is allowed the first harvest of pink salmon, the sales of which support the hatchery. By the time Alaskan fishermen were able to harvest pinks, the overall quality of the fish was poor. In addition, the average weight of the run was a scant 2.7 pounds per fish.

It seems clear that, while there may be many factors contributing to the depressed salmon prices, the basic problem is that Alaska is, for the first time, facing a highly competitive industry. Problems such as those mentioned above are of less concern when one is the dominant supplier. Since 1980, the world supply of salmon has increased from 1.2 billion pounds to 2.3 billion pounds (Knapp), and Alaska's production share during this time period has declined from 44 to 31 percent (see figure 2). In addition, the U.S. share of Japanese salmon imports has slipped from 85 to 66 percent in the last four years.

## 3. THE MODEL

A 36-equation econometric model of the international supply and demand of salmon was constructed at Washington State University in 1989. The model was originally built to study the profitability of farmed Atlantic salmon in the Puget Sound of Washington State. But since it simultaneously models the supply and demand for farmed Atlantic salmon and wild Pacific salmon, the opportunity presented itself to use the model to examine why Alaskan salmon prices have been declining.

The model accounted for the flows of fresh and frozen salmon, shown in figure 3. Because of space considerations, the entire model will not be presented here (see Herrmann 1990 for the complete model). However, the variables that were estimated are listed below.

1. *Norwegian allocation of farm-raised Atlantic salmon*

   - Quantity allocated to the EEC

2. *EEC demand for salmon*

- Quantity demanded of Scottish and Norwegian farmed Atlantic salmon
- Quantity demanded of North American high valued Pacific salmon
- Quantity demanded of North American low-valued Pacific salmon

3. *Japanese demand for salmon*

- Quantity demanded of Norwegian farmed Atlantic salmon
- Quantity demanded of North American high-valued Pacific salmon
- Quantity demanded of North American low-valued Pacific salmon

4. *North American allocation of high-valued salmon*

- Quantity allocated to Japan
- Quantity allocated to the EEC

5. *North American allocation of low-valued salmon*

- Quantity allocated to Japan
- Quantity allocated to the EEC

6. *North American demand*

- Quantity demanded of Norwegian farmed Atlantic salmon

7. *North American inventory holdings*

- Quantity of high-valued salmon inventory
- Quantity of low-valued salmon inventory

8. *North American exvessel prices*

- Price of high-valued salmon
- Price of low-valued salmon

In the above model, North American high-valued Pacific salmon consists of sockeye, chinook, and coho, while the low-valued Pacific salmon consists of chum and pink salmon. These aggregations were made, on the basis of the value received by fishermen. In 1990, the average exvessel prices received in the United States for the high-valued Pacific species ranged from $1.04 to $1.83 per pound, while the average prices received for the low-valued species ranged from $0.31 to $0.49 per pound.

The model was built primarily for forecasting purposes and was constructed using quarterly data from 1982 to 1988. Thus, a forecast of future quantity levels and prices for this model starts in 1989. Since actual data is now available for 1989 and 1990, we can see how well the model predicted the 1990 salmon season. Prices for U.S. Pacific salmon in 1990 declined from the 1988 prices by 29 to 57 percent of their 1988 price, depending on species. The model predicted the decrease in price fairly well but still predicted 1990 prices too high by 15 to 25 percent. This indicates that there were structural changes in the late 1980s that the model was unable to pick up.

Even though the model overestimated 1990 prices, it is still possible to examine why prices decreased from 1988. The year 1990 was chosen because a complete data set for the actual values of the exogenous variables was not complete for 1991 ; however, inferences from the findings for 1990 can be made for 1991.

These figures were estimated by using the conditions that existed at the end of 1988 then systematically allowing the variables to take on their true 1990 levels and noting the effect on prices.

## 4. RESULTS

Figures 4 and 5 show the relative weight of some of the factors affecting the depression of 1990 prices from 1988 levels. The increased level of high-valued landings in 1990 over the 1988 level is estimated to have caused 76 percent of the decline in the high-valued exvessel price. Other market factors included an increase in farmed salmon supplies (10 percent factor), a strengthening of the U.S. dollar against the Japanese yen (8 percent), increased Japanese landings and inventory of salmon (4 percent), and increased landings of low-valued Pacific salmon (2 percent).

The exvessel price decline for low-valued Pacific salmon was estimated to have been a result of increased low-valued salmon production (68 percent), increased high-valued landings (13 percent), increased Japanese landings and inventory (13 percent), a strengthening of the U.S. dollar against the Japanese yen (8 percent), and increased farm supplies (1 percent).

It is important to note that increased farmed salmon supplies probably have had a much larger overall effect than indicated because the analysis started from the existing 1988 conditions, which already included a large amount of world farmed supplies. It is likely that if there had never been salmon farming, Alaskan salmon prices might well be higher today, despite the increased consumer demand for salmon in general that resulted from the availability of fresh salmon year-around. Also, the ability of the marketplace to absorb the increased Pacific landings of the last three years has probably decreased due to the overall high supplies of farmed salmon (this is reflected by the sensitivity of exvessel price to landings).

Although these simulations were for 1990, inferences can be made for 1991. For instance, total 1990 Alaskan salmon production was 31 percent higher than in 1988, and 1991 Alaskan production was even higher than 1990. World farmed salmon supplies in 1990 were 21 percent higher than in 1988, with 1991 levels close to the 1990 levels. These factors alone, with the accumulating inventory, were a major reason that Alaskan salmon prices continued to decline into 1991.

## 5. ALASKA ADJUSTS

It is obvious to all concerned with the Alaskan salmon industry that there is a lot of salmon on the market, which has increased competition and has made prices more sensitive to market conditions. However, some good has come from the 1991 disaster. For the first time in Alaska, there is more discussion about the marketing of salmon than about its production. Quality of salmon has become an increased concern both for the timing of harvests and for processing techniques. The Alaska Seafood Marketing Institute has received a modest increase in its advertising budget and is heightening the domestic marketing of salmon. Lower prices have also attracted some new domestic consumers.

Product development is also proceeding at a rapid pace, with pink salmon nuggets, microwaveable pink salmon fillets, and pink salmon surimi topping the list. Researchers in Alaska are developing a salmon market newsletter and an information base that will include data from the former Soviet Union.

Finally, the Alaska legislature has funded a complete review of the state's enhancement program. A cost/benefit analysis, which will incorporate a 96-equation demand model, a cost model, and a biological model, is being constructed to determine the future level of output and the mix of hatchery salmon that Alaska will produce.

## 6. FUTURE WORK IN THIS AREA

With the salmon industry changing so rapidly, structural changes are likely to take place. The model constructed at Washington State University is being expanded for the Alaska enhancement program review to include 1991 data, canned salmon, and exvessel price equations by regions and gear type. In addition, other experts' recent work, such as Cathy Wessel's work on Japanese inventories (1990), will be incorporated into the modelling effort.

# Fisheries Modelling by J.M. Gates

Les communications de cette session abordent à l'évidence un questionnement commun. Une partie des papiers concerne l'application des méthodes de programmation multi-objectifs (MOP). Dans ce groupe on retrouve ceux de Enriquez, Sylvia, Padilla et Copes, Seijo, Defeo et Alava. Un autre groupe d'auteurs s'intéresse davantage à l'économie des unités de pêche, avec par exemple une approche micro-économique des unités de production. Parmi eux on placera Arnarson et Jensson, Sampson, Anwar *et al.*

Enfin, un ensemble de textes reprennent le moule des modèles bioéconomiques classiques des pêcheries. On trouve les textes de Eide et Flaaten, Seijo et Defeo, Pascoe, Battaglene et Campbell, Danielsson, Rodgers, Sparre et Willman ainsi que Verdelhan. Alors que les textes relatifs aux méthodes MOP mettent en œuvre également des modélisations bioéconomiques, celles-ci utilisent une méthodologie harmonisante relativement nouvelle, ce qui justifie leur regroupement dans un ensemble séparé.

Le choix de ces regroupements est purement subjectif et des différences significatives demeurent au sein même de chacun des groupes. Néanmoins ces regroupements restent cohérents au moins pour notre propos introductif. Globalement l'ensemble des papiers de cette session illustrent l'utilité d'avoir des approches variées en matière de modélisation.

*Programmation multi-objectif (MOP)*

Le papier de Sylvia est consacré au rôle de ces approches MOP pour application à la pêche et à l'aquaculture. Le papier introduit une synthèse très utile de la théorie sur ces approches, la question des pêches ou de l'aquaculture restant plus suggérée qu'évidente. Le développement sur la dynamique de la « politique de frontières » est d'un

The papers in the fisheries modelling session have a discernible "clustering" of interests. One cluster is the application of multiple objective programming (MOP) methods. In this cluster are the papers by Enriquez, Sylvia, Padilla and Copes, and Seijo, Defeo and Alava.

Another cluster of papers examine in some detail "vessel economics", i.e. the microeconomic details of the technical production unit in fisheries harvest. In this group are the papers by Arnarson and Jensson, Sampson, and Anwar *et al.*

Last but not least is a cluster of papers which fit the traditional mold of bioeconomic models of fisheries. The papers in it are by Eide and Flaaten, Seijo and Defeo, Pascoe, Battaglene and Campbell, Danielsson, Rodgers, Sparre and Willman and Verdelhan. While the MOP papers involve bioeconomic modelling too, they have a relatively new, unifying methodology which justifies including them together as a separate group.

The choice of these clusters is purely subjective and there are significant differences between papers in each cluster. However, these clusters are convenient at least for discussion purposes. Collectively, the papers in session 3 demonstrate the utility of various approaches in modelling fisheries.

*Multiple Objective Programming (MOP)*

Sylvia's paper on MOPs is devoted to the role of MOP approaches in fisheries and mariculture. The paper is primarily a useful review of the theoretical literature on MOPs; the fisheries and mariculture content of the paper is more implied than evident. Of particular interest is the development of "dynamic policy frontiers". Because it is more theoretical than the joint paper with Enriquez, the two papers are complementary; I would recommend reading the Sylvia paper before reading the other MOP papers.

intérêt évident. Du fait de ces aspects théoriques privilégiés davantage dans ce papier que dans celui présenté avec Enriquez, il est préférable de consulter celui-ci avant tout autre sur la question des MOP.

Enriquez et Sylvia développent un modèle dynamique pour la pêcherie américaine de merlan du Pacifique. Les objectifs multiples, la valeur actualisée des revenus nets dans la transformation (PVNR), le volume de produits traités (YIELD) et la viabilité de la ressource renseignée par (la borne inférieure de) la biomasse des femelles matures (LSB). Ces trois thèmes reflètent les priorités exprimées par les aménageurs. Les instruments de régulation contiennent les quotas annuels, les allocations entre les différents groupes d'utilisateurs (spécialement les flottilles côtières et flottilles hauturières) et le nombre d'unités techniques (en transformation et capture) autorisées à entrer.

La fonction d'objectif actuelle est une combinaison convexe de PVNR et YIELD ; Le troisième objectif est rajouté en contrainte comme par exemple la valeur de la borne inférieure de la biomasse des femelles matures. Selon un processus stochastique, des solutions répétées sont générées pour les valeurs du recrutement et pour LSB et le poids convexe permet aux auteurs de tracer « frontière de politique » ou ensemble de points pour lesquels l'objectif fonctionnel est maximal, étant donnée la valeur des paramètres Les points extérieurs à cette frontière correspondent à des options politiques inefficientes en ce sens que des objectifs supplémentaires sont possibles sans diminution du premier.

Padilla et Copes développent et appliquent une méthode de programmation multi-objectifs à des pêcheries de petits pélagiques. Les objectifs considérés pour les différents engins, les différentes espèces capturées, incluent un maximum de profits du secteur productif, un maximum d'emplois, une optimisation des captures, et un accès équivalent pour les différents groupes de pêcheurs concurrents. Parmi ces objectifs, seulement ceux relatifs aux profits du secteur productif et à l'optimisation des captures sont pris en compte dans la fonction d'objectif ; les autres sont ajoutés en tant que contraintes pour des raisons de commodité. Padilla et Copes utilisent le modèle pour explorer la politique d'échange au travers de plusieurs des remèdes standards de l'aménagement des pêches incluant des mesures « non économiques » et des mesures économiques. La question du travail redondant, semble spécialement introduire des problèmes dans ce champ d'étude et les auteurs discutent rapidement la possibilité du travail plus intensif du fait des technologies et pratiques de capture. L'observation de leur figure 2 suggère que les frontières d'efficience entre profit et emploi sont pratiquement

Enriquez and Sylvia develop a dynamic MOP model for the Pacific whiting fishery of the United States of America. The multiple objectives are present value of net revenues in processing, processing product volume and resource viability as indicated by the (lower bound on) female spawning biomass. These three items reflect the expressed concerns of policy makers. Policy instruments include annual quotas, allocation between user groups (specifically, "inshore" versus "offshore" fleets) and the number of technical units (in processing and harvesting) allowed to enter.

The actual objective function is a convex combination of PVNR and YIELD; the third objective is added to the constraint set as a lower bound on spawning biomass. Repeated solutions of the model with stochastically generated recruitment and alternative values for LSB and the convex weights permit the authors to trace out the "policy frontiers" or locus of points for which the objective functional is maximal, given the assigned parameters. Points off this frontier are policy inefficient in the sense that more of one objective is possible without diminution of the other.

Padilla and Copes develop and apply a MOP to the small pelagics fishery. The objectives considered for this multiple gear, multiple species fishery, include maximum harvest sector profits, maximum fishing employment, catch optimization, and equal access for competing groups of fishers. Of these objectives, only the harvest sector profits and catch optimization are included in the objective function; the others are adjoined to the constraint set on the pragmatic grounds of convenience. Padilla and Copes use the model to explore the policy tradeoffs for several of the standard nostrums of fisheries management including "non economic" and economic management measures. The issue of redundant labor appears especially troublesome in the study area and the authors discuss briefly the possibility of more labor intensive harvesting technologies/practices. Examination of their Figure 2 suggests that the efficiency frontiers between profits and employment are almost parallel. If this perception is true, then an isocline for differing levels of fishing mortality would be an straight line with positive slope expressing the marginal rate of substitution between profits and employment.

Seijo, Defeo and Alava are concerned with a coastal bivalve fishery in Uruguay. This alone makes the paper noteworthy because the sedentary nature of the organism alters the usual fisheries model specification. A second paper by Seijo and Defeo develops the biology of the fishery in more detail. The objectives were biomass of species, cumulative catch and economic rent in each locality. The optimization procedures use a minimax

parallèles. Si cela est vérifié, alors une isocline pour différents niveaux de mortalité par pêche pourrait correspondre à une pente positive traduisant le taux marginal de substitution entre profit et emploi.

Seijo, Defeo et Alava étudient eux le cas des pêcheries de bivalves en Uruguay. La nature sédentaire de ces espèces, qui oblige à modifier des spécifications usuelles des modèles en pêche, rend le papier remarquable. Un autre texte de Seijo et Defeo développe en détail les aspects biologiques des pêches. Les objectifs sont la biomasse des espèces, les captures cumulés et la rente économique dans chaque localité. Les procédures d'optimisation utilisent les méthodes minimax pour les écarts par rapport aux objectifs et une procédure Box d'optimisation non linéaire. Ils concluent que ces approches permettent un calcul efficient des échanges entre objectifs.

*Comportement économique des unités de pêche*

Arnarson et Jensson s'intéressent davantage aux complexités liées à la gestion de flottilles modernes. Bien qu'il soit commode d'agréger de tels détails dans un modèle bioéconomique, l'approche qu'ils suivent est infiniment plus pratique pour les gestionnaires des flottilles et potentiellement plus simple également pour les scientifiques des sciences sociales cherchant à comprendre le comportement humain. Leur modèle est un simulateur faisant apparaître différents modules utilisant le langage PASCAL. La construction en module facilite les modifications pour s'adapter aux différentes pêcheries. Trois aspects particuliers sont à noter, un générateur de captures aléatoires, un concept de « valeur marginale du temps » et un module de production mixte. Le générateur de capture aléatoire est log-normal mais convient pour les autocorrélations observées sur les captures et les redistributions des flottilles en réponse à des chutes de production. La valeur marginale du temps est définie comme étant le coût d'opportunité attendu du temps « acheté » en référence au futur. Ce concept est utile pour les décisions impliquant les différentes périodes de temps - par exemple les trajets de différentes durées selon les alternatives de zone. Avec le simulateur, on trouve une routine de programmation linéaire pour optimiser les décisions de choix des combinaisons de productions mixtes pour des espèces actuellement embarquées. Leur modèle est capable d'éclairer sur les conséquences des changements de quotas sur les productions mixtes. A la réflexion ce modèle n'est pas surprenant si ce n'est qu'il aborde quelques points sur lesquels les modèles conventionnels restent muets.

Le papier de Sampson est à cheval entre ce thème et la modélisation bioéconomique. Il prend en compte un criterion on deviations from goals and a non linear optimization procedure by Box. They conclude that the approach permitted efficient calculation of tradeoffs between objectives.

*Vessel Economics Papers*

Arnarson and Jensson are concerned with and delve deeply into the complexities of managing a modern fishing fleet. Although it is convenient to subsume such detail in a bioeconomic model, the approach they follow is infinitely more useful to fleet managers and potentially a useful one for social scientists seeking to understand human behavior. Their model is a simulator written in modules using the PASCAL language. The modular construction facilitates modifications to fit different fisheries. Three features of interest are a random catch generator, a "marginal value of time" concept and a product mix module. The random catch generator is lognormal but allows for the observed autocorrelation of catches and the fleet relocation response to low catches. The marginal value of time is said to be the expected opportunity cost of time "bought" from the future. This concept is useful in decisions involving different time durations - for example trips of differing duration to alternative grounds. Within the simulator is a linear programming routine to optimize product mix decisions given the species mix currently being brought on board. Their model is able, for example, to give insight into the consequences of changes in quota level on product mixes. On reflection, this product mix effect is not surprising but it is something about which conventional models of fishing are silent.

The Sampson paper actually has a foot in both this and in the bioeconomic modelling clusters. It does invoke a simple population dynamics model but the invocation is unusual; it is used to infer the technology selection response of fishers and how these selections will be influenced by the characteristics of the resource as expressed in the population dynamics relationship. It is a good companion to more descriptive approaches of gear technology and has the merit of "linking" three of isolated worlds of technology, economics and biology.

The Anwar *et al.* paper is a detailed discussion of one component (gross revenue or "stock") of a "vessel simulator" being developed for the otter trawl fisheries of Northeastern United States. Since gross stock is the single most important determinant of economic performance, it deserves particular attention. The paper estimates a regression curve whose arguments include vessel characteristics, intensity of use and qualitative variables for port and month. The functional form is

simple modèle de dynamique de population mais avec une vocation inhabituelle ; il est utilisé pour déduire une réponse des pêcheurs en terme de choix de technologie en observant comment la décision va être influencée par les caractéristiques de la ressource exprimées au travers des interactions avec la dynamique des populations. C'est un bon outil pour des approches plus descriptives des technologies de pêche et il a le mérite de relier trois domaines souvent séparés, la technologie, l'économie et la biologie.

Le travail de Anwar *et al.* porte sur une discussion détaillée d'une composante (revenu brut ou « stock ») d'un simulateur de comportement d'unité de pêche appliqué aux pêcheries chalutières de loutres de mer du nord-est des Etats-Unis. Puisque le stock brut est le plus simple des déterminants majeurs de la performance économique, il mérite une attention particulière. Le papier produit une estimation par régression sur les caractéristiques du bateau, l'intensité d'utilisation ainsi que sur des variables qualitatives par port et par mois. La forme fonctionnelle est d'élasticité variable étant de forme linéaire quadratique diagonale en log. L'élasticité en tenant compte du nombre de jours de mer par mois est proche de l'unité mais décroissante. Consécutivement une analyse des résidus est employé pour créer des variables qualitatives mesurant « l'aptitude ». Ces variables se sont révélées robustes sur toute la période avec une tendance à une distribution stable des aptitudes. Ces différences ont des implications sur l'acceptabilité politique des choix de mesures de gestion, comme par exemple les quotas individuels transférables (QIT) et plus encore pour la crédibilité des estimations des unités techniques individuelles.

*Modèles bio-économiques*

Eide et Flaaten s'intéressent au cas de la pêcherie multispécifique de la mer de Barents qui reste l'une des principales pêcheries du monde. Leur modèle (ECONMULT) contient un module économique qui est un modèle de capture multiflottilles et un modèle biologique multiespèces. Leur papier porte essentiellement sur le module économique ; il s'agit d'un modèle d'optimisation par simulation, qui apparemment peut fonctionner sur une variété de structures. Un simple modèle cabillaud-capelan est la base des résultats numériques qu'ils rapportent ici. Le couple cabillaud-capelan représente une importante ressource conjointe partagée par la Norvège et la Russie. De façon intéressante, les meilleurs résultats, bien que seulement préliminaires, indiquent une solution interne dans laquelle les deux espèces sont capturées. Les auteurs attribuent exclusive

variable elasticity due to being a diagonal linear-quadratic form in logs. The elasticity with respect to days at sea in a given month is near unity but declining. A subsequent analysis of residuals is used to create qualitative variables measuring "skill". These variables were found to persist over time but with some tendency toward a stable distribution of skills. These differences have implications for the political acceptability of management measures, such as ITQs and most certainly for the credibility of forecasts for individual technical units.

*Bioeconomic Model Papers*

Eide and Flaaten are concerned with the Barents sea multiple species fishery which is one of the major fisheries of the world. Their model (ECONMULT) includes an economic component which is a multifleet harvest industry model and biological multiple species model. Their paper focuses on the economic component; it is a simulation and optimization model which apparently can be run in a variety of structures. A simple cod-capelin model is the basis of the numerical results they report. The cod-capelin complex is an important transboundary resource shared by Norway and Russia. Interestingly, the best results, admittedly preliminary, indicate an interior solution in which some of both species is harvested. The authors attribute this to 100% post spawning mortality of capelin and overgrazing of capelin if cod stocks are unharvested. It is clear from the paper that ECONMULT rests on a broad multidisciplinary research base which may be difficult to match in other areas.

The Seijo and Defeo paper describes the authors modelling work on the yellow clam fishery of Uraguay. This paper gives much more detail on the resource characteristics including the importance of spatial distribution of the resource for fisher behavior. The allocation of effort between areas is generated via a feedback between recruitment processes and an assumed rationality of fishers.

Pascoe, Battaglene and Campbell report their research on a multiple species shark fishery in southern Australia. Their particular focus is on uncertainty which has been a strong suit of agricultural economists from Australia for three decades. In a technical sense some of the approaches to decisionmaking under uncertainty are examples of MOPs. However models of economic decisionmaking under uncertainty (especially the static case) antedated MOPs. The context of their research is a divergence among biological scientists on the endogeneity of recruitment. The authors apply a minimax and a maximin criterion. The minimax criterion minimizes the

ment cela à la mortalité postnatale des capelans et à la suralimentation des capelans lorsque les stocks de cabillaud sont sous exploités. Il ressort clairement du papier que ECONMULT repose sur une base largement multidisciplinaire qu'il pourrait s'avérer difficile de reproduire à d'autres zones de pêche.

Seijo et Defeo présentent leur travail de modélisation appliqué aux pêcheries de palourde en Uruguay. Ce papier insiste sur les caractéristiques de la ressource intégrant l'importance des distributions spatiales face aux comportements des pêcheurs. L'allocation de l'effort par zone est généré par un feed-back entre processus de recrutement et une hypothèse de rationalité des pêcheurs.

Pascoe, Battaglene et Campbell rendent compte de leur recherche à propos des pêcheries de requin dans le sud de l'Australie. Leur attention se porte essentiellement sur l'incertitude qui a été pendant près de trois décennies l'objet d'interrogation des économistes ruraux en Australie. D'un point de vue technique certaines approches relatives aux processus de prise de décision sous incertitude sont des exemples de programmation multi-objectifs (MOP). Toutefois les modèles économiques de prise de décision sous incertitude (et particulièrement les cas statiques) sont antérieurs aux MOP. Le contexte de leur recherche est une divergence entre les biologistes sur le caractère endogène du recrutement. Les auteurs appliquent les critères minimax et maximin. Le critère minimax minimise les pertes ou le « regret » dans le cas d'un autre état de la nature. Le critère maximin maximise les résultats dans les pires scénarios imaginés. Le critère maximin est extrêmement pessimiste et suppose un adversaire malveillant (Mère Nature ?). Dans les cas où le potentiel de perte est élevé et irréversible ce degré de pessimisme peut avoir un sens. Quoiqu'il en soit, les auteurs affirment que ce n'est pas le cas pour la pêcherie considérée et prônent l'emploi du critère minimax. Leur approche est en filiation directe avec « le seuil minimal de sécurité » développé il y a quatre décennies par Ciriacy-Wantrup pour les politiques de conservation des ressources naturelles. Ils trouvent que le coût de maintien d'ouverture de la pêcherie cible, même si le recrutement exogène est incorrect, est moins important que les pertes dues à la fermeture si le caractère exogène est vérifié. Ils recommandent une politique intermédiaire de réduction des captures sur les espèces cibles avec dans le même temps une prévention ou au moins une réduction des captures des espèces de requin sévèrement menacés. Cela correspond essentiellement à augmenter le critère minimax avec une combinaison convexe des profits escomptés et la nature aléatoire des profits. Pour cela, les approches en terme de « valeur de variance espérée » (E-V), « minimum des écarts absolues » (MOTAD) ou « Focus-Loss » (F-L) sont les plus communément utilisées.

loss or "regret" should an alternative state of nature be found true. The maximin criterion maximizes the payoff under worst case scenarios. The maximin criterion is extremely pessimistic and presumes a malevolent opponent (Mother Nature?). In cases where loss potentials are high and irreversible this degree of pessimism may make sense. However, the authors argue that this is not the case for the fishery in question and advocate the minimax criterion. Their approach is a direct descendant of the "safe minimum standard" advocated four decades ago by Ciriacy-Wantrup for natural resource conservation policy. They find that the cost of keeping the target fishery open even if exogenous recruitment is incorrect is substantially less than the loss from closure if exogeneity is true. They recommend an intermediate policy of reducing target species catch while preventing or at least reducing catch of the severely depleted school shark. Essentially this corresponds to augmenting the minimax criterion with a convex combination of expected profits and riskiness of profits. Of these the most commonly used would probably be the "expected value-variance" (E-V), "minimum of the absolute deviations" (MOTAD) or "Focus-Loss" (F-L) approaches. In any case the expectation and risk measures would appear to be the subjective estimates of biological scientists.

Danielsson's paper reports on the Nordic Fisheries Management Model (NFMM) in general and the Icelandic version in particular. The bulk of his paper focuses on his own responsibility (economic data) in this coordinated multiple nation modelling effort. He also sketches his approach to modelling the processing sector.

Rodgers outlines a general bioeconomic simulation model for a multispecies fishery. The author notes that the same model may be used for (1) validation, (2) prediction and (3) control or optimization. For the author, the principal objectives of the model are to test the mathematical structure of the system so that a suitable optimization method can be developed and to generate answers to questions raised by proposed fishery management measures.

The Sparre and Willman paper describes a bioeconomic model (BEAM 4) for simulating space structured multiple species and Multiple fleet fisheries. This is the latest generation of the FAO issued simulator. It is written in TURBO PASCAL for MS-DOS machines and consists of submodels for biological/technical and economics. It appears to be a well documented model and worth consideration for a user who wishes to avoid the start up costs of model construction.

The De Verdelhan paper describes a bioeconomic simulator at Institut Francais de Recherche pour l'Exploitation de la Mer (IFREMER). The simulator is

lisées. Dans quelques cas les mesures d'espérance ou de risque pourraient apparaître comme des estimations subjectives des biologistes.

Danielsson rend compte quant à lui d'un modèle général de gestion des pêcheries nordiques (NFMM) avec une version particulière pour l'Islande. Le contenu de sa communication met l'accent sur ses propres responsabilités (données économiques) dans cet effort de modélisation coordonné pour différentes nations. Il applique également son approche à la modélisation du secteur de la transformation.

Rodgers construit un modèle de simulation bioéconomique pour des pêcheries multispécifiques. L'auteur note que le même modèle peut être utilisé pour (i) des validations, (ii) des prévisions, (iii) des contrôles ou des optimisations. Selon l'auteur, les principaux objectifs du modèle sont de tester la structure mathématique du système de telle sorte qu'une méthode d'optimisation convenable puisse être développée et générer des réponses aux questions introduites par les mesures de gestion des pêcheries.

Le papier de Sparre et Willman décrit le modèle bioéconomique BEAM4 qui simule la répartition spatiale des espèces et des flottilles en action sur les pêcheries. Il s'agit là de la dernière génération du modèle de simulation de la F.A.O. Il est rédigé en TURBO PASCAL dans une version pour MS-DOS et se présente sous forme de sous modules biologique, technique, économique. Il s'agit là d'un modèle bien documenté et valable pour un usager qui désire éviter l'investissement pour mettre en œuvre la construction d'un modèle.

De Verdelhan présente quant à lui un simulateur bioéconomique développé au sein de l'Ifremer dans la continuité des programmes initiaux rédigés en 1985 et mis à jour par Olivier le Pape en 1991. La version actuelle bénéficie d'écrans d'aide, de suppléments graphiques et d'options de calcul des effets de certaines mesures de gestion des pêcheries. Il est présenté par son auteur comme un outil pédagogique. Le modèle est écrit en TURBO PASCAL et contient des options qui prévoient un modèle de recrutement stochastique prenant en compte la structure d'âge de la population exploitée.

the current generation of a program developed originally by the author circa 1985 and modified by Olivier Le Pape in 1991. The current version benefits from the addition of help screens, supplemental graphics and an option to calculate the effects of certain fisheries management measures. It is regarded by its authors as a useful pedagogical. The model is written in TURBO PASCAL language and includes an option to allow stochastic (log normal) recruitment in an age class structured model. It is available on diskette from the author. An English language version exists.

# Multi-Objective Programming : an Application to the Pacific Whiting (Merluccius productus) Fishery

**Roberto R. Enríquez [a] and Gilbert Sylvia [b]**

[a]Facultad de Ciencas Marinas, Universidad Autonoma de Baja Claifornia, AP 453, Ensenada, B.C. Mexico

[b]Coastal Oregon Marine Experiment Station, Hatfield Marine Science Center, Newport, Oregon 97365 U.S.A

ABSTRACT

*This work focuses on multi-objective programming and its applications to fishery policy analysis and implementation. The main goals are to develop a dynamic multi-objective programming model of the Pacific whiting fishery in the United States and use this model to evaluate the applicability of multi-objective programming to fishery problems. A multi-objective function of three policy objectives - rents, utilization, and female spawning biomass - was constrained by an age-structured relationship representing the biological dynamics of the stock and by a set of linear relationships representing the harvest and processing dynamics of the fishery. Uncertainty was introduced by means of a stochastic recruitment relationship. Three policy instruments were considered : harvest quotas, harvest/processing capacity limits, and allocation between shore-based and offshore sectors of the fishery. Pareto optimal solutions for three policy objectives were generated by means of generating techniques.*

*Results are presented in the form of trade-off curves, or what may be termed for this problem, a "policy frontier." The results suggest that management of Pacific whiting in the United States is composed of non complementary objectives. Benefits from the fishery to a particular region or user group due to a particular set of regulations, may be offset by loses to other groups or regions. Large information requirements and computational burden are the major obstacles for the application of multi-objective programming to the Pacific whiting problem.*

*Despite these problems, the study concludes that multi-objective programming produces information consistant with the needs of the Pacific whiting fishery policy process.*

## 1. INTRODUCTION

Pacific whiting is commercially and ecologically one of the most important fishery resources along the West coast of the United States. The fishery is currently experiencing a period of rapid and profound transformation that could cause a substantial redistribution of benefits among domestic users. A major management issue is the problem of resource allocation between the domestic offshore and shore-based components of the fishery.

The main goals of this work are : (1) to develop a dynamic multi-objective programming (MOP) model of the Pacific whiting fishery in the United States ; and, (2) to use this model to evaluate the applicability of multi-objective programming to fishery policy problems. The main purpose of the model is to generate *Pareto-optimal* solutions for three policy objectives : rents, production, and (female) spawning biomass. The set of all *Pareto-optimal* solutions (the *noninferior set*) represents the *production possibility frontier* for the fishery in terms of the relevant objectives. Ballenger and McCalla (1983) refer to the noninferior set as the "policy feasible frontier." Rather than to produce precise numerical solutions, the emphasis at this point is on the usefulness of MOP for fishery policy implementation and analysis.

## 2. BASIC STRUCTURE OF THE PACIFIC WHITING MODEL

### *2.1 A Diagrammatic Representation of the Policy Problem*

Figure 1 shows a diagrammatic representation of the model. This representation of the policy problem consists of three components :

(i) *the regulatory process*, represented by a group of decision-makers, which have at their disposition a set of pre-established policy instruments ;

(ii) a set of biological, environmental, technological, and economic constraints that determine the *state of the system* ; and,

(iii) a set of identifiable and operational *objectives*.

In Figure 1 the rectangular shapes represent endogenous components of the model, the elliptical shapes represent exogenous components, and the arrows represent the important interactions among the different components. We acknowledge that the designation of exogenous components in the model is arbitrary. In reality, no component is completely exogenous. However, a degree of abstraction is necessary to keep the problem bounded.

### *2.2 Biological Dynamics*

The relationships describing the basic biological dynamics of Pacific whiting in the model closely follow the generalized age structured model (geographical version) developed by Dorn and Methot (1989 and 1991) and Dorn et al. (1990) to estimate long and short term yields for the Pacific whiting stock. This age structured model is the tool currently being used to set harvest regulations.

The model separates the stock at the beginning of the fishing season into four regions, according to the classification developed by Dorn, 1990 (see Figure 2) : (1) Eureka, Monterey, and Conception regions (EUR) ; (2) the southern part of the Columbia region (SCOL) ; (3) the northern part of the Columbia region and the U.S. portion of the Vancouver region (VNC) ; and, (4) the Canadian region (CA). Due to Pacific whiting's migratory behavior, catches from the different areas have different age, sex, sexual maturity and weight-at-age compositions, with the northernmost regions having, on average, larger and older fish, and a larger proportion of females.

### *2.3 Recruitment Variability and Biological "Risk"*

Pacific whiting presents extreme variations in recruitment (Hollowed and Bailey, 1989). To model recruitment variability we followed the iterative sampling statistical procedure proposed by Dorn and Methot (1989). This procedure consists of the sampling with replacement from the observed recruitment time series.

The extreme variability in the recruitment of Pacific whiting obscures the relationship between stock size and future recruitment (Hollowed et al. 1989). Without the knowledge of a stock-recruitment relationship, the effect of harvesting on the ability of Pacific whiting to produce successful recruitment cannot be assessed. Associated with harvests is a "risk"

of lowering the stock to a level where it has no longer the capacity of producing successful recruitment. Dorn and Methot (1989, 1991) and Dorn et al. (1990) assess this biological "risk" by focusing on the spawning biomass. The biological "risk" of a particular harvest strategy is determined by the proportion of years that the spawning biomass drops below a cautionary level of spawning biomass (457,000 mt). The current management strategy seeks to maximize yield while keeping biological "risk" at a fixed level (Dorn and Methot, 1989). The authors acknowledge that setting a cautionary level of spawning biomass as a reference to assess biological "risk" is arbitrary.

### *2.4 Harvest and Processing Dynamics*

The domestic Pacific whiting fishery consists of two components, a traditional "shore-based" fishery and a recently initiated "offshore" fishery. The shore-based fishery is primarily composed of the delivery of whiting by mid-water trawlers to shore-based processors, while the offshore fishery consists of factory trawlers and motherships processing at sea. It is assumed that offshore harvesters have incentives to fish for Pacific whiting at the southernmost region of the fishery early in the season so they can participate in the Alaskan pollock fishery later in the year (by June first). Accordingly, the model restricts offshore harvesting activities to the "EUR" region only. The model assumes also that the offshore fishery operates an average of six weeks per season. In contrast, the shore-based fleet depends on processors that are scattered along the coasts of California, Oregon, and Washington. The model assumes that the shore-based fishery season lasts an average of twenty five weeks a year. To keep the levels of harvest consistent with observed levels, fishing mortality across regions was restricted to be no larger in average than 0.5, and annual catches to be no less than fifty thousand mt per season. Even when the shore-based fishery has been expanding rapidly, it is unlikely that it will be able to harvest and process more than 150,000 mt of whiting per year. Accordingly, the shore-based fishery was restricted to no more than 150,000 mt of harvest per season, and the offshore fishery was restricted to no more than 300,000 mt Fishing mortality by the Canadian fishery was fixed at 0.15 annually.

Both fishery sectors consist of heterogeneous fleets and processing facilities producing a variety of product forms. We abstracted from this detail by arbitrarily aggregating the industry into "typical" or representative harvesting/processing units producing surimi. A "typical" shore-based unit consists of a plant with an output capacity of eighteen mt a day served by eight small mid-water trawlers with catch rates of fifteen mt a day. An offshore unit consists either of one factory trawler with an output capacity of sixty-two mt a day or a mothership with an output capacity of sixty-two mt a day served by ten large trawlers with a capacity of forty-eight mt a day. The aggregation was done based on capacity and cost information from the *Pacific Whiting Allocation Draft Analysis* (PFMC, 1992) and the *Oregon Economic Assessment Model* (Jensen and Radtke, 1990). Per unit costs of production, which include fishing and processing, were assumed to be independent of the level of output. Since Pacific whiting is but one of the species caught and processed by both fishing sectors, it is difficult to evaluate the proportion of annual fixed costs attributable to fishing and processing whiting. We adjusted the annual fixed cost figures to reflect the time that it is actually spent fishing for whiting. The model assumes that the capacity to utilize completely the Pacific whiting resource currently exists, and that construction of new vessels or processing facilities will not take place during the time horizon considered. The reader should be cautioned that the information currently available regarding costs of fishing and processing is based on preliminary estimates, and therefore, can only roughly estimate "true" opportunity costs. This is an area where further research is needed.

Catch rates were assumed to be independent of stock size. These may be reasonable assumptions for the range of harvest considered in this study given the schooling characteristics of Pacific whiting. Because Pacific whiting is only one component of the Pacific coast groundfish fishery, and because the volume of surimi produced from Pacific is small in relation to the total market supply, factor and product prices were considered to be independent of the fishery output. The prices of other products based on Pacific whiting such as fillets and headed and gutted may depend on some attributes such as fish size and temporal availability (Sylvia, 1991). However at this point the output of these product forms is small in relation to the production of surimi.

## 3. OBJECTIVES OF MANAGEMENT

Amendment 4 (Section 2.1) to the Pacific Coast Groundfish Plan defines three broad objectives for the groundfish fishery including Pacific whiting : conservation, economics, and utilization.

**Conservation :** Given that the stock recruitment relationship is unknown, it is not possible to use an equilibrium sustainable yield harvesting strategy for the Pacific whiting stock. In this analysis, we incorporated spawning biomass size as an objective of management. We assumed that spawning biomass is inversely related to biological "risk." For the purposes of this work biological "risk" is defined in an ordinal scale. That is, for any two levels of spawning biomass, say $SB_1$ and $SB_2$, if $SB_1$ is larger than $SB_2$ then the "risk" (probability of recruitment failure) associated with $SB_2$ is equal or larger then the biological "risk" associated with $SB_1$ . Additional justification for maintaining higher levels of spawning biomass as an objective of management comes from the ecological importance of Pacific whiting (Livingston and Bailey, 1985).

**Economics** : The economics objective in the model is measured by present value of net revenues (PVNR) at the processing level. This represents a departure from traditional analysis that consider net revenues at the harvesting level only.

**Utilization :** The objective of resource utilization in the current characterization of the Pacific whiting fishery is measured by the weight of product leaving the processing lines. The model considered only production from the United States fishery.

## 4. POLICY INSTRUMENTS

To analyze the effects of resource allocation on the levels of objectives, three policy instruments were considered : (1) an annual harvest quota ; (2) allocation between the offshore and shore-based fisheries ; and, (3) the number of fishing/processing "units" that are allowed to enter the fishery.

## 5. MATHEMATICAL REPRESENTATION OF THE MODEL

The following equations describe the model (see Table I for the glossary of symbols) :

Recruitment :

$$X_{t,r} = rec_t \tag{1}$$

Numbers-at-age, medial age classes,

$$X_{t,a} = \sum_k pr_{a,k} X_{t-1,a-1} e^{(-z_{t-1,a-1,k})} \tag{2}$$

Numbers-at-age, terminal age classes,

$$X_{t,A} = \sum_k pr_{A,k} X_{t-1,A-1} e^{(-z_{t-1,A-1,k})} + \sum_k pr_{A,k} X_{t-1,A} e^{(-z_{t-1,A,k})} \tag{3}$$

Total mortality

$$z_{t,a,k} = m_t + \sum_w F_{t,a,k,w} \tag{4}$$

Fishing Mortality

$$F_{t,a,k,w} = FM_{t,k,w} S_{a,k} \tag{5}$$

Catch in numbers

$$CN_{t,a,k,w} = \frac{F_{t,a,k,w}}{Z_{t,a,k}} pr_{a,k} X_{t,a} [1 - e^{(-Z_{t,a,k})}] \quad (6)$$

Catch biomass

$$CB_{t,w} = CN_{t,a,k,w} wg_{a,k} \quad (7)$$

Annual Catch by Fishery

$$CW_{t,w} = \sum_{a}\sum_{k} CB_{t,a,k,w} \quad (8)$$

Annual Production by Fishery

$$PROD_{t,w,f} = CW_{t,w} PF_{t,w,f} rr_{w,f} \quad (9)$$

Number of Fishing/Processing Units

$$NU_{t,w} = \frac{CB_{t,w}}{C_w} \quad (10)$$

Female Spawning Biomass

$$max. \quad SB = \sum_{t}\sum_{a} X_{t,a} ma_a pf_a wt_a \quad (11)$$

PVNR

$$Max.\ PVNR = \sum_{t}\sum_{w} \frac{1}{(1+i)^t} [(p - VC_w) CB_{t,w} rr_w - N_{t,w} fc_w] \quad (12)$$

Total Output

$$Max.\ OUTPUT = \sum_{t}\sum_{w}\sum_{f} PROD_{t,w,f}. \quad (13)$$

## 6. SOLUTION TECHNIQUE

The solution approach used in this analysis is consistent with the class of solutions known as "generating techniques" (see Cohon and Marks, 1975 for an excellent overview of MOP solution techniques). In particular we used a technique studied by Wendell and Lee (1977) and Corley (1980). This technique combines the characteristics of the *weighing* method (Zadeh, 1963) and the *constraint* method (Haimes *et al.* 1971). Consequently, Chankong and Haimes (1983) call this the *hybrid* method. According to the hybrid method *Pareto optimal* solutions for the Pacific whiting management problem can be characterized in terms of optimal solutions of the following problem :

$$max.\ w_p PVNR + w_y YIELD \quad (14)$$

s.t. $SB > L_{SB}$; *and, Equations* **1** *to* **10,**

Where $w_p$ and $w_y$ represent a set of arbitrary positive "weights" (at least one strictly positive), and $L_{SB}$ is a lower bound on the level of spawning biomass . Pareto optimal solutions can be generated by the parametric variation of $w_p$, $w_y$ , and $L_{sb}$ (see Chankong and Haimes, 1983 for a proof).

## 7. RESULTS AND DISCUSSION

Sixteen *Pareto optimal* solutions were generated over a fifteen year time horizon using the costs, capacities and price figures shown in Table II ; and the biological parameters estimated by Dorn and Method (1991) shown in Table III. Each solution represents the mean of five replicate runs with randomly generated recruitment time series. Net revenues were discounted to the initial period using a.90 discount factor. Four values wer chosen for $L_{SB}$ each representing a different level of spawning biomass (and therefore different levels of "risk") :

(i) $L_{SB} \geq 11.73$ million mt (equivalent to an annual average of 782 thousand mt) - this level corresponds to the optimal spawning biomass used in the variable and hybrid fishing mortality algorithms used by Dorn and Methot (1991) to estimate "sustainable" yields ;

(ii) $L_{SB} \geq 10.920$ million mt (annual average of 728 thousand mt), corresponding to the average spawning biomass of the moderate "risk" "sustainable" yield hybrid strategy ;

(iii) $L_{SB} \geq 10.365$ million mt (annual average of 691 thousand mt), corresponding to the average spawning biomass of the moderate risk "sustainable" yield variable mortality strategy ; and,

(iv) $L_{SB} \geq 9.555$ million mt (annual average of 637 thousand mt), corresponding to the average spawning biomass of the high risk "sustainable" yield variable mortality strategy.

The results are shown in table IV. and are represented in the form of isolines of "risk" in Figure 3. A caveat related to the numerical solutions must be noted. Although it is conceded that the probability of damaging the reproductive capacity of the stock increases as the level of spawning biomass is allowed to fall, the present analysis implicitly assumes that such damage will not be manifested during the time horizon of the analysis but will occur, if at all, at a later period. The validity of this assumption may decrease for lower levels of spawning biomass.

Figure 3 shows a two dimensional representation of a segment of the policy frontier in the form of isolines of "risk." With the additional assumption of monotonicity of preferences, only solutions on the policy frontier are relevant to the decision process. The policy frontier provides several important pieces of information.

(i) It represents the combinations of policy instruments representing (Pareto) efficient utilization of the resource in terms of the objectives considered. It also shows the maximum level of objectives (or combinations of objectives) attainable given the constraints of the problem.

(ii) The policy frontier explicitly reveals the trade-offs associated with policy alternatives. Inspection of the isolines of "risk" reveals that along these lines the trade-offs increase as one attempts to generate more of one objective. This result may have important implications for the validity of traditional cost-benefit analysis of fishery policy, which considers only the maximization of PVNR. Maximization of PVNR as the sole objective of management represents a corner solution (points 4, 8, 12, or 16) in the policy frontier. However, if both objectives are valued this may not be the preferred solution since a larger amount of yield can be obtained (at points 3, 7, 11 or 15) by a relatively small sacrifice in the level of net revenues. The same reasoning applies when maximum yield is the sole objective of management. Although not immediately obvious from the graphical representation, the trade-offs related to the level of "risk" can be evaluated by means of the marginal value (shadow price) associated with the constraint $L_{SB}$ (Chankong and Haimes, 1983). The marginals of $L_{SB}$ for the corner solutions (solutions where either $w_p$ or $w_y = 0$) are reported in Table IV. As shown in Table IV the marginals of the constraint $L_{SB}$ are negative and increase in absolute magnitude as the value of $L_{SB}$ increases. These numbers can be interpreted as the proportional amount of either *PVNR* or *YIELD*, that is lost (in the absence of recruitment failure) by not allowing a marginal decrease in the level of spawning biomass - that is, by not taking a marginal increase in "risk."

(iii) The policy frontier reveals the relationship between policy instruments and policy objectives. Inspection of Figure 3 suggests that along the isolines, increased allocation to the offshore fishery tends to produce more profits but less output. On the other hand allocation to the shore-based fishery provides for a better utilization of the resource (as defined in this work) given a fixed level of "risk." In addition, the results suggest that solutions with the same weights for PVNR and OUTPUT but with lower levels of risk (compare for instance solutions 4, 8, 12, and 16) tend to favor allocation to the shore-based fishery.

The principal factors behind these results are the geographical distribution of the resource and effort, the cost structure, and the harvesting/processing capacities of the industry sectors. The offshore fishery has a larger profit margin and generates more profits but since this fishery concentrates on the southernmost region of the fishery it harvests a larger proportion of younger and smaller fish. Therefore the offshore fishery imposes proportionally larger impacts on the stock for a given level of utilization. Solutions with larger amounts of *OUTPUT* favor allocation to the shore-based fishery, but only up to the assumed 150,000 mt total annual capacity of this fishery, any leftovers are assigned to the offshore fishery. The position and shape of the policy frontier is conditional on the assumptions regarding the geographical pattern of fishing effort and on the cost figures used. Changing any assumption, constraint or parameter can cause shifts and (or) changes in the general shape of the policy frontier. Therefore it is vital that the policy makers clearly understand the construction of a multiple-objective mathematical program before using the results as a guide for policy development. From the analyst standpoint, all the solutions on the policy frontier are equally desirable (i.e. all are *Pareto efficient*). It is up to the decision-makers to select the point on the frontier that better accommodates the needs of the Country.

## 8. CONCLUSION

In spite of the many uncertainties regarding the dynamics of the Pacific whiting fishery and the obvious oversimplifications of the model, we believe that this exercise shows the usefulness of MOP for fishery policy development and analysis. Information in the form of policy frontiers can help analysts and policy actors to systematically explore regulatory options and understand how benefits can be increased to one user group while minimizing losses to another group. MOP models, by focusing on the relationship between controls and benefits, can help decision-makers to better understand the impact of their decisions on user groups, regions, and the nation. This information also may help groups with different interests to more effectively bargain in the policy arena. The information in the policy frontier, however, is intended to complement decision-making, not to replace it, as solutions from many single objective approaches attempt to do. MOP makes explicit the normative elements and trade-offs implicit in single objective models. In short, the policy frontier may provide a basis for an operational definition of the concept of "optimum" yield.

Obviously, the use of MOP models involves a cost. These models are complex, usually requiring more information and data. MOP based models of the fishery require an interdisciplinary understanding of the system. These models are costly to solve, and solutions may be more difficult to understand and evaluate by the decision-makers. Making the benefits of multi-objective techniques outweigh its costs is the challenge ahead. In the case of Pacific whiting our future research using MOP will address a wider range of issues affecting the fishery including market dynamics, seasonal shifts in effort, international allocation, community impact, and economic risk assessment.

TABLE 1.
GLOSSARY OF SYMBOLS.

**Endogenous Variables:**

| | |
|---|---|
| *C* | per unit capacity. |
| *CB* | catch biomass. |
| *CW* | catch by fishery. |
| *CN* | catch in numbers. |
| *F* | fishing mortality. |
| *FM* | fishing mortality for ages with selectivity equal to one. |
| *NU* | number of fishing units |
| *PF* | proportion of catch used in the production of product form f |
| *PROD* | production by product form |
| *S* | selectivity |
| *SB* | spawning biomass, |
| *X* | numbers-at-age |
| *Z* | total mortality. |

**Exogenous variables and Constants:**

| | |
|---|---|
| *c* | per unit capacity. |
| *fc* | fixed costs per fishing unit. |
| *i* | interest rate. |
| *m* | natural mortality. |
| *ma* | proportion of mature females. |
| *p* | product price. |
| *pf* | proportion by weight of females in the population. |
| *pr* | proportion of the stock available (in numbers). |
| *rec* | recruitment. |
| *rr* | recovery rate. |
| *s* | selectivity. |
| *vc* | variable cost. |
| *wg* | individual weight by region. |
| *wt* | average individual weight of the population. |

**Indices:**

| | |
|---|---|
| *a* | *a = r, r+1,r+2...,A* age in years, |
| *A* | terminal age |
| *f* | product form. |
| *k* | *k = 1,2,...K* geographical region, |
| *r* | age-at-recruitment |
| *t* | *t = 1,2,...T* time in years. |
| *w* | fishery ("offshore" or "shore-based"). |

# A Multiple-Criterion Optimization Approach for the Management of a Multispecies Fishery with Ecological and Technological Interdependencies

ABSTRACT

*Resource management decisions in multispecies fisheries with ecological and technological interdependencies, may involve additional conflicting criteria when accounting for the biomass effect of the non-targeted species. Currently, resource managers are increasingly concerned with the biodiversity effect of alternative management strategies.*

*This paper applies a multiple-criterion optimization approach as an aid to management of a multispecies sedentary mollusk fishery : the yellow clam (Mesodesma mactroides). In this fishery, there is incidental harvest of an unmarketed space competing species : the wedge clam (Donax hanleyanus). The approach includes coupling a bioeconomic simulation model with a multiple-criterion optimization algorithm. Fishery performance variables include the biomass effect on target species, fishery yield, net revenues received by fishermen, direct employment, and the biomass effect on the incidental species. Given the resource manager targets for the above mentioned performance variables, a min-max optimization strategy is used as an iterative procedure that finds the largest goal deviation and moves to minimize it. The method operates on all fishery management criteria until non-significant improvement can be made in the one with the largest target deviation vis-a-vis the fishery model response. Implicit in this condition is that at the end of the procedure, no further trade-offs are possible among goal deviations for additional reductions of the maximum goal deviation.*

*The result is an optimizing policy instrument vector. The min-max method, tends therefore to find multispecies Pareto optimal solutions. This can be a useful approach when conflicting multispecies fisheries management criteria are present, and target values in performance variables are made explicit by the decision maker.*

## 1. INTRODUCTION

Management of marine fisheries is significantly complicated by the fact that usually there are more than one criteria of relevance in evaluating the fishery performance. The problem is not just one of maximizing the economic rent generated by the fishery (given certain intertemporal preferences), but also of sustaining biomass of target and incidental (usually threaten) species above certain levels, and perhaps of maximizing food production, coastal employment, and export earnings. In this type of problem, decision makers must make trade-offs among conflicting criteria. Then, the goal of the optimization process must be to assist in ensuring that the best possible trade-offs are made in the given fishery management problem. This involves seeking the so-called "Pareto optimal solutions" to the multiple criterion optimization problem. A Pareto optimal solution in this context, has the property that one decision-making criterion cannot be improved by a decision without making the fishery performance worse off with respect to at least one other resource management criterion (Hannesson, 1978 ; Mendelssohn, 1979).

Optimal control theory has been applied to fisheries to identify the level of fishing effort that maximizes the net present value of economic rent in a variety of fishery contexts (Hilborn *et al.*, 1976 ; Hilborn, 1979 ; Clark, 1985 ; Cohen, 1987). Multi-criteria (Drynan and Sandiford, 1985) and/or non-linear optimization models (Agnew, 1979 ; Garrod and Shepherd, 1981 ; Kennedy and Watkins, 1986 ; Onal *et al.*, 1991) have seldom been used in fishery management. Díaz de León and Seijo (1992) developed a hybrid simulation-optimization model for the estimation of optimal management strategies of a tropical fishery that fulfill pre-existing resource manager preferences. The approach combined multi-criteria and non-linear optimization of a sequential (Willmann and García, 1985) fishery simulation model in a Pareto-optimal manner. The procedure allowed to work with multiple input-outputs, time delays, non linear functions and the natural trade-offs during the estimation process. It has been shown to be a useful decision-making aid, when explicit manager objectives are available.

The purpose of this study is to apply the above mentioned approach to a technologically and ecologically interdependent sedentary fishery, involving two intertidal mollusks of an exposed sandy beach of the coast of Uruguay : the yellow clam *Mesodesma mactroides* and its sympatric and unmarketed species : the wedge clam *Donax hanleyanus*.

## 2. RESEARCH METHODS

### *2.1 Study site and species involved*

The study was conducted on a 22 km sandy beach of the eastern coast of Uruguay comprised between Barra del Chuy (33°40'S, 53°29'W) and La Coronilla (33°50'S, 53°27'W). In this dissipative beach (*sensu* McLachlan, 1990), the yellow clam *M. mactroides* is dominant in biomass terms in the macrofauna community, being subjected to artisanal exploitation by means of simple implements such as shovels (Defeo, 1989). Another sympatric surf clam, *D. hanleyanus*, occurs in the intertidal zone of this exposed sandy beach, but in lower densities and biomass (Defeo *et al.*, 1992). Even though *D. hanleyanus* is not marketed in this area, it is also caught incidentally in this fishery and subjected to disturbance effects occasioned by fishing activities (i.e. sediment removal and resuspension). Furthermore, the observed alternance in abundance from recent long-term studies (de Alava, 1992) suggests that there are ecological interdependencies between both species.

Data was collected between March 1983 and March 1991 from 22 transects (one per km) perpendicular to the shoreline, covering ca. 200 sampling stations per season. Samples were obtained every 4 m across the beach (down to the limit of the clam bed) with a cylinder of 1/16 $m^2$ and continued in the downshore direction until at least two successive empty stations had been sampled.

The full range of sizes was covered for both species, i.e., from 1 to 76 mm for *M. mactroides* and from 1 to 30 mm for *D. hanleyanus*. In the former species, a recruit was defined as the organisms between 1 - 10 mm, and thus have been resident in the benthic population for same time. Adults were all organisms greater than 43 mm, the mean size of maturity according to Masello and Defeo (1986). In the case of *D. hanleyanus*, a recruit was defined as the organism that have attained a size comprised between 1 and 7 mm ; juveniles were considered as those included between 8 and 15 mm, the latter being the mean size at first maturity (Penchaszadeh and Olivier, 1975). Adults were all organisms greater than 15 mm.

The fishing ground was divided into four intertidal sections of similar size, with the boundaries set at right angles to the coastal line (Defeo, 1989 ; Defeo *et al.*, 1991). Population structure and abundance were examined discriminately by zones.

### *2.2 The fishery : management instruments and performance variables*

The yellow clam fishery of Uruguay has been regulated during the last few years by means of an overall catch quota, a minimum catch volume per fisherman and a minimum size regulation.

The explicit objectives of the resource management Institution have been identified as follows : (i) sustain the yield and corresponding net revenues of the fishery over time, (ii) provide employment opportunities for the artisanal fishermen of the localities of Barra del Chuy and La Coronilla, and (iii) avoid destructing resources which are incidentally caught when targeting at the yellow clam. Three management controls were selected : a) the number of authorized fishermen in each locality (Barra del Chuy and La Coronilla), b) an overall quota, and c) a minimum size restriction. The performance of the fishery system was evaluated using the following criteria : biomass of target and incidental species (ton), cumulative total catch (ton) of the yellow clam, and the economic rent obtained in each locality (US$). All variables were evaluated at the end of the season.

### *2.3 The modelling approach*

The analytic approach taken is the "min-max" optimization strategy discussed by Osycska (1984) and Manetsch (1985). The strategy involves minimizing with respect to a single criterion, namely, the maximum deviation of all fishery performance variables with respect to specific targets for each of them. The method works at the beginning with the criteria with the largest goal deviation until it no longer has the largest target deviation. Then, it proceeds to improve the next management criterion which at that point experience the worse goal deviation, and so on. The method stops when all the fishery performance criteria experience essentially the same goal deviations. M-OPTSIM (Manetsch, 1986), the optimization package used in this study, employs Box's "Complex" non-linear optimization algorithm (Box, 1965). It has proven to be an effective means of moving to the neighbourhood of the global optimum. As pointed out by Manetsch (1986), in highly complex optimization problems (such as management of ecologically and technologically interdependent sedentary fisheries), it is often difficult to locate global optimum solutions, and the method developed by Box (Kuester and Mize, 1973), is much more likely to do so than most non-linear programming methods.

A general conceptual model was built, which is composed of three blocks : the fishery model, (ii) the multi-criteria objective function, and (iii) the optimizing block that deals with the objective function, generating the optimal fishery policy vector.

### *2.4 Fishery Model*

The fishery model used is the one developed by Seijo (1986) ; Seijo *et al.* (1987) and Seijo and Defeo (this volume), expanded to consider ecological and technological interdependencies in a multispecies fishery. It is an age structured and spatial bioeconomic model designed using the systems simulation approach. The suggested ecological interaction between *M. mactroides* and *D. hanleyanus,* is that adults filter larvae out of the water column (de Alava, 1992), affecting recruitment success. The most abundant, *M. mactroides*, which have substantially larger siphons and a major filtration capacity, is assumed in this paper as the dominant competitor. Therefore, recruitment of *D. hanleyanus* is modelled through a multivariate density-dependent function which has as independent variables the density of spawning stock of *D. hanleyanus* and the density of juveniles and adults of *M. mactroides* at settlement time (de Alava, 1992).

### *2.5 The Multi-Criteria Objective Function*

Given the above mentioned model, **M**, a block diagram for the multi-criteria optimization problem which employs the Osyczka (1984) min-max strategy, is expressed in equation (1) as follows (Manetsch, 1985 ; Díaz de León and Seijo, 1992) :

$$\bar{f}_j(T) = M(\bar{\alpha}_j, T) \quad (1)$$

where :

$\bar{f}_j(T)$ = vector of values for the multi-criteria function corresponding to management option j, assessed in time horizon (0,T).

$\bar{\alpha}_j$ = decision parameter vector corresponding to the fishery management option j (j=1,2,...,J).

(0,T) = time horizon of interest for managing the multispecies fishery.

Model **M** is then operated in optimization mode as presented in Figure 1, where :

$Z_{ijk}$ = normalized deviation of the ith criterion value with respect to the management goal j and goal set k.

$\mathbf{Z_{jk}}$ can be expressed as follows :

$$Z_{jk} = MIN\,[MAX\,i\,(Z_{ijk})] \quad (2)$$

and, $\mathbf{Z_{ijk}}$ is estimated by equation (3) :

$$Z_{ijk} = \frac{(g_{ik} - f_{ij})}{|b_i|\, sgn(g_{ik} - b_i)} \quad (3)$$

where :

$g_{ik}$ = target for the ith criterion of the goal set k ($g_k$ is the target vector corresponding to the goal set k).

$b_i$ = "base" values for the ith criterion.

$\bar{\alpha}^*_j$ = parameter vector resulting from the min-max optimum $Z^*_{jk}$, $f^*_j$.

The sgn ( ) function changes the sign of $\mathbf{Z_{ijk}}$ for those goals which are less than the "base" values. This is how $\mathbf{Z_{ijk}}$ values related to different variables, different strategies and different goal sets can be compared.

The iterative procedure finds the largest deviation and minimizes it, operating on all criteria until no significant improvement can be made in the one with the largest goal deviation. The result is an optimal parameter vector. For this reason the "min-max" method tends to find Pareto-optimal solutions to the multi-criteria optimization problem.

The problem with this approach is the possibility of obtaining multiple solutions, some Pareto inferior to others. To cope with this, it was necessary to use a search procedure in an attempt to find a global optimal solution. This was achieved using the "Complex" method.

### *2.6 The Complex Optimization Method*

This method was developed by Box (1965) and applied in an enhanced manner to multi-criteria problems by Manetsch (1985, 1986). Its purpose is to find the maximum or minimum of a non-linear multivariate function subject to non-linear inequality constraints :

Objective funtion :

$$\text{Max } F\,(X_1, X_2, X_3, ..., X_n) \quad (4)$$

subject to :

$$G_i \le X_i \le H_i \text{ for } i = 1, 2, ... n..., k. \quad (5)$$

The implicit variables $X_{n+1}$, ... $X_k$ are dependent functions of the independent explicit variables $X_1$, $X_2$, ... , $X_n$, and the superior and inferior restrictions $H_i$ and $G_i$ could be either constants or independent variable functions. The method is a sequential search technique that attempts to find global optimal solutions (minima or maxima) since the initial set of

points are randomly scattered within the feasible region. Each of these sets of values corresponds to a vertex of a geometrical figure or "complex" generated in the n-dimension searching space. Associated with each vertex is a function value (calculated from the simulation model). The procedure converges towards the global optima, shrinking the search around that point (Manetsch, 1985). The problem was solved using the M-OPTSIM system (Manetsch, 1986) run on a personal computer. The solution was reached in the optimization module, calling the simulation model and the "min-max" strategy as subroutines.

## 3. RESULTS

The multiple criterion optimization approach used for this intertidal fishery was conducted for two sets of policy goals, which reflect the willingness of the decision maker to allow for tradeoffs among performance variables. These goal sets are presented in Table 1. In goal set 1, the decision maker is assumed to be willing to sacrifice biomass of the target species (*M. mactroides*) in order to increase biomass of the threatened species (*D. hanleyanus*) and economic rent perceived by fishermen of both localities. In goal set 2, the decision-maker explores the possibility of increasing the biomass of both species trying to achieve at the same time the previous level of economic rent. In order to proceed with the optimization procedure, constraints (upper and lower limits) for the policy instruments vector were specified (Table 2).

The optimized results obtained for the biologic and economic performance variables for each of the goal sets specified above, are presented in Table 3. With goal set 1, the willingness to achieve higher biomass levels in the threatened species (*D. hanleyanus*), and to increase economic rent in both localities, results in a small reduction of biomass (with respect to the base values) of the target species (*M. mactroides*). Biomass of the threatened species increases 31 %, while that of the target species decreases only 2.2 %. The economic rent obtained in each locality also increases by 17 %. The corresponding policy instrument vector involves increasing the number of fishermen, increasing the fish quota by 10 %, and a minimum size restriction of age 7 (quarters) instead of age 6. With goal set 2, the decision-maker is assumed to be willing to also increase biomass of the target species. In order to achieve the above, the optimizer selects a policy instrument vector that constraints substantially fishing effort and harvest, and further increases the minimum size restriction. This results in improvements in both levels of biomass with a substantial tradeoff in economic rent with respect to both base values and goal set 1. Optimized policy instrument vectors corresponding to each of the optimized goal sets, are presented in Table 4.

## 4. DISCUSSION

The multiple criterion optimization approach, employing min-max optimization has been found to be an effective means of generating a range of Pareto-optimal policy options which display feasible tradeoffs among economic and ecologic goals for a model of the multispecies fishery. The method allows decision making preferences and values to be incorporated explicitly by means of the goal sets specified.

The complexities of the ecological and technological interactions (Anderson, 1977) are observed in system performance when specifying goal set 1, which results in improvements in the final level of biomass of the threatened species at the cost of reducing the biomass of its dominant competitor, the target species. Here, the effect of the ecological interdependence of competitive coexistence is observed. To achieve the above, the optimizer increase the fishing pressure on the target species while increasing the minimum size restriction. It results in additional economic rent for both localities at the end of the run. The willingness to also increase the level of the target species biomass, goal set 2, results in two optimization effects. First, the level of fishing intensity is reduced (with respect to the previous goal set), which also reduces the pressure on the incidental species (technological interdependence). Second, a substantial reduction in economic rent for both localities becomes the **tradeoff**.

A number of goal sets can be explored generating a set of Pareto optimal solutions to this conflicting criteria optimization problem. To satisfy the preferences and values of those concerned with conservation of biodiversity, (and thus reducing to the maximum the threats to the incidental species), the decision-maker may have to select goal set 2, at the cost of

reducing the economic rent generated by the resource. On the other hand, the optimized solution of goal set 1, results in substantial increments in economic rent as well as in improvements in threatened species biomass, although at lower levels than with goal set 2. By selecting one or the other, the decision-maker will make also explicit its value judgements with respect to whose preferences count in the use of these renewable resources.

The approach presented here could be applied to other complex systems where conflicting criteria, and dynamic ecological and technological interdependencies are present (e.g. optimal management of transboundary resources).

# The Role of Multiobjective Policy Models in Fisheries and Aquaculture Development

**Gilbert Sylvia**

Coastal Oregon Marine Experiment Station, Department of Agriculture and Resource Economics,
Oregon State University, Newport, Oregon 97365

ABSTRACT

*The use of multiobjective policy models in fisheries and aquaculture are reviewed. Concepts form neo-classical economics and public choice theory are used to explore the potentials for these models under alternative theories of research management including pluralism, scientific management, and rights based approaches. Conceptual models in fisheries and aquaculture are developed to illustrate the discussion. Dynamic policy frontiers are then generated for purposes of comparative analysis. Results show that the class of multiobjective models known as multiattribute utility theory are consistent with a fisheries or aquaculture policy process characterized by principles of scientific management. Conversely, policy models based on more traditional multiobjective programming approaches are most appropriate when the policy process is driven by a pluralistic process. The paper concludes by emphasizing the role that multiobjective methods can play in moving the policy process from a scientific or pluralistic framework to one incorporating formal property rights.*

## 1. INTRODUCTION

Economists confront a wide range of issues when selecting approaches for analyzing natural resource problems. Economists must consider not only the issues which characterize the policy problem (e.g., policy objective(s), quality of the data, time horizons, budget constraints) but also their own analytical strengths and weaknesses. Often overlooked in the decision to develop the "best" approach, however, is consideration of the fundamental features which characterize both the policy process and the role which the economist plays within this process. Is the policy process orderly or chaotic ? Does it rely heavily on public participation or is it dominated by a few scientific managers ? Are economists important players in guiding and improving the process or are they merely perfunctory performers ?

These questions are particularly relevant to fisheries or aquacultural economists who work within a public policy process or "political marketplace". The "marketplace" may be bureaucratic if the management process is based on a closed system of scientific management, pluralistic if the decisions are reached through an open political process, or as is often the case, combine elements from both these approaches (Simmons and Mitchell 1984).

For most public policy problems analysts cannot use traditional market prices to capture and transmit information about the "highest valued" or "best" use(s) of the resource (the exception is where marketable property rights have been established). No well defined welfare function exists which can be "optimized" in order to determine the best set of public policies. In many cases decisions to manage and allocate are ultimately made using the "currencies" which characterize the political and bureaucratic arena - votes in the political arena, security and discretionary income within the corridors of bureaucratic management (Niskanen, 1975). The fundamental issue for policy economists is to determine the types of analytical approaches which will provide knowledge consistent with improving the performance of a "political marketplace".

The following paper discusses alternative approaches for developing economic policy information for fisheries and aquaculture. The first section of the paper reviews important features of the fisheries and aquaculture policy process. The next section reviews different classes of candidate modelling systems.

Concepts from neo-classical economics and public choice theory are used to explore the potential of these models under alternative theories of resource management including pluralism, scientific management, and rights based approaches. Conceptual applications are formulated to illustrate the discussion. Dynamic and capitalized policy frontiers are generated for purposes of comparative analysis. The paper concludes by emphasizing the role that multiobjective models can play in moving the policy process from a scientific or pluralistic framework to one incorporating formal property rights.

## 2. THE POLICY PROCESS

Economists have long recognized that natural resource problems including fisheries and aquaculture are characterized by more than one social objective (Crutchfield, 1972, Scott 1979). This feature is often reflected in the legislative mandates governing the use of these resources. For example, the U.S. Magnuson Fishery Conservation and Management Act (MFCMA) (United States Congress, 1976) stated as its primary goal to "provide for greatest overall benefits to the Nation" by realizing such objectives as "conserve the fisheries", "achieve optimum yield on a continuing basis", "promote sound conservation and management principles", "take into account the social and economic needs of the states", and "promote efficiency". Aquaculture policy includes similar objectives. For example, the Canadian government stated that their national goals for aquaculture development included "increasing economic returns", "improving the reliability of (seafood) supply", "creating new employment and enriching income possibilities," "being complementary to wild fisheries," and "encouraging sustainability" (Freshwater Fisheries Committee of Ministers, 1986).

However, while these objectives appear reasonable they may not be complementary. Increasing one objective such as regional benefits may decrease other goals such as national efficiency. The analyst, therefore, must determine the relative importance which society places on the alternative objectives. However, as articulated within the governing mandates and as interpreted by management agencies, objectives are seldom prioritized and often are too poorly defined to provide a consistent set of criteria for management purposes (Christy, 1977). Therefore, while mandates such as the MFCMA may stipulate comprehensive socio-economic analysis, they remain vague in describing how this information should be developed and measured (Jacobson et al., 1985).

Such a situation leads to socioeconomic analysis which is underfunded, ad-hoc, and crisis driven. Rather than socioeconomic information playing a significant role in guiding the fisheries policy process, the policy process itself significantly limits the extent of the socioeconomic analysis (Stokes 1983, Fricke 1985). Policymakers and other participants in the policy process are rarely provided the opportunity to carefully consider the implications of their decisions in terms of foregone social opportunities. One consequence is that policy decisions may become overtly "political" and represent only those interests which have successfully "captured" the policy process (Fricke 1985).

The marine aquacultural policy process shares many characteristics with fisheries. However, in a number of cases it may be even more complex because it occurs in an institutional setting known as "governance" (Dorcey, 1986, Hennessey and Robadue, 1986). Policy is not developed and implemented within a well ordered institutional process but evolves as multiple agencies attempt to formulate and implement policies based on vague legislative mandates. The process is characterized by extensive bargaining and the failure of the process to produce effective policies for aquaculture development is often due to the failure of the process to provide "functional" policy information, i.e., information which

demonstrates the relationships between socio- economic goals and institutional behavior (policy instruments) (Dorcey, 1986). Without this information bargaining agents cannot determine how their own goals can best be achieved "in light of agreements that appear possible and which provide benefits to all groups or result in the least costly trade-offs."

## 3. MODELING SCHEMES

Developing functional socioeconomic policy information requires sophisticated skills on the part of the policy analyst. These skills can be combined with powerful desktop computers and efficient solution algorithms. With the appropriate models, biological, economic, sociological, and regulatory information can be integrated and analyzed in a form consistent with the public policy process and guiding legislative mandates.

Sophisticated operational techniques exist to take advantage of this computational power. Although a detailed description of these techniques are beyond the scope of this paper, these techniques include multiple objective programming (Cohen and Marks, 1975), generating and goal programming (Willis and Perlack, 1980), adaptive learning (Rausser, 1978), and multilevel programming (Candler et al., 1981). While each approach (or combination of approaches) has distinct advantages, most analysts have considered multiple objective models to be superior to single objective approaches. Some analysts have also preferred multiple objective models which do not require a prior articulation of preferences, such as goal programming, since preferences are rarely known in most public policy problems. In addition, while some researchers believe that multiple objective models should simulate the bargaining process, other researchers believe that such an approach is too ideal in light of the complexity of most public policy issues (Cohon and Marks, 1975).

Some fisheries analysts, especially academic researchers, have attempted to develop formal policy models and operational programming techniques consistent with the policy process. Many of these approaches are summarized in Healey (1984) and Charles (1989). Although approaches have varied, including static and dynamic, single objective versus multiple objective, and passive versus active learning, multiobjective based techniques have received the most recent attention.While a multiple objective goal programming model has been used by Drynan and Sandiford (1985) for Scottish near-shore fishing fleets, and dynamic multiobjective programming by Charles (1989), the multiobjective approach receiving the most recent attention has been multiattribute utility analysis (MUA) (Keeney and Raiffa, 1976 ; Edwards and Newman, 1982).This technique has been applied to a number of fisheries including the New England herring fishery (Healey, 1984, 1985), the Skeena river salmon fishery (Keeney, 1977 ; Hilborn and Walters, 1977 ; Healey, 1984), the Oregon coho salmon fishery (Walker et al., 1983), and a Canadian invertebrate commercial fisheries (Boutillier et al. 1988). For aquaculture policy problems, dynamic multiobjective multilevel approaches have been developed by Sylvia (1992).

While the operational techniques related to the different multiple objective approaches vary, the modeling strategies fall into two general classes : (1) those strategies which are designed to ultimately identify a single policy optimum ; (2) and those strategies designed to identify only ranges of policy options. For most problems the first class of techniques are appropriate when the policy process is relatively well ordered, involves only a few decisionmakers, and is short-term in nature. In many cases this is consistent with a policy process driven by scientific management, i.e., a policy process which relies primarily on the decisions of a few select scientifically trained managers. This allows techniques like MUA which use multiple objective analysis, to identify the policymaker(s) derived utility function(s) through the use of strategic questionnaires and then to integrate this function with other elements of the policy problem in order to determine a single or narrow range of potentially optimal policy solutions. Note, however, that consistent with public choice theory, the utility functions generated by MUA are actually reduced form functions. The values on policy objectives generated from MUA may not represent the "true" values on the explicit policy objectives, but rather may include values on subjective goals not measured by the survey techniques. These goals may include such private objectives as increasing discretionary income or obtaining job promotions. Therefore, the derived utility function may be useful only in the short run since it will vary with respect to changes in the relationship of public policy objectives and the private welfare of the decision makers.

In contrast, approaches characterized within the second class may be more useful when the policy process is disorderly, when it involves many policy participants, and when it is characterized by extensive bargaining, i.e., a pluralistic process. Operational methods included under this approach such as generating techniques and multi-objective/multi-level programming would not be designed to determine an optimal policy position, but rather to reveal the implications of

policy options. This information would then be developed for helping decisionmakers and agency administrators explore the policy problem and structure the policy debate. The focus, therefore, is on information designed to improve the entire policy process, rather than the insular decisions of a select group of decisionmakers.

Multiobjective models also provide an important heuristic function : their operational design requires that the analyst explicitly choose which management objectives, regulatory policies, and operational constraints to include in the analysis. Their design also compels the decisionmakers and policy actors to explore important policy relationships and to recognize that selecting certain regulatory schemes implies relative values on social objectives. Finally, it forces policymakers to acknowledge the concept of policy frontiers, that is, that for any given set of relative management values, there are policy choices which can increase one objective, without necessarily decreasing the levels of other objectives.

## 4. THE DYNAMIC MULTIOBJECTIVE FISHERIES PROBLEM

Using the dynamic framework developed by Clarke and Munroe (1975), the relationship between single and multiobjective analysis for the fisheries problem can be illustrated where

$\delta$=discount rate,

h(t)=harvest level,

x(t)=stock size,

$\pi(h(t), x(t))$ = profit function [where $\pi_h > 0$, $\pi_{hh} \leq 0$, and $\pi_x > 0$, $\pi_{xx} \geq 0$],

$F(x)$ = the function describing the natural growth rate of the stock, [where $F_x \leq 0$, $F_{xx} < 0$],

and the state equation $\dot{x} = F(x) - h$.

The well known equilibrium solution to maximizing rents in the fishery is

$$F_x = \delta - \frac{\pi_x}{\pi_h}, \tag{1}$$

where at optimal equilibrium stock size (x*, h*) $F_x$, the marginal physical product of the resource stock equals the social discount rate ($\delta$) minus the "stock" effect, $\pi_x/\pi_h$.

If society's only interest, as represented by the decisions of scientific managers or the outcomes of a pluralistic processes was to maximize rents from the fishery, then the optimal stock size and harvest levels would equal x*, h* respectively. However, society could be interested in other objectives such as revenue. Such a case would occur where owners of capital live in areas distant from the location of the fishery and relatively isolated coastal communities are highly dependent on the direct and indirect income and employment impacts generated from the fishery. In this case society, through its representatives and decision makers, would be ambivalent regarding the "optimal solution" since maximizing either objective might lead to outcomes which were not considered to be in society's overall interests.

In this case, multiobjective analysis could provide information in a form consistent with the policy problem. This can be most easily demonstrated by reformulating the objective function :

$$Maximize: \int_t^{\infty} e^{-\delta t}[a\pi(x(t), h(t)) + bR(h(t))]\, dt\,. \tag{2}$$

where R(h(t)) is the revenue function and a and b are relative values on the objective of profits and revenues ($a + b = 1$ ; $0 \leq a, b \leq 1$). The Hamiltonian of the problem is :

$$H = E^{-\delta t}[a\pi(x(t), h(t)) + bR(h(t))] + \lambda(t)(F(x(t)) - h(t))\,, \tag{3}$$

where (t) is the adjoint variable or shadow price of the resource.

The optimality condition for an interior solution is :

$$e^{-\delta t} a\pi_h + bT_h - \lambda = 0\,, \tag{4}$$

the adjoint equation is equal to :

$$e^{-\delta t} a\pi_x + F_x = -\dot{\lambda} \tag{5}$$

and the transversality conditions include $e^{-\delta T} \lambda \geq 0$, $e^{-\delta T} \lambda X \geq 0$, and $H(T = \infty) = 0$. Taking the time derivative of (4), equating with (5) and substituting in for $\lambda$ from (4), and solving for long run equilibrium where $\dot{x}$ and $h = 0$ (i.e. $e^{-\delta T} \lambda X = 0$, where $T = \infty$) yields :

$$F_x = \delta - \left[ \frac{a\pi_x}{a\pi_h + bR_h} \right]. \tag{6}$$

The optimal equilibrium marginal growth rate of the stock is equal to the discount rate minus the "stock effect". The "stock effect" now includes the relative values on profit and revenues, and the marginal "supply costs" include the weighted value of marginal revenues. As the relative value on profits approaches one ($a \rightarrow 1$) and the value on revenues approaches zero ($b \rightarrow 0$) the optimal level of stock ($x^{**}$) and harvest ($h^{**}$) approaches $x^*$, $h^*$. In contrast as b1 and a0, the "stock effect" approaches zero and the marginal product of the stock approaches the discount rate, i.e. the solution where use of the resource is assumed costless.

## 5. THE MULTIOBJECTIVE MARINE AQUACULTURE PROBLEM

Similar to the fisheries case, marine aquacultural policy issues will inevitably involve multiple policy objectives. Commonly, however, the policy issues will focus on the negative externalities, rather than the positive social benefits which marine aquaculture (Sylvia, 1992) may generate. The policy problem, therefore, is to determine the effectiveness of policy instrument(s) in controlling externalities, while generating other aquaculture benefits including profits, employment, income, or consumer surplus.

For example, suppose that two primary objectives are profits and water quality. Note that in many cases the debate will focus on the amount of effluent, but not necessarily the welfare losses generated from effluent since this relationship may not be well understood. In these cases multiobjective analysis can generate values on effluent and demonstrate the costs of effluent control in terms of foregone profits, revenue, or employment (or any other positive objective that may be generated by the industry).

The aquacultural objective function may be formulated as :

$$Maximize : \int_0^{\infty} e^{-\delta t} [a\pi(Y(t), E(t)) - bE(t)]\, dt \tag{7}$$

$$\text{s.t. } \dot{E} = G(Y(t), E(t)) \tag{8}$$

where $\dot{E}$ = effluent and $G(Y(t), E(x))$ is the effluent state equation. In this case the effluent stock is increased by greater fish production ($G_y > 0$, $G_{yy} \leq 0$) but decreases due to natural physical and biological forces acting on the effluent stock ($G_E < 0$, $G_{EE} \leq 0$). The profit function is not only a function of production ($\pi_y < 0$, $\pi_{yy} \leq 0$) but also a function of effluent which is assumed to negatively impact fish growth ($\pi_E < 0$, $\pi_{EE} \leq 0$). The control variable or policy instrument is the allowable level of fish production.

The Hamiltonian is :

$$H = e^{-\delta t}(a\pi(Y(t), E(t))) - bE(h(t)) + \lambda G(Y(t), E(t)) . \tag{9}$$

The optimality condition for an interior solution is

$$e^{-\delta t} a\pi_y + \lambda G_y = 0 , \tag{10}$$

and the adjoint equation is equal to

$$e^{-\delta t} a\pi_E - e^{-\delta t} b - \lambda G_E = -\dot{\lambda} . \tag{11}$$

Using these conditions and solving for the equilibrium solution (where $\dot{Y}$ and $\dot{E} = 0$) as the ratio of relative weights or marginal social prices yields :

$$\frac{b}{a} = \pi_y \frac{(G_E - \delta)}{G_y} - \pi_{.E} \tag{12}$$

To help illustrate the solution suppose

$$\pi = pY - hY - kY^2 - qE , \qquad \text{and} \tag{13}$$

$$\dot{E} = uY - vE . \tag{14}$$

By substitution the ratio of marginal values of effluent and profit equals :

$$\frac{b}{a} = (p - h - 2kY^*) \frac{(\delta + v)}{u} - q , \tag{15}$$

or rearranging terms :

$$Y^* = \frac{p - h}{2k} - \frac{qu}{2k(\delta + v)} - \frac{b}{a}\left(\frac{u}{2k(\delta + v)}\right) , \tag{16}$$

$$E^* = \frac{u}{v} Y^* . \tag{17}$$

The optimal level of fish production and effluent is a function of the set of parameters associated with profits and the state equation, but also includes the ratio of weights on effluent and fish production. The right hand side of (16) includes three sets of terms : the first term shows the effects on optimal equilibrium production as a function of the parameters directly related to fish production ; the second term shows the indirect effects on fish production as a result of costs related to effluent production ; and the third term shows the effects on production due to the relative weights or "values" on profit and effluent. Unambiguously, as the value on effluent approaches unity (b1, a0) the equilibrium level of fish production and effluent decrease ; conversely as the value on profit increases (b0, a1) the last term in (16) vanishes and the optimal fish production equals the level which maximizes the firm's profits.

## 6. THE POLICY FRONTIERS AND THEORIES OF RESOURCE MANAGEMENT

Three types of policy frontiers are generated by parameterizing on policy weights and repetitively solving the dynamic fisheries or aquaculture multiobjective policy problem : 1) a single equilibrium frontier ; 2) a single capitalized frontier, and ; 3) a set of dynamic frontiers. These frontiers are illustrated in Figures 1-3. The capitalized frontier (Figure 1) demonstrates the highest aggregated discounted levels of achievable objectives given sets of alternative weights. Associated with each position on the frontier is a unique set of policy goals, weights, and instruments. Positions within the frontier are inferior since higher levels of either objective are possible given the admissible set of policy instruments. The equilibrium policy frontier (Figure 2), represents the combinations of objectives achievable in long run equilibrium (if an equilibrium exists). The position and shape of this frontier can be compared with solutions generated by more conventional static multiobjective programming approaches to determine how discount rates, initial conditions, and permissible approach paths affect policy goals. Figure 3 shows the dynamic frontiers, i.e., policy frontiers which shift through time. These dynamic frontiers show the combination of objectives achievable at each time period for each set of policy weights. If policy instruments are allowed to vary through time, associated with each point on each dynamic frontier is a unique set of policy instruments. If points across time periods are connected according to common weights, the dynamic changes for each set of weighted objectives can be traced out as they approach the equilibrium frontier. While Figures 1-3 show generalized frontiers, the precise shape of these frontiers will depend on the particular features of the problem, including the characteristics of the state equations, the autonomy of the problem, the degree of non-linearity in controls and states, and the initial conditions.

These frontiers can be used to illustrate the relationship between analytical approaches and alternative theories of resource management. For example, if the management process was driven by the decisions of scientific managers, multiobjective techniques such as multiattribute utility analysis could be used to identify a single position on the frontier consistent with maximizing the manager(s) utility (for example, point A). Alternatively, if management involved a small group of decisionmakers with different utility functions (represented by point A and point C), various compromising techniques could be used to reach consensus at, for example, point C (Nijkamp, 1979). In most cases, however, fisheries and aquaculture policy problems will be resolved within a process dominated by pluralism. The "best" modelling approach would not be designed to locate a single position (on the frontiers), but to demonstrate the shapes and positions of the frontiers. The information represented by these frontiers would then be used to facilitate the policy process and compel policymakers and policy actors to recognize choices which are clearly "irrational" or inferior (e.g., sacrificing "large" amounts of marginal profits to achieve "small" amounts of marginal revenue or marginal water quality ; or selecting an inferior position such as point D relative to point A in Figure 1).

## 7. THE PROBABILITY OF POLICY ADOPTION

There may be cases where policymakers believe that certain policy instruments have a low probability of adoption. For example, suppose that in our fisheries problem the probability of selecting harvest levels was a function of the associated stock size (e.g., policymakers or groups of policy actors are reluctant to select harvests levels which result in relatively "small" stock levels). Using the approach developed by Zeckhauser (1981), the dynamic multiple objective problem can incorporate these probability functions. In our generalized multiobjective fisheries problem, revenue would now be a function of stock size :

$$Maximize : \int_t^{\infty} e^{-\delta t}[a\pi(x(t), h(t)) + bR(h(t), x(t))]\, dt . \tag{18}$$

Taking the appropriate conditions and solving yields an equilibrium solution of the form :

$$F_x = \delta - \left[ \frac{a\pi_x + bR_x}{a\pi_h + bR_h} \right] . \tag{19}$$

If $\pi = ph\rho(x) - c(x)h\rho(x)$ and $R = ph\rho(x)$ where $\rho(x)$ is the probability of adopting any harvest level as a function of the stock size ($\rho_x > 0$, $\rho_{xx} \gtreqless 0$) then,

$$F_x = \delta + F\left[\frac{ac_x}{a(p-c)+bp} - \frac{\rho_x}{\rho}\right]. \tag{20}$$

For all weighted objectives the marginal growth rate of the equilibrium stock is now smaller than the case where the probabilities of adoption are not included in the analysis. The term $\rho_x/\rho$ which describes the rate of change in the probabilities of policy adoption as a function of marginal changes in stock size, causes the policy frontier to shift in. The position and shape of the new frontier would depend on how changes in the stock size affects the probability of adopting various harvest rates. This shift could be significant if policy actors including biologists were, for example, uncertain about the relationship of stock size and recruitment, or if the stock was perceived to be important to other fisheries or other species, including species which may be considered threatened or endangered.

In using a Zeckhauser approach, however, the economist, may inadvertently limit policy outcomes. The Zeckhauser approach may be valuable when the policy debate involves only a few groups or individuals, e.g., where the debate is dominated by scientific management. However, in a more pluralistic process, it may be difficult to estimate with any precision the probabilities associated with selection of policy instruments such as harvest levels, especially if the timing and availability of information can affect the policy outcome. The analyst, therefore, could ultimately affect policy outcomes by limiting the availability of the policy information.

An alternative approach more consistent with a pluralistic process would be to demonstrate to policy actors how their "attitudes" toward policy instruments could affect the potential levels of achievable policy goals. For example, if stock levels have some "value" other than for the fishery in question, this value can be expressed by expanding the multiple objective framework to include the stock level explicitly. Our multiple objective fisheries model would now take the form :

$$Maximize: \int_0^T e^{-\delta t}[a\pi(x(t), h(t)) + bR(h(t)) + cx(t)]\,dt \tag{21}$$

$$\text{s.t. } \dot{x} = F(x(t) - h(t))$$

where c is the relative value on stock (a+b+c=1 ; $0 \leq$ a, b, c $\leq 1$). Setting up the Hamiltonian and using the first order conditions yields the following equilibrium solution :

$$F_x = \delta - \left[\frac{a\pi_x + c}{a\pi_h + bR_h}\right]. \tag{22}$$

As the value on stock increases (c$\rightarrow$1, a, b$\rightarrow$0), a and b decrease and the second term on the right hand side of (22) approaches infinity. Therefore, as the value on stock increases, harvest rates decrease, stock size increases, and both profit and revenue decrease.

Including three objectives results in a three dimensional policy frontier. In two dimensions the frontier can be represented as a set of isoquants. Figure 4 illustrates the case for the capitalized policy frontier where isoquants are generated for fixed weights on stock size but varying weights on profit and revenue (this is analogous to having alternative probability distribution functions associated with harvest levels). The isoquants show the loss in revenues and profits for increasing "gains" in stocks. In this form, decisionmakers and policy actors must address the relevant tradeoffs and determine whether the marginal loss in terms of other social objectives are "worth" the gains in stock size. Therefore what was an internal issue under a Zeckhauser approach, now becomes an important economic question that can be addressed within the pluralistic public policy debate.

## 8. CONCLUSION

Multiobjective techniques applied to fisheries and marine aquaculture policy problems provide important analytical tools for broadening analysis beyond traditional cost-benefit approaches. Rather than attempting to identify a single or narrow

set of solutions for a select groups of decisionmakers, this information can provide "functional" policy information to improve the effectiveness of the bargaining process. Information can be developed in the form of dynamic and equilibrium policy frontiers which can help the managers guide the policy debate while constraining "unreasonable" policy choices.

If used effectively multiobjective approaches also have the potential for addressing management issues related to allocation of formal and informal property rights in fisheries and aquaculture.

Multiobjective analysis can help analysts uncover the implicit tradeoffs implied by initial allocation of property rights to alternative user groups. Multiobjective analysis also has the potential to help understand how different institutional arrangements can affect bid prices by focusing on the types of social returns which alternative user groups may seek to maximize.

In summary, multiobjective approaches in fisheries and aquaculture provide a valuable tool for helping decisionmakers understand the policy problem and guide the policy debate. While these approaches are characterized by the same limitations that confront all bioeconomic analysis, their most important attribute is that their structure is consistent with the nature of the policy process. These approaches can provide the analyst with important tool for addressing the difficult management issues which will confront decisionmakers in fisheries and aquaculture during the last decade of the 20th century.

# Bioeconomic Multispecies Modelling of the Barents Sea Fisheries

**Arne Eide and Ola Flaaten**

Norwegian College of Fishery Science, University of Tromsø, Breivika, N-9037 Tromsø, Norway

ABSTRACT

*The aim of this paper is to present a multispecies and multifleet model which integrates biology, harvesting, and economics. The model, ECONMULT, is designed, developed and implemented as a management tool for the Barents Sea fisheries. The economic part of the model includes several homogeneous fleet segments ; each has a specific species, or cohort, as its main target, and other species as bycatch. Fleet productivity coefficients and costs as well as ex-vessel fish prices are input data. The economic part of the model may be linked to any biological multispecies model whose stocks are described by a biomass vector. Present value of net economic benefit from different harvesting paths is computed.*

*A preliminary two-species model of cod and capelin, MULTSIMP, developed by the Institute of Marine Research, Bergen, has been used for model experiments with ECONMULT. The combined model, ECONSIMP, has been implemented on a SUN computer using Mathematica software.*

*Preliminary simulations with MULTSIMP indicate that for current Norwegian effort costs and fish prices, the combined harvesting of cod and capelin is more profitable than harvesting just one of the two species.*

## 1. INTRODUCTION

This paper describe an economic multifleet harvest industry model which together with a biological multispecies model is integrated into a bioeconomic multispecies model. This model is called ECONMULT, first outlined in Eide and Flaaten (1991) and fully documented in Eide (1991 and 1992). The bioeconomic model will be used for simulation of past and future fisheries, as well as for optimization of the fisheries. With respect to the latter point, the aim is to develop the bioeconomic model into a useful tool for fisheries management in Norway. In the design and the development of ECONMULT special consideration has been taken to the development of biological multispecies models by the Institute of Marine Researach, Bergen (IMR), to the actual structure of the Norwegian fishing fleet operating in the Barents Sea/Norwegian coast area, and to the availability of data. However, ECONMULT is designed so generally that it can be applied to other fisheries as well.

The theory of optimal management of renewable resources is fairly well developed within the single species context ; see e.g. Munro and Scott (1985) for a review of the fisheries economics litterature. Several authors have extended single species analysis to include multispecies interactions and harvesting, for example :

i) Theoretical analysis of management of competing species and predator-prey systems, e.g. Clark (1976) ch. 9, Hannesson (1983), May et al. (1979), Silvert and Smith (1977), Flaaten (1989 and 1991) and Getz (1979). The latter is especially concerned about the optimal path towards the long run steady state harvesting regime.

ii) Analysis of harvesting interactions, e.g. Clark (1976) ch. 9, Clark (1985) ch. 5, Lipton and Strand (1989) and European Communities (1987). The latter is especially concerned about particular fisheries and of assessment methods.

iii) Applied studies on interacting species, e.g. Conrad and Adu-Asamoah (1986) on competing species of tuna and Flaaten (1988) on plankton feeders-fish-sea mammals interactions.

This paper reports on applied work that include species interactions and harvesting interactions, i.e. groups b and c. Flaaten (1988) studied the Barents Sea fisheries on a highly aggregated level with a three-species model without harvesting interactions, whereas we have developed a more detailed model that allow bycatches and several vesselgroups fishing each stock. Similarities and differences in the economic solutions from the use of different types of vessels and gear are analysed, and the implications for management are derived.

The next section of this paper gives a brief review of the ecosystem of the Barents Sea. Then the ECONMULT-model is presented, followed by a section on the integration of this model with a cod-capelin testmodel, MULTSIMP, from the Institute of Marine Research, Bergen. Discussion and conclusions conclude the paper.

## 2. THE ECOSYSTEM OF THE BARENTS SEA

The Barents Sea occupies 1.405 million square km between the coast of North Norway, Svalbard, Novaja Semlja and the Murman Coast. The southwestern part of the Barents Sea never freezes to ice, and the northern and eastern parts are ice-free for part of the year.

The total number of zooplankton species of the Barents Sea is relatively few, consisting of 145 species (Zenkevitch, 1956). The copepoda make up the main zooplankton biomass : 90 % in the southwestern part of the sea. As in other seas of the world, the copepods are the basic food components for fish and other inhabitants. In addition to the zooplankton, there is another important main source of food for the fish : the benthos inhabiting the sea bottom.

There are 114 known species of fish inhabiting the Barents Sea, of which the commercially most important families are : the cod family (12 species) and the flounder (11 species). There are especially two species of zooplankton preying fish which have been of great commercial value : capelin (*Mallotus villosus*) and herring ( *Clupea harengus*). The pelagic fish species are important food sources for larger fish species, sea mammals and birds. So also is krill (*Euphauciacea*), feeding primarly at the second trophic level. In the transference of energy from phytoplankton through the food web to fish, krill is an important link (Mauchline and Fisher, 1969).

Larger fish of high commercial value are cod (*Gadus morhua*), haddoc (*Melanogrammus aeglefinus*) and saithe (*Pollachius virens*). On average for the years 1950-1990, these three species yielded approximately 90 % of the total annual catch of demersal and semipelagic species (excluding pelagic species like herring, capelin and polar cod). Other demersal species of commercial value are : red fish (*Sebastes sp.*), halibut (*Hippoglossus hippoglossus*), Greenland halibut (*Reinhardtius hippoglossoides*), plaice (*Pleuronectes platessa*). Of high-valued species, deep water prawn (*Pandalus borealis* ) and salmon (*Salmo salar*) are the most important ones.

The main food sources of cod are known consisting of small pelagic fishes such as herring, capelin, young cod, haddock and polar cod and large planktonic crustaceans. (see e.g. Zenkevitch, 1956 and Mehl, 1989).

The 7 species of seals of the Barents Sea and adjacent areas are great consumers of fish, krill, zooplankton, benthos, etc. The most important species for commercial purposes has been harp seal (*Pagophilus groenlandicus*). Its opportunistic feeding behaviour is probably a very important explanation of the large stock to be found in the Barents Sea, including the White Sea.

Fish and seals occupy the Barents Sea area all the year round, whereas 17-18 species of whales utilize the area through intensive feeding in summer. Since the early 1930s the minke whale (*Balaenoptera acutorostrata*) has been the most important commercially exploited whale species. Aslo the minke whale is an opportunistic feeder, consuming several species of fish, krill and zooplankton.

In the mid 1980s the Institute of Marine Research, Bergen (IMR), started a systematic research on multispecies interactions in the ecological system of the Barents Sea and adjacent area. The aim was to make this work an integrated part of IMR's research and to design and implement a detailed multispecies model for this area. The model, named MULTSPEC, is documented in Tjelmeland and Bogstad (1989). Even long before this particular multispecies research started, Norwegian, Russian and other scientists have investigated different parts of the Barents Sea ecological system (for references, see Flaaten, 1988). The MULTSPEC model is probably too detailed to be used for management purposes, therefore aggregated versions will be developed, and a preliminary one, MULTSIMP, already exist (Tjelmeland, 1990). The IMR's multispecies models will include (1) plankton preying species, especially capelin and herring, (2) carnivore fish species, especially cod, and (3) fish consuming sea mammals, especially harp seal and minke whale.

The economic multifleet, multispecies model presented in the following section will be integrated with one or more of the biological models from IMR, with the aim of developing better management tools for the Barents Sea fisheries.

## 3. THE ECONMULT MODEL

ECONMULT is a simulation and optimization model with several groups of homogenous fishing vessels. Each group may harvest one or more of the fishstocks and each stock includes one or more cohorts. A vector of cohort biomasses is an important interface between the biological and the economic part of the model. Alltogether there are u cohorts and s stocks, with $s \leq u$, as shown in figure 1. A fishery is defined as a combination of one vesselgroup and its main targeted fish stock. However, every cohort may in principle be caught in every fishery, either as being part of the main targeted stock or as bycatch. With m vesselgroups there are alltogether $m \cdot s$ fisheries in the model, and $m \cdot s \cdot u$ types of catches. Future extensions of the model may include geographical distribution of the fish stocks.

In figure 2 is shown a general outline of the ECONMULT-model. For a specific objective funtion the fisheries should be managed to maximize the objective. The harvest rates for the cohorts in one period will be deducted from the cohort biomasses before the start of next period. The cohort biomasses and catches thus are very important links between the biological and the economic part of the multispecies model.

In the presentation of the mathematical equations of the model the following symbols are used.

*List of variables and parameters*

| | |
|---|---|
| i | Refers to stock |
| j | Refers to vesselgroup |
| k | Refers to cohort |
| $a_{ijk}$ | Price function's constant term |
| $b_{ijk}$ | Price function's variable term constant |
| $cm_{ij}$ | Contribution margin |
| $d_{ijk}$ | Cohort's areal distribution and availability for catch |
| $e_{ij}$ | Days of fishing per vessel (fishing effort per vessel) |
| $fc_{ij}$ | Fixed costs |
| $h_{ijk}$ | Vessel catch of one cohort |
| $h_{ij}$ | Vessel catch of all cohorts in a given stock |
| $q_{ijk}$ | Catchability parameter |

| | |
|---|---|
| m | Number of vesselgroups |
| $n_{ij}$ | Number of vessels in each fishery group |
| $p_{ijk}$ | Ex-vessel price of fish |
| s | Number of stocks |
| $tc_{ij}$ | Total vesselcosts |
| $tr_{ij}$ | Total vesselrevenues |
| u | Number of cohorts in the model |
| $vc_{ij}$ | Variable vessel costs (costs per day of fishing) |
| $x_{ij}$ | Biomass of one cohort |
| C | Priceaffecting catch |
| $E_{ij}$ | Total fishingeffort of the vesselgroup |
| $H_{ijk}$ | Vesselgroup's catch of given cohort |
| $H_k$ | Total catch of cohort |
| $\alpha_{ijk}$ | Effort - output elasticity |
| $\beta_{ijk}$ | Stock- output elasticity |
| $\delta$ | Discount rate |
| $\pi_{ij}$ | Vesselprofit |
| $\Pi_i$ | Vesselgroup profit |

All the variables are related to specific periods of time. Some parameters are constants, other may vary between periods. To simplify the notation, subscripts are omitted in the equations that follow.

### *3.1 Catch*

The catch of a specific cohort in a given fishery is modelled by a Cobb-Douglas harvest function :

$$H = q\, E^{\alpha}\, x^{\beta} \tag{1}$$

where $E = n\, e$. Catch per vessel is

$$h = H/n = q\, e^{\alpha}\, n^{\alpha-1}\, x^{\beta}. \tag{2}$$

### *3.2 Price*

Ex-vessel price of fish is either constant or a linear function of a specific segment of the catch :

$$p = a - b\, C, \tag{3}$$

where C includes relevant catch of one or more cohorts from the vessels in one or more fisheries. The pricefunction may be on stock basis or on cohort basis.

### *3.3 Revenue*

The revenues of the vessels come from the sale of fish :

$$tr = p\ h \tag{4}$$

*3.4 Costs*

The harvesting costs consist of fixed costs, which is mainly capital costs, and variable costs, which are proportionate to the number of fishing days.

$$tc = fc + vc \cdot e. \tag{5}$$

This means that the average total costs of fishing effort is decreasing with increasing effort per vessel.

*3.5 Contribution margin and profit*

With constant ex-vessel prices of fish the contribution margin per vessel in a given fishery is

$$cm = p \cdot h - vc \cdot e, \tag{7}$$

and the profit is

$$\pi = cm - fc. \tag{8}$$

In case of elastic demand the constant price in equation (7) should be substituted by the price function (3).

The total profit of a given fishery is

$$\Pi = n \cdot \pi, \tag{9}$$

and the present value of the profit is

$$PV = \int_0^\infty e^{-\delta t}\, \Pi(t)dt. \tag{10}$$

*3.6 Simulation*

The fisheries of ECONMULT may be simulated by using one of the following combinations of management means :

i) fishing effort per vessel (e) and catch per vessel (h),

ii) fishing effort per vessel (e) and total catch (H),

iii) number of vessels (n) and fishing effort per vessel (e),

iv) number of vessels (n) and catch per vessel (h),

v) number of vessels (n) and total catch (H).

In the short run the number of vessels are fixed and the procedure i) or ii) may be the most relevant. In the long run, however, the number of vessels are not fixed, and the procedures iii) - v) may be more useful. The details of the simulation procedures are explained in Eide (1992).

*3.7 Optimization*

With a deterministic biological multispecies model and constant economic parameters ECONMULT as well is deterministic. This implies that long run equilibrium may be attained, with stocks of fish and number of vessels being

constant. Sustainable profit in a given fishery therefore in principal is a function of the number of vessels in all vesselgroups and fisheries. However, since only the most costeffective vesselgroup will be used to fish each stock, this fact is useful in the numerical optimization procedure described in detail in Eide (1991a). The simplest cases arise when there are no bycatches and zero discount rate. Such an example with maximization of sustainable economic rent in an applied bioeconomic model is given in the next section.

## 4. SIMULTATIONS WITH THE COD-CAPELIN MODEL ECONSIMP

The model ECONSIMP has been tested by using a simple cod-capelin model, MULTSIMP, made by IMR for experimental purposes. The integrated model is named ECONSIMP and it consist of 24 vesselgroups in the cod fisheries and 4 in the capelin fisheries. The data used for the 28 vesselgroups are given in table 1 and table 2.

### *4.1 The Multsimp model*

The biological model MULTSIMP is more aggregated than models currently used for management of the Barents Sea fisheries. Even though the MULTSIMP stocks are divided into yearclasses, catches are not. Recruitment may be deterministic or stochastic, however, in this paper only the former version is used. The recruitment of cod is constant, whereas that of capelin is an increasing, concave funtion of the spawning biomass. Agespecific individual weight for capelin is constant, while that of cod is an increasing function of the available food, the capelin biomass. For capelin the mortality is an increasing function of the predator stock, the cod biomass, while the natural mortality of cod is constant. The parameterized equations of MULTSIMP is shown below, where the following symbols are used :

| | |
|---|---|
| $N^{cap}$ | Number of capelin, in billions of individuals. |
| $N^{cod}$ | Number of cod, in billions of individuals. |
| $SB^{cap}$ | Spawning biomass of capelin, in thousand tons. |
| $R^{cap}$ | Capelin recruits, in billions of individuals. |
| $w^{cap}$ | Vector of age specific (1-5 years) capelin weights, in gram. |
| $w^{cod}$ | Individual weight of cod, in gram. |
| k | Refers to yearclass. |
| t | Refers to year. |

The recruitment of capelin is

$$R^{cap}(t) = \frac{2000.0\ SB^{cap}(t - 1)}{500.0 + SB^{cap}(t - 1)} \tag{11}$$

and the recrutiment of cod is constant :

$$R^{cod} = 0.500. \tag{12}$$

For a given yearclass of cod the number of individuals decreases over time due to constant natural mortality and fishing :

$$N^{cod}(t) = N^{cod}(t\text{-}1)\exp\text{-}[0.2 + F^{cod}(t)]. \tag{13}$$

For a given yearclass of capelin the decrease in numbers also come from predatory mortality :

$$N^{cap}(t) = N^{cap}(t\text{-}1)\ \exp\text{-}[0.636 + M^{pred}(t) + F^{cap}(t)] \tag{14}$$

where $M^{pred}(t) = 0.000325\ B_{pred}(t)$ and $B_{pred}(t)$ is the capelin eating fraction of the cod biomas, i.e. ages 3 years and above.

The agespecific weights of 1 - 5 years old capelin are constant :

f

$$w^{cap} = (3.4,\ 12.4,\ 22.8,\ 21.0,\ 21.0). \tag{15}$$

Individual weights in a given yearclass of cod depend to some extent on the availability of capelin as food :

$$w^{cod}(t) = w^{cod}(t-1)\left(1.0 + \frac{0.2(B_{prey}(t) - 4.000.0)}{4000.0}\right), \tag{16}$$

where $B_{prey}(t)$ is the eatable fraction of the capelin biomass, i.e. ages 1 year and above.

### *4.2 Simulation results*

According to the mutual agreements between Norway and the Russian Republic the Barents Sea cod stock is shared equally between them, and the capelin is shared 60-40 % in the favour of Norway. In this analysis we assume that the two parties have mutually interests and apply the same means. However, the reported figures are always that of Norway's, and we shall report on the results from 9 different simulation runs. Starting with stocklevels estimated by IMR for January 1, 1989, using reported catches for 1989, 90 and 91, the proper simulation period commences with estimated model stocks January 1, 1992 and runs for another 27 years. The number of vessels in each vesselgroup in the constant effort period are related to 1989 or 1990 figures for the cod fisheries and to 1991 for the capelin fisheries (cfr. table 1), due to the 1987-90 moratorium for the latter. The number of vessels are held constant during the 27 years simulation period, and a constant 7 % p.a. social rate of discount has been used. The effort used in each of the nine simulations and the present value of the corresponding resource rent is shown in table 3.

Of the nine simulations no. 5 gives the best economic result. This is for constant fishing effort 50 % higher than the 1990-effort for the cod fisheries and 50 % higher than the 1991-effort for the capelin fisheries. For the Barents Sea fisheries 1990 was a very bad year with no capelin quota and a record low quota of cod. It is obvious from the results in table 3 that interior solutions with simultanous fishing of cod and capelin are better than no harvesting of either of the two stocks. The worst result appear when there is no fishing of the cod stock in simulation 9, and the second worst in simulation 8 with no capelin harvest.

### *4.3 Maximizing economic rent*

Using only the bioeconomic most costeffective vesselgroups within the cod and the capelin fisheries, respectively, maximization of sustainable economic rent gives the results in table 4. Of the total profit of 1.85 billion Nkr. per year 70 % comes from the cod fishery. Increasing the price of cod 25 %, ceteris paribus, increases both the total profit and the cod fishery's share. Increasing the price of capelin, ceteris paribus,also increases the total profit compared to the basic case. In this case the optimal effort level in the capelin fishery increases 20 % and the effort level in the cod fishery increases 8 %. The latter result helps decreasing the cod stock, thus saving more of its prey, the capelin, for profitable harvesting.

## 5. DISCUSSION AND CONCLUSION

An important reason why the best result of the 9 simulations includes some harvesting of capelin, is the 100 % postspawning mortality of capelin in the MULTSIMP model. In reality some fraction of the spawning biomass is belived

to survive, but how much is disputed. In simulation 9, which is the worst case, the increased cod stock preys so heavily on the capelin that this stock is extinct with a constant fishing effort 50 % above the 1991 level. Even without harvesting of capelin the MULTSIMP model of the Institute of Marine Research is such that in the long run the capelin stock approaches zero if the cod stock is not harvested. Future biological research will probably reveal whether this is an appropriate characteristic of a cod-capelin model of the Barents Sea, or not.

Within the cod fisheries the cost effectiveness of trawl compared to other gear depend, to some extent, on the stock - output elasticities. For trawl in the Barents Sea there hardly exist significant estimates of such elasticities. In this work we have assigned trawlfishing a stock - output elasticity in between those estimated for longline and gillnet. Future work should investigate these problems more thoroughly.

The analysis of this paper has shown that whether one should harvest cod or capelin, and to what extent, depend on parameters such as the relative harvest prices of the two species. Based on another biological model Flaaten (1988) came to a similar result, in addition to the conclusion that harvesting sea mammals contribute significantly to the profitability of the cod and the capelin fisheries. Together, these works indicate that to maximize total profit from the fisheries the managers should encourage relatively weaker exploitation of capelin than of cod. However, one should not put too much emphasis on fine tuning the relative rate of exploitation before more reliable bioligical models are developed and implemented. Since some species of seals and whales are important predators on and competitors to fish in the Barents Sea, these stocks will be included in the coming models from the Institute of Marine Research, and in our bioeconomic research.

THE STRUCTURE OF THE ECONMULT MODEL.

# A Bioeconomic Model for Fish Harvest Technology

**David B. Sampson***

Oregon State University, Coastal Oregon Marine Experiment Station, Newport,
Oregon 97365, United States of America

ABSTRACT

*The catches and profits in a fishery depend on the technology employed, on the utilization of human and capital resources, on the abundance and distribution of the fish stock, and on the prices for fish, fuel, and labor. Here a harvest function is constructed that includes parameters for the main technical components of the fishing process : travel to the fishing grounds, catching fish, and handling those that have been caught.*

*The fishery system does not have the same sensitivity to each technical parameter. Furthermore, small changes in a parameter can result in catastrophic alteration of the system's dynamics. Fishing technology in part determines the behavior of the fishery system ; the technology in turn evolves in response to changes in the fishery. It is argued that fishing technology will tend to evolve more rapidly in those components that have the greatest impact on the flow of fishing profits.*

## 1. INTRODUCTION

During this century there have been dramatic improvements in the methods used for harvesting fish. However, the literature on fisheries economics gives little regard to the technical details of the fishing process and their influence on the dynamics of fishery systems. The yield from a fishery depends in general on the fishing technology, the rate of application of human and capital resources, and the current size of the fish stock. Most fisheries models incorporate these

* This paper is the result, in part, of research sponsored by Oregon Sea Grant with funds from the National Oceanic and Atmospheric Administration, Office of Sea Grant, Department of Commerce, under grant no. NA89AA-D-SG108 (project no. R/ES-16) and from appropriations made by the Oregon State Legislature. elements into a production or harvest function that links the economics of fishing with the population dynamics of the fish. Fishing technology influences the behavior of the system through the harvest function. The status of the system, in turn, determines the suitability of different technologies.

In this paper I construct a harvest function that explicitly includes parameters for the three major technical components of the fishing process and I show that these different components do not exert the same influence on the stability and dynamic behavior of the fishery system. My objective is to develop a framework for examining the evolution of fishing technology and fishery systems. For a given set of conditions, what forms of technological change have the greatest impact on profitability ?

## 2. A GENERALIZED HARVEST FUNCTION

The harvest function in a bioeconomic model of a fishery should account for the full variety of human activities required for the production of catches of fish. In most fisheries the basic time span of the production cycle is the fishing trip (Doll, 1988), and each trip involves three distinct activities : traveling to and from the fishing grounds, operating the fishing gear on the grounds, and handling the catch. Improvements in fishing technology can affect any or all of these activities.

Consider the catch that accumulates while a fisherman deploys his gear on the fishing grounds. Assume that the fish encounter the gear randomly and that the encounter rate is jointly proportional to the number of fish near the gear and to the amount of time spent fishing. During the short interval of a fishing trip the average the number of fish caught is given approximately by

$$C_N \approx N \cdot q \cdot tF,$$

where N is the number of fish initially available to the gear, q is a technical parameter that measures the instantaneous probability of capturing a particular fish (the catchability coefficient), and tF is the amount of time the gear is fishing. This is a simplified version of the standard catch equation of fisheries (Gulland, 1983). If the diffusion of individual fish on the grounds is sufficiently rapid, then the number of fish within range of the gear and the catch rate at any particular location are both proportional to the total stock of fish on the grounds (Sampson, 1991a).

The definition of time spent fishing (tF) depends on the type of fishing technology. For trawl fisheries it is the amount of time the net drags through the water. For purse seine fisheries it is the time spent searching for suitable schools of fish. For a hook and line fishery it is the time a baited hook is in the water. Similarly, the meaning of the catchability coefficient (q) also differs with the type of technology. With a trawl it corresponds to the rate at which the net strains water. With a purse seine it is a measure of the fisherman's proficiency at locating fish schools. For a hook and line fishery it corresponds to the ability to attract and hook a fish.

The equation above ignores some important activities : fishermen spend time traveling to and from the grounds ; they spend time handling and processing their catch. For convenience let the term "travel" refer to those activities whose duration is independent of the size of the catch ; e.g., travel, vessel maintenance, sleeping and eating ; and let the term "handling" refer to those activities that inhibit the catch of additional fish and whose duration is proportional to the size of the catch ; e.g., sorting and icing the catch from a trawl, pumping out a purse seine, or removing fish from the hooks of a longline.

Let tF denote the time spent fishing, let tH denote the time spent handling the catch, and let tO denote travel time and all other time expenditures. The total duration of a fishing trip is

$$T = tF + tH + tO.$$

Note that the different activities do not occur simultaneously. This time partitioning is inappropriate for fishing operations in which the catch is taken by unattended gear, e.g., the trapping of lobsters or the capture of salmon in weirs.

The average number of fish caught during a trip is approximately equal to $N \cdot q \cdot tF$ ; if different sized fish are equally vulnerable to capture, then the weight of the catch is

$$C \approx B \cdot q \cdot [T - (tH + tO)],$$

where B is the biomass of the fish stock on the fishing grounds (N times the average weight of a fish). If each unit of fish biomass that is caught requires a handling time of h, then the total time spent handling the catch is tH = C . h and

$$C \approx B \cdot q \cdot [T - tO] / [1 + B \cdot q \cdot h].$$

Let $\tau$ be the ratio tO/T and let T shrink to zero. This results in a differential equation that describes the instantaneous catch rate for a single fishing operation,

$$dC = \frac{B \cdot q \cdot (1 - \tau)}{1 + b \cdot q \cdot h}.$$

If there are E independent and identical fishing operations, which act concurrently, competitively, and without interference, then the total catch rate by the fleet (the yield) is

$$Y = dC \cdot E = \frac{B \cdot q \cdot (1 - \tau)}{1 + B \cdot q \cdot h} \cdot E.$$

This form of equation, with $\tau = 0$, has been used for modeling the capture of schooling fish (Paloheimo and Dickie, 1964), for modeling whaling operations (Beddington, 1979a), and for modeling hook and line angling (Deriso and Parma, 1987).

The graph of catch rate as a function of fish biomass is a rectangular hyperbola (Figure 1, upper panel). Catch rate increases with increasing biomass, but at a decreasing rate. The catch rate per vessel has a slope of $q \cdot (1 - \tau)$ at the origin, and it approaches $(1 - \tau)/h$ at high levels of abundance. Changing the number of fishing operations alters the scale of the vertical axis, but does not otherwise affect the shape of the curves.

Parameters q, $\tau$, and h characterize the fishing technology, but each has a different effect on the relationship between catch rate and fish biomass. Parameter h exerts a major influence over the asymptotic catch rate. Parameter q determines the rate of approach to the asymptotic catch rate. Parameter $\tau$ modifies both the level and the rate of approach to the asymptote.

## 3. A STATIC EQUILIBRIUM ANALYSIS

Assume that the fish stock's biomass dynamics are governed by logistic growth and that, in the absence of fishing, the stock's instantaneous growth rate is given by

$$G = r \cdot B \cdot (1 - B/K),$$

where r is the intrinsic growth rate and K is the environmental carrying capacity (Schaefer, 1954 ; Pielou, 1974). The exploited fish stock will be at equilibrium if the rate of removals by the fishery exactly balances the stock's natural growth. The lower panel of Figure 1 illustrates this by the points of intersection between the growth curve and the different yield curves. Notice that the fishery system can develop an unstable equilibrium if there are enough active fishing vessels in the fleet. At such an unstable point of equilibrium any perturbation to the fish biomass will force the stock either to the origin and extinction, or towards the other stable point of equilibrium.

The instability in this fishery system is a direct consequence of the curvature in the yield function. Several authors have discussed this system and its properties (e.g., Beddington, 1979b ; Condrey, 1984 ; Clark, 1985). However, in order to understand fully this system's behavior we need to consider the dynamics of the fishing fleet (below).

## 4. THE SHORT-RUN ECONOMICS OF FISHING

In the shortrun the captain of a fishing vessel cannot readily alter the technical characteristics embodied in his vessel and gear. Instead, the captain controls the production process by deciding whether or not to go fishing. We can expect that he will not knowingly engage in fishing if he will lose money by doing so. Unless the revenues generated by a fishing trip exceed the costs of making the trip, no fishing will occur.

We can use the harvest function to construct an equation for the flow of fishing revenues. However, it is more problematic to derive an equation for the flow of fishing costs. Although there are numerous published accounts from cost and earning surveys, there have been few detailed studies of the factors that determine fishing costs. As a consequence, it is difficult to assess the suitability of any particular cost function. If fish density varies with distance from port, then the most profitable distance for fishing depends on fish abundance and fish price, and the flow of fishing costs changes with variation in either of these external variables (Sampson, 1992, 1991b).

For simplicity assume that operating costs (e.g., wages, food, and fuel) are incurred whenever a fishing trip is made and that the flow of these costs is constant. These operating costs, although fixed per trip, only accrue if a trip is made ; they are the variable costs of production. Also assume the following : (1) the members of the crew receive a share of the catch in addition to their wages ; (2) the captain of the fishing vessel is also its owner ; (3) the captain pays the operating costs from his share of the catch ; and (4) each captain must accept the going price for fish. Given these assumptions, the flow of net income to the captain is described by

$$I = p \cdot (1 - S) \cdot dC - oc$$

where p is the price for fish, 1 - S is captain's share of the catch, and oc is the rate of flow of the operating costs.

Unless the flow of net income is positive, the captain will not operate his vessel. As a consequence, for a given level of fish biomass, the price for fish must be greater than some minimum supply price or the vessel stays in port,

$$p_{min} = \frac{oc \cdot (1 + B \cdot q \cdot h)}{(1 - S) \cdot (1 - \tau) \cdot B \cdot q}$$

Alternatively, for a given price for fish, the biomass of the fish stock must exceed the minimum economic biomass or fishing will not occur,

$$B_{min} = \frac{oc}{q \cdot [p \cdot (1 - S) \cdot (1 - \tau) - h \cdot oc]}$$

The upper panel of Figure 2 illustrates these relationships.

Provided the price for fish is greater than the minimum supply price, the captain goes fishing and supplies fish at a rate determined by the level of fish biomass. The short-run supply curve is perfectly inelastic (Doll, 1988).

## 5. THE LONG-RUN ECONOMICS OF FISHING

There are several important long-run features of a fishery for which the short-run model makes no provision. Fishing operations must pay the fixed costs of the vessel. The captain may be able to modify the technical characteristics of his operation. The number of active fishing vessels may change in response to variations in profitability.

The profit flow to the captain is given by

$$\pi = \begin{cases} -fc & \ldots \text{ if } p < p_{min}, \\ I - fc & \ldots \text{ otherwise}, \end{cases}$$

where fc is the flow of fixed costs, the sum of all the fixed costs divided by the vessel's working lifespan. If the fish price is less than the minimum supply price (and B < Bmin), then the captain does not go fishing and losses accrue at the rate of flow of the fixed costs. If the price for fish is greater than the minimum supply price (and Bmin < B), then the captain makes a profit (or loss) at a rate equal to the difference between the flow of net income and the flow of fixed costs. Profit flow is zero when the fish biomass is at the break-even biomass level,

$$BB = \frac{oc + fc}{q \cdot [p \cdot (1 - S) \cdot (1 - \tau) - h \cdot (oc + fc)]}.$$

Given a fixed price for fish, the profit flow per vessel varies with the fish stock's biomass (Figure 2, lower panel). If fish biomass is greater than the break-even level, participating vessels will make super-normal profits which will encourage others to join the fishery. If fish biomass is less than the break-even level, vessels will incur losses and some will leave this fishery and find alternative employment. If the fish stock is at the break-even level, the fleet will be at equilibrium.

## 6. THE DYNAMICS OF THE FISHERY SYSTEM

Assume that the rate at which fishing vessels enter (or exit) the fleet is proportional to the current profit flow per vessel ;

$$dE / dt = e \cdot \pi$$

where parameter e is the entry (exit) coefficient ; and assume that the rate of growth of the fish stock is determined by

$$dB/dt = G - E \cdot dC.$$

These coupled differential equations govern the dynamics of the fishery system. We can deduce the behavior of the system by examining the ratio dE/dB ; we can represent solutions to this ratio as curves in the {B,E} plane, the phase plane.

When any solution crosses the fleet isocline (the set of points {B,E} for which dE/dt is zero, the break-even biomass level), it must move parallel to the B axis because the size of the fleet is constant whenever B = Bmin. By similar logic, when any solution crosses the biomass isocline (points for which dB/dt is zero), it must move parallel to the E axis. The intersections of the two isoclines depict equilibria.

The biomass isocline has a discontinuity if B is less than or equal to Bmin because the catch rate dC is zero under these conditions. If B is greater than Bmin, the biomass isocline is

$$EE = (1 - B/K) \cdot (1 + B \cdot q \cdot h) \cdot r / [q \cdot (1 - \tau)]$$

and the graph of EE(B) is a quadratic with roots at

$$B = K \text{ and } B = - 1/(q \cdot h)$$

The (local) maximum value for EE occurs when B is equal to

$$BmaxEE = 1/2 \cdot [K - 1/(q \cdot h)]$$

The location of BmaxEE relative to the break-even biomass (BB) determines whether the fishery system has a stable equilibrium point (if BmaxEE < BB), or instead has a stable limit cycle (if BB < BmaxEE). Figure 3 shows the alternate forms of the system. In the upper left panel, break-even biomass (the vertical dashed line) is to the right of the local maximum of the biomass isocline (the solid curved line), and the system has a stable equilibrium point. In the upper right panel, break-even biomass is left of the local maximum of the biomass isocline, and the system has a stable limit cycle. In this example a small (15 %) improvement in handling induces a significant alteration in the system's behavior.

Notice the relationship between the phase plane diagrams at the top of Figure 3 and the corresponding static equilibrium analyses at the bottom. In particular, observe that the unstable equilibrium point shown in the lower right panel generates a limit cycle for the system, rather than the possible extinction of the fish stock suggested by the static analysis.

## 7. THE EVOLUTION OF FISHING TECHNOLOGY

Certain forms of technological change will be more advantageous than others. It seems reasonable to assume that fishermen will prefer to adopt those innovations that have the greatest positive impact on the flow of profits. Although there are numerous factors that affect a fishermen's decision to invest in new fishing technology (Whitmarsh, 1990), it may be possible to anticipate developments in fishing technology by examining the sensitivity of profit flow to the different technical parameters.

Let X denote the set of technical parameters (q, $\pi$, h) that determine the harvest function. The profit flow to the captain (and owner) of a fishing vessel is determined by

$$\pi = R(\underline{X}) - [oc(\underline{X}) + fc(\underline{X})],$$

where R denotes the flow of revenues, and oc and fc denote the flow of operating and fixed costs. We can measure the relative sensitivity of profit flow to a particular technical parameter X by means of an elasticity coefficient,

$$s(X) = \pi'(X) \cdot X/\pi = (d\pi/\pi) / (dX/X),$$

$$s(X) = [R'(X) - oc'(X) - fc'(X)] \cdot X / \pi.$$

For the harvest function developed earlier the partial derivatives of the revenue function are

$$R'(q) = R / [q \cdot (1 + B \cdot q \cdot h)],$$

$$R'(\tau) = -R / (1 - \tau), \text{ and}$$

$$R'(h) = -B \cdot q \cdot R / (1 + B \cdot q \cdot h)$$

If we assume for simplicity that the potential improvements in the different technical parameters all require the same increase in flow of costs, then we can examine how the relative sensitivities vary as the fishery system changes. Figure 4, for example, compares two fishery systems, one (on the left) with a large value for the handling time parameter (h) versus one with a small value for h. The bottom panels show how the relative sensitivities change through time as a fishery develops on a stock that is unexploited initially. The system on the left is most sensitive to the handling time parameter (h) and least sensitive to the catchability coefficient (q). The system on the right, however, is most sensitive to q and the sensitivity to h versus $\tau$ depends on the size of the fish stock.

ABSTRACT

*In sessile and sedentary invertebrates the assumptions underlying traditional population dynamics are not always valid, mainly due to the heterogeneous distribution of the stock and the corresponding allocation of fishing intensity. Consequently, strategies for managing invertebrate fisheries differ from those employed in finfish populations. This study reports an application of the systems simulation approach for short and long-run analysis of the intertidal yellow clam Mesodesma mactroides fishery of Uruguay. A non-linear and stochastic model was built to represent the short-run spatial dynamics of fishing intensity. The space-time distribution of fishing effort is represented in an indicative way as a function of estimates of the dynamic catch per unit effort in alternative grounds, their distances from different localities, the perceived probability of finding species at profitable levels, and the corresponding net revenues of the previous fishing trip. The long-term dynamics of the fishery considers time lags in spawning, hatching and settlement processes, as well as in fishermen entry and exit to the fishery. The distributed delay model is applied for this purpose. A density-dependent function characterizes the dynamics of the stock-recruitment relationship. Because of relatively low total costs, the bioeconomic equilibrium is estimated at high levels of fishing effort, which in turn increases the risks of exhausting this highly vulnerable sedentary species. Simulation experiments with alternative management strategies are conducted to observe the effect on fishery performance.*

## 1. INTRODUCTION

The modern approach to fisheries management is to characterize and predict the behaviour of a stock and the fishing effort exerted, through comprehensive mathematical models (Walters, 1986 ; Charles, 1989). Since the 50's these have been designed for finfish populations (Schaefer, 1954 ; Beverton and Holt, 1957 ; Pella and Tomlinson, 1969). An important characteristic of these models is that they consider the stock as a closed, self-sustaining unit of population with

uniform distribution over the whole area, so that the effect of fishing effort (also assumed to be uniformly distributed) is absorbed by the whole stock through recruitment and/or redistribution of organisms (Ricker, 1944 ; 1975). Hence, fluctuations in stock size may be reflected by the size of the catches (Hancock, 1979).

In sessile and sedentary organisms, the above assumptions are not always valid: the patchy distribution of populations (Elliott, 1977) and their relative or null mobility, introduce important restrictions on the application of traditional finfish models. Mollusks cannot redistribute themselves quickly over a fishing ground, and thus gaps in patches are produced as a result of a sequential depletion pattern produced by the heterogeneous allocation of fishing effort (Hancock, 1973, 1979 ; Caddy, 1975 ; Conan, 1984 ; Orensanz *et al.*, 1991). In addition, their population dynamics is extremely dependent on environmental conditions and biological interactions even between small distances, thus making a high short-term variability in stock size and availability for harvesting (Conan, 1984). Consequently, strategies for managing invertebrate fisheries differ from those employed in finfish populations. As a result, for this type of species, it has been considered appropriate to relax the assumption of spatial homogeneity of resource distribution. Extensive fishing grounds with variability in environmental conditions and related heterogeneity in abundance, growth and mortality patterns, can be divided into smaller areas which are considered as independent units (Caddy, 1975, 1989a, 1989b ; Hall, 1983 ; Sluczanowski, 1986). A comprehensive approach may be used to integrate the results obtained by the discrete analysis.

In this paper we report an application of the systems simulation approach for short and long run analysis of the intertidal yellow clam *Mesodesma mactroides* fishery of Uruguay. Biological, environmental and economic factors are integrated in a comprehensive model, also incorporating some of the more important features of resource management under uncertainty.

## 2. MATERIAL AND METHODS

### *2.1 The study region*

The study was conducted on a 22 km sandy beach of the eastern coast of Uruguay comprised between Barra del Chuy (33°40'S, 53°20'W) and La Coronilla (33°50'S, 53°27'W). This dissipative beach (*sensu* McLachlan, 1990) has the highest values in species richness and diversity among Uruguayan sandy beaches, being the yellow clam *M. mactroides* dominant in biomass terms in the macrofauna community (Defeo *et al.*, 1992a). Artisanal exploitation of species such as the yellow clam and penaeid shrimps constitutes a regional source of employment (Defeo, 1989).

### *2.2 Sampling design : field procedure and fishery statistics*

Sampling was done seasonally between March 1983 and March 1991, along the 22 km of sandy beach where this clam is fished. One transect per km perpendicular to the shore was defined, and samples were collected every 4 m across the beach (down to the limit of the clam bed) with a 1/16 $m^2$ cylinder. Sampling continued in the downshore direction until at least two successive empty quadrats had been sampled. The sediment collected to a depth of 50 cm was sieved through a 0.5 mm mesh and the organisms retained in each quadrat were measured and weighed in the laboratory with 0.5 mm and 0.01 g of precision.

The full range of sizes were covered (i.e. 1 to 76 mm). A recruit was defined as the organisms included between the length interval 1 - 10 mm, and thus have been resident in the benthic population for some time. Adults were all organisms greater than 43 mm, the mean size at first maturity according to Masello and Defeo (1986).

Taking into account the alongshore population structure variability along the 22 km of beach (Defeo *et al.*, 1986), the study beach was divided into four zones, with the boundaries set at right angles to the coast line : zone A, from km 1 to km 5 ; B, from km 6 to km 10 ; C, between km 11 and 15 ; and D, from km 16 to km 22. Population structure and abundance, as well as daily catch/effort data, were examined discriminately by zones. Thus, statistical fishing areas coincided with those selected as independent units for research purposes.

### *2.3 The fishery model*

The systems simulation approach as applied to fisheries (Seijo, 1986 ; 1989) was employed to build and implement a dynamic, non-linear and stochastic bioeconomic model for the yellow clam fishery. The general components of the

fishery were disaggregated in order to specify the interdependencies of relevant ecologic, economic and resource management variables. Using such scheme, the corresponding sets of equations were developed for the main processes involved in the fishery system:

### 2.3.1 Dynamics of population structure

The age-structured population through time was estimated separately for each fishing ground. Growth parameters of von Bertalanffy growth equation were used (Defeo *et al.*, 1992b). Values of $L_\infty$, K and $t_0$ were respectively 75.47 mm, 0.9 1/year and -0.04 year. A length-weight relationship of the form $W=aL^b$ ($a=5.88*10^{-5}$ ; b=3.03 ; n=2839 ; r=0.97 ; $p<0.0001$) was employed for biomass estimations.

The dynamics of the population structure for *M. mactroides* was modeled applying the main concepts of Life Tables (Begon *et al.*, 1990). This method is based on the dynamic accounting of inflows and outflows of individuals to each cohort a of the population structure. The number of individuals in each cohort in ground g was obtained in time t+DT, $(N_{ga}(t+DT))$, by integrating in the interval [t,t+DT] the number of individuals of age *a-1* that survive and grow into cohort *a* in time *t*, minus the total mortality rate (*sensu* Gulland, 1983) of individuals of cohort *a*, $(A_{ga}(t))$, minus the rate at which organisms surviving cohort *a*, $(SR_{ga}(t))$, are incorporated into cohort *a+1* in the time *t*. For a set of initial conditions of the population structure in time t=0, the above is expressed in equation (1) as follows :

$$N_{ga}(t+DT) = N_{ga}(t) + \int_t^{t+DT} (SR_{ga-1}(\tau) \cdot N_{ga-1}(\tau) - (SR_{ga}(\tau) + A_{ga}(\tau)) \cdot N_{ga}(\tau))\, d\tau \qquad (1)$$

$SR_{ga-1}(t)$ denotes the survival rate (*sensu* Gulland, 1983) of organisms of age *a-1* in ground *g* over time t. The survival rate was expressed as :

$$SR_{ga-1}(t) = 1 - [MR_{ga-1}(t) + FR_{ga-1(t)}] \qquad (2)$$

being $MR_{ga-1}(t)$ the rate of natural mortality and $FR_{ga-1}(t)$ the rate of exploitation (*sensu* Gulland, 1983). Both rates were derived from previous determinations of the corresponding coefficients of natural and fishing mortality. The fishing mortality coefficient of organisms of age *a* in ground *g* over time t ($F_{ga}(t)$) was estimated by multiplying the age/site specific catchability coeficient ($q_{ga}$) by the fishing intensity implemented by fishermen from the locality *p* in site *g* over time ($f_{pg}(t)$). A dynamic and density-dependent natural mortality ($M_g$) was estimated as a function of the initial density of settlers and salinity at settlement time in each fishing ground *g*.

Given equations 1 and 2, the spatial dynamics of the population structure was implemented in the computer model using Euler numerical integration (Cheney and Kincaid, 1985) as follows :

$$N_{ga}(t+DT) = N_{ga}(t) + DT \cdot [SR_{ga-1}(t)\, N_{ga-1}(t) - N_{ga}(t)] \qquad (3)$$

Recruitment density was spatially generated over time by Table Look-up functions (Ruckdeschel, 1981 ; Cheney and Kincaid, 1985) which have adult density (number/$m^2$) as the independent variable. Peak recruitment time within a year occurs as specified by Defeo *et al.* (1992b) and is distributed using the distributed delay model (gamma function of order 3) in accordance to the corresponding recruitment period (Manetsch, 1976). Observations related to the main spawning and recruitment periods were obtained from Masello (1987) and Defeo *et al.* (1992b).

### 2.3.2 Short-run spatial dynamics of fishing intensity

The effective fishing effort (man-hours/day) per fishing ground, effective fishing days/month, and average daily catches per fishermen, were used to model fishermen behaviour over time. The number of fishable days per month and effective fishing hours per day were available from 1985 on. The fishery was closed to fishing operations between April 1987 to December 1989.

In this paper, fishing intensity $f_{pg}(t)$ was estimated spatially over time, taking into account fishermen locality of origin $p$, the distances between these localities and the alternative fishing sites, the perceived probability of finding the target species in economically feasible amounts, and the net revenues obtained in the previous fishing day in those grounds :

$$f_{pg}(t + DT) = f_{pg}(t) + \int_{t}^{t+DT} SAE_{pg}(\tau) \,.\, DAYS \,.\, FISHER_{p}(\tau)\, d\tau \tag{4}$$

where :

$FISHER_p(t)$ = number of fishermen from locality $p$ allocating their fishing effort to *M. mactroides* in time t.

$SAE_{pg}(t)$ = a (0,1) daily optimum spatial distribution of fishermen from locality $p$ into grounds $g$ in time t.

DAYS = Average number of fishing days per month.

$SAE_{pg}(t)$ was estimated by the following equation :

$$SAE_{pg}(t) = \frac{\dfrac{\pi_{pg}(t) \,.\, PROB_{g}}{D_{pg}^{n}}}{\sum_{g} \dfrac{\pi_{pg}(t) \,.\, PROB_{g}}{D_{pf}^{n}}} \tag{5}$$

Short-run (daily or per fishing trip) net revenues $\pi_{pg}(t)$ obtained by fishermen of locality $p$ in site $g$, were estimated considering the unit cost of effort and the returns obtained. $D_{pg}^{n}$ is the distances from each locality to each fishing ground where $n$ is the corresponding friction of distance parameter. Short-run net revenues per locality and fishing ground $\pi_{pg}(t)$ were estimated by :

$$\pi_{gp}(t + dt) = \pi_{gp}(t) + \int_{t}^{t+dt} [TR_{gp}(\tau) - TC_{gp}(\tau)]\, d\tau \tag{6}$$

where $TR_{gp}(t)$ and $TC_{gp}(t)$ are respectively the total returns perceived and total costs incurred by the fishermen of the locality $p$ harvesting in ground $g$ over time. This equation was also implemented in the computer model using Euler numerical integration.

The uncertainty, inherent to fishermen decision-making concerned with the spatial allocation of fishing effort over time, and space-time resource variability, was modelled using the catch standard deviations estimated for each season. Random variables (with zero mean) were generated with an observed exponentially autocorrelated probability density function and added to the catch equation obtained for the different fishing grounds.

### 2.3.3 Long-run dynamics

In the long-run, the effort dynamics (number of fishermen from locality $p$ present in the fishery over time) is modelled by spatially applying Smith (1969) equation :

$$\frac{dV_p}{dt} = \delta \cdot \sum_{g} \pi_{pg}(t) \tag{7}$$

where $\delta$ is a positive constant. Equation (7) states that in the long- run, if the sum of net revenues obtained from all fishing grounds is positive, there will be entry to the fishery. Exit is expected to occur if net revenues are negative. If profits are equal to zero, the fishery will be in bioeconomic equilibrium and there will be no stimulus for entry or exit to the fishery.

Price of the yellow clam for the local market was estimated in 1 dollar/kg ; opportunity cost of labor (Pearce, 1981) was estimated in US$ 6 per day, and operating costs in 160 US$ per year.

Simulation experiments were conducted with three management strategies to observe the dynamic impact on performance variables. The impact of three policy vectors were simulated and compared with the base run representing the current management scheme (minimum size restriction of 50 mm, and 50 fishing licenses). The policy vectors were the following : 1) the current management scheme plus a catch quota of 50 ton/year ; 2) a minimum size restriction of 43 mm (size at sexual maturity) and 150 fishing licenses ; 3) 150 fishing licenses and minimum size restriction of 50 mm.

### 2.3.4 Model assumptions

Some of the most important assumptions of the above described simulation model are the following :

i) Recruitment is assumed to be dome-shaped as the classic Ricker function (Ricker, 1954). The distribution of recruits within the recruitment period, modelled with the distributed delay method, is not assumed to occur in a single point in time, but within a period with certain distribution.

ii) The spatially disaggregated dynamic natural mortality is assumed constant for all ages. Fishing mortality is made a function of catchability, selectivity at age (Sparre *et al.*, 1989), fishing intensity, and dynamic age specific resource abundance in each ground.

iii) The spatial allocation of fishing intensity of fishermen from different localities, is assumed to be a function of the probability of finding the target species at profitable levels, the net revenues obtained from different fishing grounds in previous trips, and the distances to alternative fishing grounds.

iv) For long-run effort dynamics, the estimated time lag of fishermen entry or exit to the fishery is assumed to be six month. For short-run effort dynamics (within the fishing season), the estimated average time lag (mean of the probability density function describing the delay process) to enter the seasonal fishery is two weeks.

v) Gear characteristics are assumed constant. In this case, all fishermen harvest the yellow clam by means of shovels.

vi) Fishermen price-taking behaviour is assumed for prices of yellow clam.

vii) Costs of inputs needed per fishing trip remain constant along the fishing season.

### 2.3.5 Stability and validation analyses

Concerning model stability, an appropriate value for the time increment (DT) was determined. This value was selected taking into account the numerical integration operations involved in the computer model (Cheney and Kincaid, 1985). After the stability condition was satisfied, DT was reduced to a size that allowed to achieve a specified numerical integration error.

The model was validated through the comparison between observed and estimated values. The non-parametric Kolmogorov-Smirnov test (K-S) for two samples was applied to test the null hypothesis of equality of distributions (Graybeal and Pouch, 1980).

## 3. RESULTS

### *3.1 Population fluctuations*

Abundance of adults and recruits varied markedly through time. Mean densities of adults reached maximum values in 1984 and 1985, and decreased dramatically between 1986 and 1987, from which a closed season was established (Fig. 1).

A rapid recovery of the resource was observed from 1988 on, as a result of a heavy recruitment in absence of adults (Fig. 2). Statistical comparison of the actual and simulated annual densities of the spawning stock and recruits did not reveal significant differences (K-S test : $p > 0.1$ in both cases).

### *3.2 The fishery : short and long term variability*

The fishery showed a strong seasonal component. A marked increase in fishing intensity during summer and spring was a common pattern observed during the study period (Table 1). A decline in demand for consumption in the local market (Defeo, 1989) and a reduced availability of the resource because of downward migration towards the infralittoral (Defeo *et al* ., 1986) explains the diminished catches in autumn and winter. As a result of the seasonal behaviour of the resource and the fishery, catches were always greater during spring and summer (Table 1).

Figure 3 shows the comparison of the historical trend of recorded annual landings from 1983 to 1990, with respect to predicted landings. No significant differences were found between these two sets of data (K-S test ; $D=0.14$ ; $p > 0.5$). Total landings fluctuated between 62 ton from 1981 to a peak of 219 ton in 1985. From 1985 to 1987, declining yellow clam abundance produced an important fall in landings, and a temporal closure of the fishery between 1987 and 1989. Since the reopening of the fishery in 1990, catches are constrained by an overall quota which did not exceed 50 ton in 1990 and 1991 (Fig. 3).

### *3.3 Spatial variability of the resource and the fishery*

The four grounds differed in terms of abundance and population structure. Adults of yellow clam were prevalent in the central zones (i.e. B and C, see Fig. 4a), while it was always lower in zone D. Water salinity (recorded at the time of settlement) showed gradients towards both margins of the study area, but the stronger one was observed in zone D (Fig. 4b). Concerning this variable, exceptionally low values were recorded for 1986 during the settlement period (i.e. from February to May), coinciding with the major decreasing trend in population abundance (see Fig. 4a). In this year, as well as in 1987, the salinity-induced natural mortality was the main source of natural deaths in the yellow clam population in the four fishing grounds.

Spatial fluctuations in catches and fishing intensity showed the same trend as the above mentioned space-time variability of the stock, i.e. zones B and C had a major amount of fishing activity (Fig. 4c).

### *3.4 Simulation of management strategies*

Results of the simulation experiment of alternative management strategies are shown in Table 2. With policy 1, final catch increased 8 % and economic rent raised in the order of 10 %. Adult density did not change significantly. With policy 2, which allowed harvesting of organisms reaching the size at maturity, a substantial increase in harvest and economic rent resulted in a tradeoff of adult density, which decreased 17 %. With policy 3, that kept minimum size restriction 7 mm above sexual maturity, a more modest increase in harvest and economic rent is observed with non-significant reductions in adult density.

## 4. DISCUSSION

### *4.1 Short term model*

The spatially disaggregated analysis of the resource and the fishery resulted a useful approach in interpreting the behaviour of this exposed sandy beach population.

Spatial decisions concerning the use of sedentary marine resources (Caddy, 1975), are made in the short-run. It is every day or, more precisely, before every fishing trip, that artisanal fishermen consider three decisions : (1) to go fishing next

day or not, (2) if fishing is the choice, to select the target species, and (3) to select the fishing site to harvest such species (Bockstael and Opaluch, 1983 ; Eales and Wilen, 1986). Therefore, to correctly represent the spatial dynamics of fishing intensity, the analyst must make an effort to model the short-run behaviour of fishermen concerning site selection. In the long-run, a spatial pattern of fishing intensity can be depicted but only as a result of short-run resource behaviour and spatial decisions of fishermen.

In the present study, the short-run behaviour of fishermen concerning site selection was correctly represented through the validation of the spatial dynamics of fishing intensity and catches. It can be stated that the magnitude of catches and thus the economic rent obtained in previous days in certain fishing ground, was a good indicator of the future location of fishing effort (see also Eales & Wilen, 1986).

Moreover, even though in the present study the distance between localities did not constitute a key factor (only 22 km), in most artisanal fisheries the friction of distance could be a more significant variable in explaining fishermen behaviour.

### *4.2 Long-term model*

The long-term field study conducted at Barra del Chuy beach suggest two cycles of population variation of different magnitude, governed by overcompensatory changes (*sensu* Fogarty *et al.*, 1991) in recruitment success. The long term model put in evidence that the yellow clam population is "recruitment conditioned", with increments/decrements in recruitment strength defining future adult population sizes (Roughgarden *et al.*, 1985 ; Hughes, 1990). Moreover, unexpected heavy recruitment occurred in the presence of lower adult densities (e.g. 1983-1988 cohort) and *vice versa*. Considering the mobility of exposed sandy beach organisms, space could not be regarded as a limiting resource (McLachlan, 1988 ; 1990). Thus, the overcompensatory mechanism of population regulation suggested is that adults filter larvae out of the water column, as mentioned by Woodin (1976) and André and Rosenberg (1991) for suspension feeders of soft-bottom communities.

Simulation of alternative management strategies also suggests that, if the population is closed to fishing activities for a long period, high adult densities would inhibit recruitment success and hence the magnitude of the stock available for fishing. In this sense, human impact due to fishing also affected the population regulation of *M. mactroides*, mainly between 1983 and 1987, when the increase in fishing effort and catches leading to decreasing values of CPUE and stock size (Defeo, 1989), and the closure of the fishery (austral autumn of 1987). Because of very low levels of unit cost of effort, bioeconomic equilibrium was estimated at very high levels of fishing intensity.

Furthermore, a variable incidence of environmental driven variability due to salinity fluctuations through time (e.g. 1986 and 1987) was also an important source of population oscillations, already mentioned by Defeo *et al.* (1986).

Considering the above mentioned factors, the observed long-term trends in population fluctuations should be explained by a combination of biotic factors (density-dependent recruitment), environmental variability (salinity), and fishing pressure. In this sense, the constructed dynamic and non-linear model allowed us to verify this kind of interdependencies for the first time in a long-term study of an exposed sandy beach population.

An optimal harvest strategy (*sensu* Parma, 1990) could be used to minimize the effects of density-dependence effects, as well as those of fishing intensity.

### *4.3 Spatial dynamics of the resource and the fishery*

Density gradients were observed in the alongshore distribution of *M. mactroides*, as well as in fishing intensity and catches.

Spatial heterogeneity in stock distribution was explained by a differential response of the species to differences in habitat quality, defined in terms of the marked gradient in salinity through the 22 km sandy beach. In this sense, spatial salinity fluctuations coincided in their continuous gradient with respect to both adults and recruits abundance.

As a result, the fishing effort is usually focussed primarily on central grounds (zones B and C). Such characterisitics of the resource and fishermen behaviour were successfully reproduced by the model. Considering the marked seasonality in stock abundance and availability, as well as in catches and fishing intensity, a spatial management scheme based upon

an optimum rotation of fishing grounds were proposed as a feasible option to manage the fishery (Defeo, 1989 ; Defeo *et al.*, 1991). Fishing grounds A and D can be selected as exploitation units for seasons of low demand of clams (i.e. autumn and winter), whereas the central sections B and C can be preserved for periods of higher demand.

*4.4 Impact of alternative management strategies*

Assuming a stable environment, simulation of alternative management strategies suggested a great capacity of population recovery following human perturbation (fishing pressure) due to : 1) an overcompensatory response, i.e. the occurrence of heavy recruitment at low levels of parental stock, and a density-dependent natural mortality; 2) the fact that the size at first capture is greater than the size at maturity. As observed in Fig. 4a, the incorporation of organisms to the adult population (i.e. > 43 mm) usually occurs in austral summer, but this fraction reaches the minimum legal size commercially harvested during winter (i.e. two seasons after), characterized by very low exploitation levels and less accesibility to hand-gathering exploitation because of downward migration to lower intertidal levels (Defeo *et al.*, 1986). Results obtained in this study highlighted the concepts proposed by Caddy (1990), in the sense that this strategy increases the reproductive potential of the population, spawning at least once before capture. The rotation of areas with the periodicity mentioned above, constitutes a good complement of this management strategy.

ABSTRACT

*This paper explores a possible approach to the management of a multispecies and multigear fishery in the circumstances of a developing country. The analysis is applied to the small pelagic fishery of Guimaras Strait and adjacent parts of the Visayan Sea in central Philippines. It is carried out in three stages. In the first, a biological model is developed, using a dynamic pool approach to represent the population dynamics of the stocks. The status of the stocks is evaluated on the basis of yield-per-recruit measures for selected important species. The second stage of the analysis models optimal allocation of the fish catch across competing gears or fleets, having regard for distributional considerations. The allocation process explicitly considers the technological interactions in harvesting, as well as optimization in the pursuit of two conflicting objectives, namely maximizing employment and maximizing vessel operating profits. In the third stages alternative management schemes are explored. The regulatory regimes considered are those potentially applicable in the institutional environment of the Philippine region in which the fishery takes place.*

*The results of the analysis indicate that, on the basis of the criteria used, the optimal fleet size would amount to a relatively small fraction of the existing fleet size. The displacement of a large number of vessels and fishers that such optimization would involve, would represent an enormous social problem. Calculation of increased target yields that could be achieved through the regulation of fishing selectivity, shows that the resulting increase in the optimal fleet size would not be significant. The reason for this is that the current level of exploitation is close to that producing the maximum yield-per-recruit. The results confirm that overemployment and overcapitalization in the fishery are considerable. The paper concludes with discussion of an agenda for exploration of further management alternatives appropriate to the social and economic policy objectives of a developing country.*

## 1. INTRODUCTION

Tropical fisheries are complex resource systems. First, fishery resources in the tropics are mostly multispecies. The degree of biotic diversity and interaction between species is more complex in tropical environments than in their

temperate counterparts (Pauly, 1989). Second, there tend to be significant technological interrelationships in the harvesting process. Most of the large number of fishing gears being used have limited selectivity and every haul of the net is likely to yield a mix of many targeted and nontargeted species. All of there contribute to the complexity of the fishery resource system and, consequently, to a limited understanding of the fishery.

Most tropical fisheries are in developing countries where there are serious economic and social problems. Fish resources here are used to achieve various ends. FAO (1983) classifies the objectives in the exploitation of fishery resources into three groups - maintaining the resource, economic performance and equity (social needs). In addition to the above, other authors (Charles, 1988 ; Regier and Grima, 1985 ; Copes, 1969) include, among others, the following : food production, maintaining employment for fishers and the well-being and viability of fishing communities. Often, the objectives are non-complementary and this poses difficulties in managing the resource.

As most tropical fisheries are already overexploited, fishery programs should be directed increasingly toward improved resource management rather than further development of fishing operations. However, tropical fishery resource systems should be understood first to be able to design proper management programs. The multispecies and multigear nature of tropical fisheries and the pursuit of several objectives in the exploitation present difficulties in understanding the system and in the formulation of appropriate management plans. This paper attempts to develop a methodology that takes into account such characteristics of the fishery. The model is then applied to a specific fishery.

## 2. METHODOLOGY

The model that is formulated consists of several sub-models that accomplish the following tasks : the estimation of fishery yields, the allocation of these yields to competing fishing fleets and the analysis of alternative management schemes. The biological model used to describe stock dynamics is an adaptation of the dynamic pool model developed by Beverton and Holt (1957) :

$$Y_t = FRe^{-M(t_p - t_r)} W_\infty \sum_{n=0}^{3} \frac{\Omega_n e^{-nKt_p}}{F + M + nk} \qquad (1)$$

where $t_p$ is the age-at-first-capture, $t_r$ is the recruitment age, K is a curvature parameter which indicates the speed at which fish approaches the maximum possible weight attainable ($W_\infty$), R is recruitment and $\Omega_n$ is equal to 1, - 3, + 3, - 1 for n equal to 0, 1, 2, 3, respectively. In equation 1, $t_0$ is assumed to be zero.

The above equation gives the yield for each species over the exploitable life span of a given year-class. It also gives the annual yield for all cohorts if recruitment is assumed constant and yearly. The yield-per-recruit is a function of the following parameters : R, M, F, $t_p$, $T_r$, K and $W_\infty$. Of these, only F and $t_p$ may be manipulated and are considered policy variables.

Most of the applications of the Beverton-Holt model of stock assessment as enumerated above are on temperate and sub-temperate fishery stocks. Pauly (1989) noted that the M/K ratio is generally higher for tropical stocks than for temperate stocks. This has implications with regard to the kind of management advice that can be designed for the fishery when using yield-per-recruit stock assessment models in tropical environments.

Most tropical fisheries support a large number of gears whose biological impact (effectiveness in catching fish) and economic performance vary. In this regard an important task is determination of the optimum size of each fleet to be supported by the fish stock. In the process of determining the optimal fleet size, the goals of fishery management need to be considered. Multi-objective mathematical programming may be employed to determine the desirable allocation of fishery yields while pursuing several fisheries management objectives.

Following Evans (1984), the allocation problem is that of selecting the values of a vector of decision variables $f = (f_1, f_2,..., f_n)$ in order to optimize $p$ ($p \geq 2$) objective functions $h_1(f)$, $h_2(f)$,..., $h_p(f)$ subject to a constraint matrix imposed on the decision variables expressed as $f \in \Phi$ . Mathematically, the allocation problem is stated, in general form, as

$$\text{Max } h(f) = [h_1(f), h_2(f),..., h_p(f)] \qquad (2)$$

subject to $f \in \Phi$

Here f is the vector of standardized fishing efforts for the n fishing fleets and $\Phi$ represents the set of feasible values of f. It is implicit in the constraint matrix that f should be nonnegative.

A solution which maximizes each of the objective functions simultaneously is called a superior solution. Since at least two objectives in a multi-objective programming problem are typically conflicting in nature, a superior solution rarely exists. Hence, the concern is on generating the set of efficient or nondominated solutions. There are several methods of generating the set of nondominated solutions. One, the weighting method, transforms the multi-objective problem into a single objective programming format and then, by variation of the parameters used to effect the transformation, the set of nondominated solutions can be generated. A complete listing and description of methods to generate the nondominated set is found in Goiceochea et al. (1982).

It may be that the number of efficient solutions is large and that narrowing down the set to a more manageable number of alternatives is necessary. However, the methods for reducing the number of efficient solutions involve an articulation of the preferences of the decision maker. To avoid any subjectivity in the modeling process, an evaluation of a number of extreme points may be done and their characteristics compared. Some sort of a "menu" may be prepared from which the decision maker chooses the "desired" allocation. This becomes clearer in section 4.

To date, the applications of multi-objective programming to fisheries analysis are rather few. One of the earlier works is by Bishop *et al.* (1981) although they just outlined the procedure. Kendall (1984) outlined a multi-objective approach to regional resource management planning but without an empirical application. Healey (1984) developed a multi-objective fisheries model by considering conservation, economic development and social development goals. He used multi-attribute analysis, specifically, a linear utility model to assess the optimality of alternative yield strategies. He then applied the model to the New England herring fishery and the Skeena River salmon fishery.

## 3. AN APPLICATION OF THE MODEL

The model developed here is applied to the small pelagics fishery of Guimaras Strait and the Visayan Sea in the central Philippines. The fishery is multispecies, multigear and based on Philippine fisheries policy. Several objectives are pursued in its exploitation. The application of the model considers only two management objectives explicitly ; hence the problem becomes a special case of multi-objective programming. There are several advantages of a bicriteria programming model. First, numerical results may be easily derived and the tradeoffs between objectives may be clearly shown. Second, the procedure can be run in most linear programming packages and, hence, can be easily applied without use of specialized computer packages. More importantly, such formulation is adequate in representing the fisheries problem at hand.

In the case of the small pelagics fishery of Guimaras Strait and the Visayan Sea, the following objectives have been selected as appropriate for analysis in this paper : maximization of fishing enterprise profits (in respect of capital inputs), maximization of fishing employment (in respect of labor inputs), catch optimization (in respect of resource utilization), and provision of equal access to competing groups of fishers (in respect of equity). Of the possible fishery management objectives, the first two objectives remain as objective functions while the others are captured in the constraints. The rationale is that the other two objectives (catch optimization and equity) may be more conveniently expressed as constraints.

The two objectives in the programming model are as follows :

$$\text{Max } h_1(f) = \Sigma_i \Sigma_j \Sigma_s p_i q_{ijs} f_{js} - \Sigma_j \Sigma_s c_{js} f_{js} \quad (3)$$

$$\text{Max } h_2(f) = \Sigma_s \Sigma_j l_{js} f_{js} \quad (4)$$

Equation 4 specifies the maximization of fishing profits where *i* denotes species of fish and *j* the fleet (gear) while *s* is the sector ("municipal", i.e., small inshore vessels, or "commercial", i.e., larger offshore vessels). $P_i$ is the unit price of the *i*th species and $c_{js}$ is the unit cost of standardized effort for gear *j* in sector *s*. The objective of maximizing employment in the fishery may be expressed in equation 4 where $l_{js}$ is the labor component for every unit of standardized fishing effort.

The constraints imposed in the allocation process are :

$$H_i = \Sigma_j \Sigma_s q_{ijs} f_{js} \leq Y_i \quad (5)$$

$$f_{j1}/f_{j2} = CR_j \text{ for all j, and} \quad \Sigma_j f_{j1}/\Sigma_j f_{j2} = CR \quad (6)$$

$$f_j \leq \min (f_j) \quad (7)$$

In equation 5, catches for each species are limited to the biological potential of the resource. Total catch (H) for a given species, *i*, is the sum of the catches (or fishing mortalities) generated by all fleets 1, 2,..., *j* in each of two sectors *s* (commercial and municipal). It must be less than or equal to $Y_i$, the target yield for each species group.

Equity constraints are captured in equation 6. Since fishery rationalization entails an inevitable displacement of vessels and fishers, an important issue to resolve is from which fleet and sector (municipal and commercial) this reduction should come. For equity purposes it is considered that management regulation should not favor any group of fishers. Hence in the allocation process the current proportion of fishing effort exerted by the two sectors ($f_1$ and $f_2$) in each fleet ($CR_j$) and for the entire fishery (CR) should be maintained.

Equation 7 imposes minimum fleet size constraints to prevent the elimination of certain fleets in the optimal solution. The elimination of any fleet reduces the flexibility in adapting to changes in the course of managing the fishery in the future.

The $q_{ij}$ in equation 5 is the catchability coefficient for species *i* taken in fishery *j* and by sector *s*. In a mixed species fishery, the $q_{ij}$ or the coefficient of proportionality between landings and fishing effort varies across $q_{ij}$ species and fleets, owing to differences in the availability of the various species and their vulnerability to the gear.

Fishing effort captured in the f vector is standardized. It is a production function involving fishing inputs, labor (measured by crewdays - CD) and capital (represented by the gross tonnage of the vessel - GRT). Dummy variables are added to include seasonal effects. A Cobb-Douglas specification is selected as it incorporates the restriction of separability in the production technology. The fishing effort index is expressed as follows :

$$f = e^{\beta 0}(GRT)^{\beta 1}(CD)^{\beta 2} e^{\Sigma i \sigma i Si} \quad (8)$$

where f is standardized effort, $\beta_i$s and $\varsigma_i$s are the parameters to be estimated and $S_i$s are the seasonal dummies.

Although the small pelagic fishery is exploited by a large number of gears, only five are included in the model. These are the Danish seine, encircling gill net, purse seine, trawl and gill net fleets. The combined landings of these gears are at least 80 % of the total catch for each small pelagic species group specified below. The small pelagic fishery draws on seven major families and in each family are several species.

The biological parameters were estimated for dominant species in each category. The following species accounted for the largest share in each category of small pelagics : *Sardinella gibbosa* (sardines), *Rastrelliger brachysoma* (mackerels), *Selaroides leptolepis* (crevalles), *Stolephorus indicus* (anchovies), *Decapterus macrosoma* (round scads), *Dussumieria acuta* (round herring), *Selar crumenupthalmus* (big-eye scads). The parameters required by the Beverton-Holt equation and the bicriteria programming model are estimated by Padilla (1991). An important assumption with regard to the population dynamics parameters is that of knife-edge selection of the sample gear.

## 4. EFFICIENT ALLOCATION OF FISHING EFFORT : BASE CASE RESULTS

The Interactive Mathematical Programming System (IMPS) (Love and Stringer, 1987) was used. The weighting method is employed to generate the set of efficient solutions. The corner or pivot points of the feasible region in decision space, i.e., in terms of the composition of fleet, are first identified. From these pivot points, the efficiency frontier is derived in objective space, i.e., in terms of the values of the objective functions. Target yields set equal to the average annual landings for the period 1978-1987 constitute the base case model.

The feasible region and the efficiency frontier, drawn in objective space, show the trade-offs between the two objectives (Figure 1). The frontier indicates where the fishery can operate optimally depending on the desired combination of profits and employment. No specific point will be suggested as such decision is political. Instead, a "decision menu" will be presented to the decision maker from which a desired point may be chosen. The extreme points of the efficiency frontier and one intermediate point may adequately describe the set of efficient solutions, hence these constitute the menu. The characteristics of each menu item are described below.

The decision menu consists of corner points on the efficiency frontier A and C and the intermediate point B, all of which are corner points. Point A corresponds to profit maximization ($P_{max}$) where total fishery profits amount to 416.9 million pesos (P 416.9 M) and incidental employment generated is 3.50 million crew-days. At C, on the other hand, employment is at a maximum at 3.93 million crew-days and profits equal P 374.5 M. Point B is where the values of profits and employment are in between their respective minimum and maximum values. Between $P_{max}$ and B, and B and $L_{max}$, respectively, profits decrease by 2.72 % and 7.64 % while labor utilization increases by 3.98 % and 7.96 %.

The output from the bicriteria programming model is the standardized fishing effort for each fleet. These provide values for the following variables : total catch, number of vessels, investments in fishing assets and the number of fishers, given information on the temporal operations of sample vessels. The three points on the efficiency frontier are compared with respect to these variables. The values are found in the first column of figures in Table 1.

The point $L_{max}$ offers the highest catch at over 76.03 million tons although the difference in catch with the other corner points is only a few million tons. The catch is valued at about 931.78 million pesos at $P_{max}$ and 975.24 million pesos at $L_{max}$. The target yields are not fully utilized at the various points of the efficiency frontier. At $P_{max}$, the limiting species are sardines, mackerels and anchovy while at $L_{max}$ these are sardines, mackerels and crevalle. Less than half of the target yields for round scads, round herring and big eye scads are utilized at all corner points in the efficiency frontier. However, that part of target yields not caught by the fleets included in the model does not represent waste to the extent that these are caught by the other fleets not included in the model.

There exist surplus vessels in the Danish seine and trawl fleets in both commercial and municipal sectors while more vessels are required over their current levels for the rest of the fleet. A transfer of the excess vessels from the Danish seine and trawl fleets to other fleets can only partially offset the significant reduction in the number of vessels in other fleets at each corner point. Along this line, the results of this regional study on small pelagics support the findings of Dalzell *et al.* (1987) in a nationwide study on the small pelagics fishery.

The preceding discussion shows that there are excess inputs in the fishery. Such is not an aberration as economic theory predicts that an open-access fishery has a tendency to attract input resources, especially capital, beyond what is optimal. The small pelagics fishery of Guimaras Strait in its present state is not an exception. The estimated investment in fishing equipment for the nine fleets is currently about 614 million pesos, more than half of which is accounted for by the Danish seine fleet. Indeed the corner points of the efficiency frontier prescribe capital resource withdrawal from the fishery by as much as 52 % of the present level.

The resulting distribution of fishers across fleets maximizes labor utilization (crewdays) as specified in the employment objective. The fishery currently provides part-time and full-time employment to about 76,000 fishers from the provinces of Iloilo and Negros Occidental. (On top of this number are fishing operators, shore-based workers, fish traders and other allied workers who depend largely on the fishing industry for employment.) The points on the efficiency frontier, however, call for a considerably smaller number of fishers. Up to 50,375 (66 %) of the current number of fishers will be displaced from the fishery or conversely 34 % (25,845) will remain in the fishery.[1] This occurs at $P_{max}$. The largest number of fishers that may be optimally accommodated is 31,616 (41.5 % of total) which corresponds to $L_{max}$.

The displacement of a large number of fishers creates the greatest difficulties. But is the inevitable consequence of the process of rationalizing the fishery. Although employment-sharing arrangements have been observed in the study area, the employment effects of such would not be substantial. At most, such arrangements could only provide temporary employment to displaced fishers but at the expense of reducing the length of participation of those left in the fishery. However, there are other possible adjustments, e.g., regulating other components of fishing effort, that may be implemented to reduce the negative employment effects of rationalization.

1. Optimal employment is underestimated if the unutilized yields of some species are harvested by other fleets not included in the model.

## 5. ANALYSIS OF ALTERNATIVE FISHERIES MANAGEMENT SCHEMES

The fishery regulations analyzed in this section (regulations of F and $t_p$) may be considered complementary to a licensing scheme. The latter may be viewed as the primary regulatory scheme for the fishery, while the former are instruments that may be implemented to "fine tune" the fishery to the desired status.

### *5.1 Fishing mortality regulations*

Regulations targeting two particular levels of fishing mortality are examined. The first aims at $F_{0\,1}$ mortality, which corresponds to an effort level at which the marginal yield-per-recruit (from an additional unit of effort) is 0.1 of the yield-per-recruit at very low levels of fishing. The basis of $F_{0.1}$ is arbitrary. Its merit is that it is conservation-oriented by comparison with a fishing strategy aiming at maximum (sustainable) catches. An alternative fishing mortality target is $F_{max}$, which corresponds to the fishing intensity that gives the maximum yield-per-recruit for each species. However, $F_{max}$ may not be an appropriate target for the small pelagic stocks as it occurs at a high fishing mortality. This may lead to extremely low stock biomass and to recruitment failures if there is a strong stock-recruitment relationship. Nevertheless, $F_{max}$ is often regarded to be a management strategy worth considering.

Total fishery yield corresponding to $F_{0.1}$ is 93,475 tons while at $F_{max}$ it is 113,667 tons. While these are greater than the current fishery yield of about 90,146 tons, the yields of species (sardines and mackerels) which are binding biological constraints in the allocation model have actually declined, but only at $F_{0\,1}$. The largest increase in yield is for anchovy since current exploitation gives a very low yield-per-recruit which is less than half of that at $F_{0\,1}$ and at $F_{max}$.

The values of the key indicators (Table 1) have actually declined for $F_{0\,1}$ because of the reduction in yields of the constraining species. For $F_{max}$ the values have generally increased compared to the base case figures. Hence, the two regulations of fishing mortality cause changes in the optimal composition of the fleet. A more interesting result is that in the process of maximizing fishery profits or labor utilization in the fishery, neither of the yields corresponding to the two target mortality rates can be obtained simultaneously across species. As in the base model, at least two species are fully exploited while there are surpluses in some species.

The efficiency frontiers are plotted in Figure 2. Only the frontier is drawn to show the full extent of the shifting. The two regulations increase the range of efficient points although the number of corner points is not changed. This means that the decision makers have a wider range of choices particularly at $F_{max}$ which represents a substantial increase in profits and labor utilization in the fishery. This also allows an increase of about 19 % in the number of vessels and the number of fishers at $L_{max}$. The employment effect will be greater if the unharvested yields by the fleets under study can be captured by other fleets. However, the levels of displacement of vessels and fishers remain large at about 39 % and 51 %, respectively.

### *5.2 Mesh size regulations*

Regulations restricting mesh size of fish gears involve changes in the biological constraints following the concept of eumetric yield (Beverton and Holt, 1957). A given yield for each species would be the maximum yield for a specific mesh size. However, the estimation of these yields requires selection data for each mesh size by species and by gear, which is not available.

To examine the effects of mesh size regulations, a simplifying assumption is made. The results in this section, based on this assumption, are illustrative in nature. Fishery yields are estimated by looking at a uniform fish length across species where each length is assumed to correspond to a specific mesh size. Three arbitrary lengths are considered and target fishery yields are computed given the yield per recruit curves and recruitment.

Combined fishery yield is at a maximum at 10-cm length and decreases with time (or length). This is because for most species, the gain from individual growth is outweighed by loss in natural mortality beyond the 10 cm length. The lengths (10 and 12 cm) considered give a larger yield-per-recruit for the two constraining species, sardine and mackerel. The inclusion of 14 cm length in the analysis is to show that there are limits of increasing the target length for the small pelagic fishes.

The values of the important indicators of fishery performance are given in Table 2. The values of the two objective functions increase for the 10 and 12 cm lengths. The efficiency frontier is illustrated in Figure 3. For the 10 and 12 cm lengths, the number of corner points remains at three, while for the 14 cm fish length the number of corner points is two. Only two of mesh sizes considered yield an improvement over the base results in terms of employment. The number of fishers increased although the results are mixed with regard to the number of vessels. However, the increase in the number of fishers is rather insignificant and there would still be a large displacement of labor from the fishery. Optimizing yields with mesh size regulations alone does not reduce significantly the capital and labor displacement from the fishery.

## 6. POLICY RESPONSE AND FURTHER MANAGEMENT ALTERNATIVES

This paper has developed a framework for evaluating management options in multispecies multigear fisheries and has applied it illustratively to the small pelagics fishery of Guimaras Strait and the Visayan Sea, which is typical of many fisheries in tropical developing countries. From a productivity perspective, the paper confirms severe overcapitalization and overemployment in the fishery. This is a common finding for open access fisheries in regions with low alternative employment opportunities.

For the fishery under review, the calculations of this paper suggest that an efficient allocation of fishing effort would displace much more than half of the current labor force, along with a correspondingly large number of vessels, which would thus also reduce the level of capital investment considerably. However, capital invested in this fishery, generally, appears to be earning healthy returns. This may signify a high opportunity cost for capital, owing to its relative scarcity and mobility. It may also reflect monopsonistic access for fishery entrepreneurs to a large supply of cheap, underemployed labor in fishing communities. Given the foregoing, one may well expect government policy to give greater weight to employment maximization than to profit maximization in balancing these dual objectives.

Some specific management alternatives were modeled in the paper and tested for their ability to improve the fishery's performance in meeting the twin objectives of profit and employment maximization, subject to resource productivity and equity constraints. The results were not greatly encouraging. The base case modeled in this paper set target catches equal to the historical average yield for 1978-1987. Results were also modeled for two alternative regulated mortality levels. Catch regulation to meet the $F_{0.1}$ mortality criterion gave decidedly poorer results than the base case. The conservationist impact of $F_{0.1}$ management strategies has given reasonably good results with fisheries on longer-lived species in danger of stock depletion. With the shorter-lived species under consideration here, $F_{0.1}$ criteria appear inappropriate.

The model of this paper was also used to test the results of an $F_{max}$ strategy, aimed at maximum yield-per-recruit for each species. Indeed, the calculations based on this strategy offered the prospect of decidedly higher maxima for profits and employment than obtained in the base case. However, as noted above, the pursuit of $F_{max}$ in a small pelagics fishery, with relatively short-lived species, is of dubious merit because the high level of mortality it calls for may involve a significant risk of recruitment overfishing and stock collapse. Given the foregoing considerations, neither the $F_{0.1}$, nor the $F_{max}$ strategy warrants a recommendation for policy adoption.

A biologically low-risk management strategy is to regulate mesh size, with the aim of optimizing size-at-first-capture, in order to maximize annual net growth in the stock and thereby increase the surplus available for harvesting. Calculations showed, indeed, that modest improvements in the maxima for profits and employment could be achieved with mesh sizes targeting fish of 10-12 cm length. It is suggested that government give consideration to a policy of optimal mesh size regulation, after detailed study to determine the precise biological and economic impacts, as well as the costs and benefits of effective enforcement.

Probably the greatest dilemma in most fisheries rationalization schemes is how to deal satisfactorily with the question of employment levels in the fishery (Copes, 1987). The pursuit of economic efficiency, narrowly defined, almost always calls for a substantial reduction in labour inputs to the fishery. But, in very many cases, there are few realistic prospects for alternative jobs, at least in the short to intermediate term. This makes any substantial reduction in the number of fishers employed socially unacceptable and politically unrealistic. Such appears to be the case also in the fishery studied in this paper. The question then arises whether it is possible to achieve some improvement in economic efficiency without reducing the number of workers participating in the fishery.

What is required is a more labor-intensive fishing strategy. This does not (necessarily) mean any regression to a less advanced technology, but it does suggest a reduction in capital inputs relative to labor inputs. It should be noted that labor

inputs in this case are measured in terms of the *number* of workers employed and not (necessarily) the number of *worker-days* expended. The reduction in investment should be reflected in both capital and operating cost savings, with a corresponding improvement in net earnings for the fishery. Essentially the approach suggested is one in which much the same amount of fish is caught as before, with the same number of workers, but with much less equipment. The precondition of overcapitalization in the fishery should make this a feasible proposition.

A number of approaches may be considered. The possibility of "employment sharing" has already been mentioned above. This could be achieved by reducing the number or vessels and running them with alternate crews. Undoubtedly there would be transaction costs involved in setting up and maintaining such an arrangement. On the other hand, with shorter individual working-times, there would be opportunities to enhance incomes with greater inputs to household production.

Another approach would be to maintain existing fishing units with their full crews, but to reduce their operating costs by rationing gear use and/or fishing time. Gear rationing could be achieved, for instance, by limiting permissible headline lengths on trawls, numbers and sizes of traps used, fathoms of gillnet allowed, number of hooks permitted, and length of longline authorized. Time rationing could be achieved either by periodic closures of the entire fishery or (if this caused undesirable interruptions in supply) by requiring different fleet components to fish in alternate periods.

The foregoing discussion suggests that there is room for exploration of additional approaches to achieve more effective management of fishery resources, with better returns to those dependent on the fishery for their livelihood. There are particularly severe difficulties in determining optimal management techniques in the complex case of multispecies and multigear fisheries. The authors hope that the model developed in this paper will prove capable of adaptation and expansion, to make it a useful tool in testing new management designs for complex fisheries and in evaluating the prospects for successful implementation.

# The Usefulness of Bioeconomic Models under biological Uncertainty : a Case Study of the Australian Southern Shark Fishery

**Sean Pascoe, Tony Battaglene and David Campbell**

Australian Bureau of Agricultural and Resource Economics GPO Box 1563 Canberra ACT 2601, Australia

ABSTRACT

*An common feature of fisheries management is the need to make management decisions in the presence of uncertainty. Much of this uncertainty arises because information about the true biological state of the resource is incomplete. Fisheries scientists, conscious of their lack of a full understanding of the stock dynamics, have been hesitant in providing firm advice to fishery managers, and often present a range of biological scenarios. Where uncertainty is high, managers have been reluctant to impose strict management controls because these would cause economic hardship for some fishers.*

*There has been evidence of this recently in relation to the management of Australian southern shark fishery. Despite general agreement between biologists that the stock was severely overexploited, uncertainty as to the sustainable level of catch resulted in managers not imposing firm controls.*

*To examine the likely economic outcomes of various management options, ABARE developed a bioeconomic model of the southern shark fishery. The several management options were examined under a range of alternative biological assumptions. While the magnitude of the economic effects changed if these management options changed with different biological assumptions, the relative effects remained fairly consistent for most of the alternative biological assumptions. The costs of imposing an "optimal" policy based on the wrong biological assumptions was also estimated. As a result, a risk minimising/profit maximising strategy was developed for management of the fishery.*

## 1. INTRODUCTION

Unlike most other resource managers, fishery managers are expected to formulate policies for the optimal utilisation of an often unseen and mobile resource. In many cases, information on the resource is limited to historic catch records, the

accuracy of which may have been influenced by previous management policies. While most Australian fishers record details of their catch and effort in logbooks, this is not mandatory in all fisheries. Where a fishery covers waters under several different jurisdictions, requirements for keeping logbooks may vary between operators. Consequently, complete and consistent information is not always available.

As a result, fisheries researchers may not have enough information to accurately assess the biological state of the resource. Fisheries scientists have been cautious in providing firm advice to fishery managers, and often present them with a range of biological scenarios. Where uncertainty is high, managers have often been reluctant to impose strict management controls because the imposition of such controls would lead to certain economic hardship for some fishers.

There has been evidence of this recently in the management of the Australian southern shark fishery. This fishery includes Commonwealth waters as well as the waters of three states. Logbook requirements differ between the states, resulting in only partial catch records being obtainable. Available logbooks are not always complete or consistent, resulting in further difficulties in obtaining information on the stock. Despite these difficulties, most biologists are in general agreement that the shark stock is severely overexploited. However, uncertainty as to the true state of the resource and the sustainable level of catch has made managers hesitate before imposing firm controls.

Fisheries management in Australia, however, is concerned with more than just maximum sustainable catch rates. A requirement of all Australian Commonwealth fisheries management plans is to ensure that the resource is harvested at the level that results in the greatest returns to society over time. An optimal management strategy under this criterion may require catch rates below the maximum sustainable level. To examine the likely economic outcomes of various management options, ABARE developed a bioeconomic model of the southern shark fishery. The various options were examined under a range of alternative biological assumptions. Decision criteria under uncertainty were employed to establish an optimal management strategy.

## 2. THE SOUTHERN SHARK FISHERY

The southern shark fishery, located in waters off south-eastern Australia (figure 1), produced a catch of around 3000 tonnes carcass weight (about 4500 tonnes liveweight) valued at over $15 million in 1990.

The fishery is based primarily on catches of gummy shark (*Mustelus antarcticus*), which make up just over 40 per cent of the catch, and school shark (*Galeorhinus australis*), which also make up just over 40 per cent of the total catch. Other shark species, such as common saw shark (*Pristiophorus cirratus*), southern saw shark (*Pristiophorus nudipinnis*) and elephant fish (*Callorhynchus milii*) account for most of the remainder of the catch.

Most of the shark is caught using either gillnets or long lines, although some shark are also captured as a by-catch of trawlers operating in the south-east trawl fishery. The shark fishery is managed jointly by the Commonwealth and state governments, with most of the catch being taken by Commonwealth licensed boats.

Concerns have been raised about the status of the shark stocks in the southern shark fishery for a number of years. Catch per unit effort in the southern shark fishery over the past decade has declined markedly. This decline has been largely attributed to over-fishing (Southern Shark Restructuring Task Force 1991).

In December 1990, the Southern Shark Assessment Group suggested that the fishery faced collapse unless catches in the fishery were immediately reduced to 500-800 tonnes carcass weight (less than one third of the 1990 catch level). Scientists advised managers to reduce the number of nets by at least half. Fishery leaders, however, argued that there was too much uncertainty in the models to undertake such a drastic reduction. As a result, management measures were introduced in 1991 that were designed to reduce the number of nets in the fishery by about a third rather than by a half.

## 3. MAKING DECISIONS IN AN UNCERTAIN ENVIRONMENT

The hesitancy of fishery managers to reduce catch levels in the southern shark fishery is understandable given the amount of uncertainty that still remains about the status of the biological stocks. This uncertainty arises because of incomplete data from commercial fishers and less than complete knowledge about the biology of the fishery. On the other hand, managers are well aware that reducing catch levels will most likely cause financial hardship for a number of operators.

Much of what is known about the fishery is open to a number of equally plausible explanations. These explanations, however, have implications which differ significantly. Two models have been proposed by biologists to explain the historic patterns of fishing effort and catch. The basic difference between the models arises from their assumptions about the degree of migration of the shark. If the shark are highly migratory throughout the fishery as suggested in model 1, there is a single breeding stock of each species of shark, since areas would be restocked through migration. The alternative assumption, associated with model 2, is that the sharks are not highly migratory, and that when regional breeding stocks are depleted, they will not be replenished readily through in-migration.

Under the assumptions of model 1, both school and gummy shark stocks have been significantly depleted. To save the fishery from collapse, catch needs to be reduced. The exact level of the reduction is not known, however, given the uncertainty about the values of some of the key biological parameters. Again, alternative values result in different estimates of sustainable catch rates.

Model 2 is based on the possibility of a series of regional stocks that have progressively been fished down to a sustainable level. Under this alternative set of assumptions, the gummy shark component of the fishery is not in danger of collapse, and is likely to be sustained at its current level of catch. This is because there is thought to be a breeding stock of gummy shark off southern Tasmania that has previously been unexploited due to being located in water which is too deep or too rough to fish. This stock is thought to be supplying a constant recruitment of juvenile gummy shark to Bass Strait (J. Prince, Southern Shark Research Group, personal communication, 25 October 1991). The school shark stock, however, may have been severely depleted in some regions. Under model 2, some reallocation of effort may be desirable to protect breeding stocks, resulting in current catch levels being sustained, at least for gummy shark.

Both models are capable of explaining (to some extent) changes in the historical pattern of catch and size distribution of the sharks. Eliciting from scientists the probability of each model being the correct one is difficult. Most scientists believe strongly in either one model or the other, and acknowledge only a scant possibility that the other model is correct.

Despite this uncertainty, managers need to decide now on the future management of the fishery. In the absence of 'reasonable' subjective probabilities[1] , managers will need to employ decision criteria that do not require any knowledge of the states of nature (Anderson, Sweeny and Williams 1982). Most of the formal decision criteria under uncertainty are based on extreme adverse outcomes that may arise from the decisions (Hinchy, Jones and Thorpe 1992). For example, the maximin criterion attempts to identify the option that has the best worst-case outcome. Similarly, the minimax criterion identifies the option that results in the least cost if the wrong decision is made.

As part of the research effort in assessing future management options, a bioeconomic model of the fishery was developed by ABARE. The model was used to estimate the fleet structure, catch rates and net present value of total fishery profits over time for a number of possible policy options. The model was run with the alternative biological assumptions. The criteria for decision making under uncertainty were applied to the results of the simulations to indicate the optimal management strategy.

## 4. THE BIOECONOMIC MODEL OF THE SOUTHERN SHARK FISHERY

The bioeconomic model of the southern shark fishery draws on the biological relationships developed by Olsen (1984), Walker (1991) and the South Australian Department of Fisheries (1991). Economic and physical features that affect, and are affected by, fishery management decisions are imposed on these biological relationships. The model can be used to examine the impact of various management options on both the profitability of the fishery and the biological state of the fishery. Complete technical details of the model are given in Pascoe, Battaglene and Campbell (1992).

Previous biological models of the fishery have highlighted the need for urgent action to protect the resource. While effective biological tools, these models can only be used to estimate the consequences of applying given amounts of fishing effort in a fixed sequence. They cannot be used to estimate the best sequence to achieve certain objectives, except through trial and error. Furthermore, they exclude the effects of management decisions on the economic performance of the commercial operators in the fishery.

1. Subjective estimates of probabilities are considered 'reasonable' if there is a low variance in the probabilities assigned by acknowledged experts on the events in question (Hinchy, Jones and Thorpe 1992).

The ABARE model, in contrast, is an optimisation model, which means that it can be used to maximise an objective, such as profit, subject to a set of constraints such as the relationships between fishing effort, catches and biological stocks. In this case, the model is used to estimate the number and types of boat, the type of gear used and the timing of fishing (that is, in which years the boats fish) that will maximise the net present value of either profits, gross margins or revenue over time, given the constraints imposed by the shark stock and by management action.

The principal components of the model are shown in figure 2. Together these components enable the user of the model to estimate the biological, economic and physical outcomes for the fishery under different management strategies.

### *4.1 Biological characteristics*

The biological features of the model include the parameters of growth, mortality, catchability, size selectivity, and reproduction. Most of these parameters for gummy shark were derived by Walker (1991). Olsen (1954, 1984) derived similar biological parameters for school shark.

The model focuses on the two major target species – school and gummy shark. For the purpose of the analysis, school shark were considered to be asexual, but gummy shark were divided into males and females. This is because male and female gummy shark grow to substantially different sizes and at different rates, whereas male and female school shark are similar in size and weight at a given age. Other shark species are considered as by-catch in the model. While the catch of these other species is included in the model through a simple by-catch/target catch ratio, the biological implications associated with their catch are ignored.

Sharks age in the model, and this affects their catchability, weight and fecundity. Sharks are not usually caught until they are three years old, a function of both the behaviour of the juvenile shark and gear selectivity. The starting stock of shark in 1992, by age, was estimated using 'SharkSim' (South Australia Department of Fisheries 1991) with historical and 1991 estimated effort levels. As the population age structure changes over time, the survival rate of juvenile shark (less than three years old) is affected. The juvenile mortality rate, which affects the survival rate, increases as the number of older shark in the population increases (a density dependent mortality effect). While the exact cause of this increase is not certain, competition for food and cannibalism have been suggested. Juvenile sharks, being physically limited (due to their smaller size) in the range of food that they can eat may be more affected by competition arising from increased population size than older sharks, which have a broader food base. The reproductive capacity of the stock is also affected by changes in the age structure over time.

The catchability of shark may also be related to the number of shark in the fishery. A constant catchability coefficient (the link between the amount of effort and the level of fishing mortality) would be associated with catch rates which decreased in proportion to a decreasing stock size. However, as shark tend to aggregate into schools, catch rates do not necessarily decrease in direct proportion to the decrease in stock size. This feature is captured in the model by having the catchability coefficient increase as the number of recruited sharks decreases.

### *4.2 Physical and economic characteristics of the fleet*

Boats in the southern shark fishery can be divided into five main types, an outcome of the management regime that has been in place since 1988. Commonwealth endorsed boats fall into three categories – A10, A6 and B. The A10 boats are limited to fishing with a maximum of ten nets, while A6 boats are limited to six nets. The B class boats are limited to between one and five nets, depending on their historic involvement in the fishery. While a small number of Commonwealth endorsed boats operate using longlines rather than gillnets, for the sake of simplification all of these boats are assumed to use nets. The remaining two groups are comprised of state endorsed boats. These boats may use either nets or hooks, and their historic choice of gear determines the group to which they belong.

The main physical information used in the model was the number of boats in each group, the amount of effort employed by each boat (in thousands of hook lift hours or kilometre net lift hours), types of fishing gear used and the selectivity of each type of gear. The different types of effort (hook and net effort) are standardised in the model through the use of relative fishing power. This measure of the relative catching efficiency of vessels is based on the relative catch per unit of effort from the different types of fishing gear.

Information on the cost of fishing in 1988-89 was collected from an economic survey of the southern shark fishery. The key economic information used in the model includes: the variable cost per unit of effort and the fixed cost of operating in the fishery, for each boat type, and the average price received for shark.

The main variables examined using the model were catch and effort levels and the net present value of fishery profits over time. For the purposes of the analyses, profits were defined as total returns less all cash costs, including an allowance for owner operators. No allowances were made for non-cash costs such as the opportunity cost of the capital or depreciation.

While many shark boats are endorsed to operate in some other fisheries, such as in the southern rock lobster fishery, shark boats are still prevented from operating in most other fisheries. Even when they do hold endorsements to operate in other fisheries, the ability of operators to increase their income from those fisheries is limited because these fisheries are heavily fished. Consequently, the opportunity cost of the boats used to catch shark is low, and was assumed to be zero.

## 5. MANAGEMENT OPTION SIMULATIONS

ABARE's bioeconomic model of the southern shark fishery was used to estimate the likely outcomes of a number of different management strategies proposed for the fishery by the fishing industry, by fisheries scientists and by fisheries managers. These options included: a continuation of the existing management plan; total or partial closure of the fishery to allow stocks to recover; or a reduction of the catch to 1200 tonnes, 800 tonnes or 400 tonnes. A number of key areas of uncertainty were also identified and the effect of varying these parameters was investigated. Each option was simulated under a range of alternative biological assumptions.

The baseline simulations, based on model 1, used a 'best guess' set of biological parameters that were current in early 1991. These parameters are very similar to those used in the 'SharkSim' model (South Australia Department of Fisheries 1991). Recent analyses of the biological status of the fishery suggest that the biomass of the fishery may be twice as large as was assumed in the baseline simulations (Reichelt and McLoughlin 1991). The effect of this on the results of the ABARE model was tested by doubling the starting stock size in the model and rerunning the simulations. The options were also examined assuming alternative density dependent mortality and growth rate assumptions to those used in the baseline model.

Not all options were examined using model 2, in which there is assumed to be a series of regional stocks in varying degrees of depletion. It has been suggested that one such stock of gummy shark may exist off southern Tasmania that has previously been underexploited due to being located in water either too deep or too rough to fish. It is further postulated that this breeding stock may result in a relatively constant recruitment of juvenile gummy shark to the Bass Strait region of the fishery (J. Prince, Southern Shark Research Group, personal communication, 25 October 1991). This possibility was modelled by splitting the bioeconomic model into two distinct parts – one each for gummy and school sharks. Each part was optimised separately.

As the number of variables increases rapidly with a longer time frame, the simulations were restricted to a thirty year period[2]. Thirty years represents about one complete life cycle of school sharks and about two life cycles of gummy sharks. The longer life cycle of school sharks may result in some longer term effects being inadvertently excluded from the analysis.

## 6. COMPARISON OF THE MANAGEMENT OPTIONS

Under model 1, using the baseline simulations, closure of the fishery for between 8 and 12 years will result in the greatest net present value of profits despite the uncertainty associated with the biological parameters (figure 3). However, when

2. The model could be run successfully over a longer time period only if the fishing activities were excluded. For example, the model was run over a 40 year period as part of the validation process for the biological component (Pascoe, Battaglene and Campbell 1992). Running the model with the fishing activities over a longer period resulted in problems with both resource constraints and infeasible solutions.

the starting stock size is doubled (the higher stock size assumption), the net present value of profits associated with a total closure is not substantially greater than that obtained by reducing the catch to 400 tonnes (figure 3). Given that the higher stock level is thought to be more accurate than the stock level used in the baseline simulation, there may be little to be gained from a total closure of the fishery.

Assuming that the gummy shark component of the fishery can sustain the current catch level of 1500 tonnes (model 2), then the optimal fleet configuration will be about twenty boats, each catching about 75 tonnes. This will result in an annual profit of about $3 million, giving a net present value over thirty years of about $48 million. Closing the school shark component of the fishery for a period of twelve years will result in further profits in the future. Under current price and cost conditions, this would result in a net present value of profits of about $24 million, and involve a small number of additional boats (between four and ten) once the fishery re-opens. Based on model 2, the optimal use of the fishery may result in a net present value of profits of about $72 million over the next thirty years.

It is unlikely that these levels of profitability could be realised under the current management plan irrespective of the true biological state of the fishery. The lack of adequately defined property rights for fishers over the fish stock results in most (if not all) profits being dissipated through unnecessary (from an economic perspective) competition between fishers. Continuing with the current management plan is likely to eventually result in the school shark stock being depleted below the point of commercial viability, even if the operators concentrate on the gummy shark fishery. While some short term profits may accrue, these are likely to be short lived as the school shark stock continues to be fished down.

For the school shark, the optimal management policies derived from model 1 and model 2 are quite similar. However, for the gummy shark, the two models yield very different results. Under model 1, the optimal strategy would be to close the entire fishery for 8 to 12 years. Under model 2, the optimal strategy would be to keep the gummy shark fishery open at around the current catch level and to prevent further catches of school shark for 8 to 12 years. In the absence of reasonable subjective probabilities on which model is correct, the minimax or the maximin decision criteria may provide useful guidance to managers on which model to accept and, hence, on what management action to take.

Under the maximin criterion, the decision maker would choose the option that had the best outcome under a pessimistic (worst case) scenario (Anderson, Sweeney and Williams 1982). Model 1 with higher juvenile mortality rates represents the worst case scenario for all uncertain biological parameters (figure 3). Based on the maximin criterion, the 'best' option would be to close the fishery for about 8 years (assuming the higher current stock level).

Under the minimax criterion, the decision maker would choose the option that results in the least opportunity loss or regret if an alternative scenario were discovered to be the true state (Anderson, Sweeney and Williams 1982). If model 1 is correct, the potential loss from keeping the gummy shark component of the fishery open may not be great. Under the baseline simulation of model 1 the gummy shark fishery contributed only $3 million out of a net present value of $27 million over 30 years. Conversely, the cost of closing down the gummy shark fishery, if model 2 is correct, may be as much as $3 million a year. The cost of maintaining the current management policy is the forgone potential profits from closing the fishery. This may be $35 million over the next thirty years if model 1 and the higher stock assumption are correct, or $70 million if model 2 is correct. Based on this, the manager using the minimax criterion would accept model 2, and choose to reduce boat numbers and prevent further catches of school shark.

The maximin criterion represents extreme risk aversion (Meyer 1975). In cases where uncertainty is high and the outcomes are irreversible, the maximin criterion may well be appropriate. However, fisheries management decisions may be reviewed on an ongoing basis as more information comes to light, and are likely to be reversible unless stocks have been reduced to a very low level. As a result, the stock can usually be expected to recover if the wrong decision is made as long as it is recognised in time. Consequently, the minimax criterion is more appropriate in this circumstance and model 2 may be the best model on which to base management decisions.

The optimal strategy derived from model 2 is to prevent further catches of school shark for 8 to 12 years while maintaining the catch of gummy shark at around current levels. However, in practice it is very difficult to catch gummy shark without catching some school shark. Depending on the mesh size used, at least 20 per cent of the catch is likely, on average, to be school shark, even when gummy shark are targeted. Since it is unlikely that catches of school shark can be prevented without a total closure of the fishery, the catch of gummy shark may need to be reduced well below the current catch level to ensure that the school shark component of the fishery can recover.

Ongoing monitoring of the fishery will provide more information on which biological model is more likely to be correct. As a result, management decisions can be reviewed as this information becomes available.

## 7. DISCUSSION AND CONCLUSIONS

The advantage of using models in policy analysis is that they can improve our understanding of the ways in which a system is likely to behave in circumstances where it is not possible (for economic, technical, political or moral reasons) to experiment with a real world situation (Lee 1980). In the case of the southern shark fishery, the alternative to modelling is experimentation through trial and error in the fishery. If model 1 is correct, error could mean the further depletion of the resource and a fishery which produces much lower profits than otherwise.

While management decisions need to be made in the light of uncertainty, these decisions are not necessarily final. Ongoing evaluation and revisions to the biological models will reduce the uncertainty and management decisions can then be reviewed in the light of the new information.

The purpose in this paper was to demonstrate how bioeconomic models may be useful management tools even with biological uncertainty. Although biologists generally do not like using models that contain a high degree of uncertainty, management decisions need to be made on the basis of the information that is currently available. In the case of the southern shark fishery, the cost of keeping the gummy shark component of the fishery open even if the constant recruitment assumption of model 2 is wrong is substantially less than the cost of closing the entire fishery if the constant recruitment assumption is correct. Based on this, a risk minimising/profit maximising strategy is to reduce effort on the gummy shark component of the fishery whilst preventing, or at least reducing, capture of school sharks.

# Simulation Model of Factory Trawler Operation

**Ingólfur Arnarson and Páll Jensson**

Faculty of Engeenering, University of Iceland 15-107 Reykjavik Iceland

ABSTRACT

*Simulation models have proved useful in analyzing operations of complex systems, in particular if the decision problems are of dynamic and stochastic nature. In these cases, optimization models are often too far from the reality, whereas simulation can be more credible to the decision makers and serve them in a better way.*

*The operation of a fishing vessel can certainly be characterized as being subject to both a high degree of randomness and dynamic decision processes. During a fishing trip of several days or weeks, the captains often observe great fluctuations in catches and weather. Many decisions have to be made on the basis of these observations, regarding fish finding and on board processing.*

*The paper describes a model which simulates a factory trawler, haul by haul and trip by trip. The case of a factory trawler is chosen because it has both the catching and the processing operations. A LP model is embedded to plan the processing of each haul's catch. Among the many potential applications of the model, the two discussed in the paper are the testing of decision support systems and an analysis of the impacts of different fisheries management schemes on the individual firms.*

## 1. INTRODUCTION

A great and an increasing deal of fish, at least in the more developed fisheries of the world, is caught by trawlers. These are mainly stern trawlers, towing the trawl from the stern of the ship. Typically, the trawl is towed for few hours, and then hauled and emptied and set again, possibly after some relocation of the vessel. Trawlers with onboard processing capabilities (beyond gutting and heading) are called factory trawlers. Examples of the products processed are various types of frozen fillets or surimi. The main production stages in fillet production are gutting, heading, filleting, skinning, trimming, packing and freezing. Some or even most of these stages (except freezing) can be skipped, and therefore many products are possible, differing in price and in processing speed. In surimi production, different operations strategies can result in different quality grades of the surimi products, and different prices.

Factory trawlers can vary in size from 200 to 5000 BRT (metric tons), and in crew size from 15 to 150 men. Similarly, the length of trips varies from say 20 days to many months. The average catch rates are also very different at the various

fishing grounds of the world, and might range between 0 and more than 100 tons/hour. In most cases, the freshness of the raw material is important for the processing. Hence, the catch of one haul is usually processed while the next haul is being towed, even though some storage time is possible.

The operation of a modern factory trawler is a complex management process. In addition to the better known tasks like navigating and fish finding, the captain frequently has to make important decisions regarding the onboard processing. After each haul, he must decide if time should be taken to produce the most valuable, however usually also the most time consuming products, or if "faster" but less valuable products should be chosen.

The random fluctuations in catch rates, and in many cases also weather conditions, add to the complexity of the management process. Low catches could trigger the steaming to other fishing grounds, despite the cost of fuel and lost time in catching. During high peaks in catch rates, the captain might consider synchronizing his catching with the processing rate of some chosen product.

These decisions are highly dependent on whether the vessel has open access to the fishing grounds, or it is constrained by, say, an individual quota, i.e. on the fisheries management scheme applied. Many different schemes are either being discussed or have been implemented. These schemes can have different impact on operations fishing vessels.

Because of the stochastic and dynamic nature of the operations of factory trawlers, it was decided to build a simulation model. By this, we hope to be able to study the decision processes in a more realistic way than an optimization model would allow. Also, the model should enable us to study the impacts of the various fisheries management methods on the firms.

Sigvaldason et al. 1969 describe a similar model of a wet fish trawler, with the main purpose of studying the supply of raw material to freezing plants in Iceland, and comparing vessels of different sizes. In Jensson 1981, a simulation model of a fishing fleet is reported, emphasizing the decisions regarding the choice of harbor and congestion problems. Digernes 1982 and Arnarson 1986 discuss the value of time, when captains are making decisions about cruising speed and choosing fishing grounds. The value of time also enters the following discussion, when the product mix, as described in Jensson 1988 for freezing plants, is being decided. Many of the scenario assumptions for the case studied here, the cod fishery in Iceland, are based on Arnarson 1984, as well as on Andrason 1990 and Teitsson 1990, which describe work on the first prototypes of the model.

In the next section, the main logic of the model is described. Three of the most significant modules are then described in a more detailed way : The random catch generator, the important concept of the value of time, and the product choice module. As the product mix problem is a reasonably well defined decision problem, we embed a linear programming unit to simulate the decision behavior of a rationally thinking captain.

In section 6, we show an example of the possible applications of the model, in this case for analyzing the impact of introducing individual quotas in a fishery. In the concluding remarks, other potential applications are suggested.

## 2. MODEL DESCRIPTION, MAIN LOGIC

The simulation model is programmed in PASCAL (TURBO-PASCAL 5.5) and runs on PC computers. The main reasons for the choice of PASCAL, a general programming language, instead of some special purpose simulation language or package (like GPSS, SIMULA, SIMSCRIPT etc.), are the following :

(i) More flexibility in modelling and report design

(ii) The need to call a fast simplex routine for a speedy solution to the product mix problem after each haul (note that thousands of hauls may be trawled each year)

(iii) The simulation can be characterized by "time slice incrementing (haul for haul)", as opposed to the common "event driven" simulation, which in turn is made much easier by using simulation languages.

The overall structure of the model is as follows :

FACTORY TRAWLER SIMULATOR : A Structure Chart :

READ assumptions (from files and/or keyboard).

INITIALIZE parameters.

WHILE Years < Number of years to be simulated
DO NEXT YEAR :

WHILE Accumulated Catch < Individual Quota (infinite if none)
AND Elapsed Time of Year < One Year
DO NEXT TRIP :

Revise an OPERATIONS PLAN for the rest of the year, providing a framework plan for the (next) trip. See section 4.

[CHOOSE fishing grounds. Planned for a multi species/grounds version]

SAIL to the fishing grounds.

WHILE Accumulated Production < Fish Hold Capacity
AND Elapsed Time of Trip < Maximal Trip Length
DO NEXT HAUL :

GENERATE CATCH and time span of the haul, see section 3.

Revise the VALUE OF TIME, i.e. the processing strategy (reflecting how much emphasis should be put on time versus price value of products). See section 4

Solve the PRODUCT MIX (product choice) problem, i.e. what to do with the catch of the haul. Here it is solved as a linear program, with a simplex outine embedded in the simulation. See section 5.

UPDATE time elapsed, accumulated catch, production and other statistics influenced by the results of each haul.

NEXT HAUL ->

END of Trip :

[CHOOSE harbor to land the catch]
SAIL to harbor
LAND the catch [Refill supplies, repair work etc.]
UPDATE Trip Statistics (Catch,Time,Income,Costs,...)
WRITE Trip Report (if requested by user)

NEXT TRIP ->

END of year :
UPDATE Year Statistics
WRITE Year Report (if requested)

NEXT YEAR ->

END of Simulation :
UPDATE Totals and Averages
WRITE Totals and Averages, for all years simulated.

END.

This main structure is composed of modular units, in a flexible manner so that additional units can be included. Some of the planned units are shown in brackets above.

Many of the units are trivial or plain programming work and not of interest here. Those deserving further discussion are explained in the following three sections.

## 3. THE CATCH GENERATOR

Because of the extensive use of the modular features provided by PASCAL 5.5, it is relatively easy to change the model and replace modules, to adapt to different types of factory trawlers and fisheries. In this paper, the case considered is, as said before, the cod fishing in Iceland. The following description will be based on that case.

The probability distribution for hourly catches was estimated by sampling statistics from reports of some Icelandic trawlers, which are required to keep and send to the Icelandic fisheries authorities a diary recording information (date, start of haul, trawling time in minutes, fishing grounds, depth, and catches in kg by species) on every haul.

The statistical work is described in Teitsson 1990. The Log-Normal, LN(a,b), distribution was found to be a convenient model of catches per hour. It is interesting to note that Sigvaldason et al. 1969 used the LN distribution for catches per day, which was the unit of time in their study. The daily catch of a trawler is simply the sum of catches from several (a fluctuating number) hauls, however probably too few to give the daily catch a typical Normal distribution form.

Another and even a more likely explanation for this is the high egree of autocorrelation observed in the catches from haul to haul. The catch per hour series was modelled as a 1. order autoregressive process :

$$\text{Catch}(t) = A^* \text{ Catch}(t-1) + \text{Residual}(t) \quad (1)$$

The Least Squares Estimate for the coefficient A is the correlation coefficient, in this case estimated to be 0.26. This would also be the Maximum Likelihood estimate if the residuals were normally distributed, which however is not the case here. Higher order coefficients were found not to be significantly different from zero.

The residuals provide the random fluctuations in the process above. By using the well known relationship between LN and Normal distributions, see for example Derman et al. 1973, we can generate the fluctuating catches by (1) and :

$$\text{Residual}(t) = \text{EXP}( \text{Mean}(t) + \text{StDev}(t) * \text{Normal}(0,1)) \quad (2)$$

where

Normal(0,1) is a realization of the standardized normal distributionwith mean = 0 and standard deviation = 1. This is generated bycalling and summing 12 uniformly (0 to 1) distributed numbers andsubtracting 6 to get a mean of 0.

Mean(t) is the mean value of the normal distribution, which will give the desiredmean value of the Log-Normal according to seasonal catch fluctuations scenario described in Arnarson 1984.

StDev(t) is the standard deviation of the normal distribution calculated in a similar way as the mean value.

The high autocovariance in catch rate from hour to hour makes it more difficult to plan the production and smooth out the randomness. Also, it is in accordance with the fact that the captains often change fishing grounds rather frequently, as soon as they observe low catches. This is simulated in the model by a threshold criteria, such that whenever catch rate lower than the threshold is observed, the vessel is relocated,which takes time from fishing. This time is simulated by an exponential distribution, so that moving the vessel short distances is most common.

The trawling time for each haul is dependent on the catch rate. Modern techniques allow the captains to "see" on a graphical computer screen approximately how much is in the trawl. When catch rate is high, he will haul the trawl earlier, sometimes even after one or two hours of trawling. If catch rates are low, however not under the threshold criteria, he might trawl for say 4 to 6 hours. This is modelled by a set of rules, reflecting the behavior of captains found by examining the diary recordings.

## 4. THE CONCEPT OF TIMEVALUE

The concept of "Timevalue", as applied to decision making in fisheries, was introduced by Digernes 1982, see also Arnarson 1986. A thorough discussion on the concept is out of range of this paper. In short, the timevalue is the expected opportunity cost of time, "bought" from the future, or the expected shadow price of future time.

In the references cited above, the concept was proposed to help making short term decisions about cruising speed, for example when steaming to the fishing grounds. Intuitively, if no use can be made of the next hours, because the weather is too bad for fishing, or reported catch rates are very low, then time has no or low value, and the captain should choose low cruising speed. The opposite case could justify maximal speed.

Also, the timevalue enters more long term decisions. Consider planning a fishing trip of several days or weeks, and comparing two alternatives (choosing between different fishing grounds), that differ in length of trips as well as net revenues. Then, the question rises how to evaluate the time from the finish of the shorter trip until the longer trip is finished. A long term timevalue is then suggested to make the two alternatives comparable. This will depend on the quota left and the remaining time of the year, as well as on expected catch rates for the time interval considered.

In our model, we apply an expected opportunity cost of future time, or timevalue, to describe how the captain trades processing speed with product prices. This will become clearer in the next section. In the following, we discuss the difficult problem of assessing the timevalue.

The assessment of a long term (however within a year'shorizon) timevalue can theoretically be regarded as an evaluation of the shadow price of a time constraint in an optimization model. This model, which will be discussed in another paper, describes an aggregate plan for the operations of the vessel for there maining part of a year, with a given quota left, and subject to forecasted catch rates, prices and costs throughout the year.

In the simulation model, a more pragmatic and heuristic approach was used, based on a study of how the operators actually plan the fishing trips in real life. After all, the purpose of building this simulation model is to be able to study a wide range of questions, all however based on a realistic description of the actual decision behavior of the operators and the captains.

The approach used is as follows :

### *4.1 Revision of an OPERATIONS PLAN for the remaining part of the year*

This is done at the beginning of each trip :

(i) Plan Number of Trips Left, NTL :

NTL = (Year - Time Elapsed of year)/Maximal Trip Lengthround up (unless excess time is very small if rounded down).

(ii) Find Average Quantity per Trip, AQT (tons) :

AQT = (Vessel Quota - Accumulated Catch)/NTL

If AQT < Minimum, then reduce NTL by 1 and do 1.2 again. This means one or more trips will be skipped. If AQT > Maximum, then use the maximum value.

This could be the open access case, where vessel quota is infinite, or a case where the annual vessel quota cannot be reached.

(iii) Modify AQT with a seasonal (by months) Index of Catch Rates ICR(t), describing how the next month is compared to the remaining months of the year. This gives the Planned Quantity for the (next) Trip, PQT (tons) :

PQT = AQT * ICR(t)

### *4.2 Revision, after each haul of the EXPECTED VALUE OF TIME for the next haul :*

(i) Find the Planned Processing Rate for the remaining part of the trip, PPR (tons/hour), in accordance with the operations plan and the planned quantity for the trip :

PPR = (PQT - Accum. catch of trip)/Time left of trip

PPR is, however, never less than a given minimum rate.

(ii) Revise, if necessary, according to possible changes in prices and variable costs, the Net Revenue per ton of Fish caught, NRF (IKR/ton) [1] :

NRF = Reference Sales Price * Yield Coverage - Variable Costs

(iii)Estimate the Expected Catch Rate, ECR (tons/hour), for the next few hours, on basis of the last hauls. Here, various sophisticated forecasting methods could be applied. In the simulation model, we simply use the last haul :

ECR = Catch rate observed in last haul

(iv) Revise the Expected Value of Time, EVT (IKR/hour) :

EVT = NRF * MIN( PPR, ECR )

In this way, the long term plan PPR "sets the pace" for the assessment of the time value, unless it is so high (or the catch rates so low) that the catch rates, in short term, become a bottleneck.

## 5. PRODUCT MIX PLANNING

Each time when a trawl has been hauled onboard, the captain has to make two closely related decisions regarding the processing of the catch of the haul :

i) How much time should be allocated to the processing, i.e. should he wait to start the next tow, or should he allocate the expected trawling time for the next haul and go onwith continuing catching ?

ii) What product, or products should he chosen for the processing, considering that they can differ a great deal in prices and labor requirements ?

Given a certain expected value of time EVT, this is a reasonably well defined decision problem. Here, we assume that the captain is a rational optimizer, and we model the decision behavior by solving a linear program (LP), similar to the one reported in Jensson 1988. In fact, modelling an irrational behavior seems rather difficult.

Decision variables in the LP model are :

X(j) : Quantity produced of final product j (tons of product)

time : Time allocated for processing (hours)

Coefficients :

P(j) : Sales Price for product j (IKR/ton)

W(j) : Work Requirement in processing for product j (man hours/ton of product)

R(j) : Raw Material Requirement for product j, i.e. the reciprocal of the yield coverage (tons of fish/ton of product)

F(j) : Filleting Machine Time Requirement for product j (machine hours/ton). This is zero for whole frozen fish.

EVT : Expected Value of Time, see last section (IKR/hour)

MEN : Crew size on shift working in processing

RAW : Raw Material, i.e. catch of last haul (tons of fish)

FIL : No of Filleting Machines

1. USD = 55 IKR

FRC : Freezer Capacity (tons of products/hour)

ETT : Expected Trawl Time for next haul, here simply equal to the trawl time of last haul (hours)

The model maximizes the sales value of the products minus the opportunity cost of time, with respect to manpower, raw material, filleting and freezer capacity :

max z = SUM(j : P(j) * X(j) ) - EVT * time (IKR)

Manpower : SUM(j : W(j) * X(j) ) <= MEN * time (man hours)

Raw mat : SUM(j : R(j) * X(j) ) <= RAW (tons of fish)

Filleting : SUM(j : F(j) * X(j) ) <= FIL * time (machine hours)

Freezing : SUM(j : X(j) ) <= FRC * time (tons of products)

Time : time >= ETT (hours)

X(j) >= 0

Data for our case is given in Table 2. This is a simplified version of the model, whereas a full version has the following additional features :

- *Size grading of the fish, which affects filleting time and work requirements.*
- *The possibility of calling extra people, not on duty, to work.*
- *Aging of the raw material, as the yield coverage and labor requirement get worse after rigor mortis.*

Although the full version was the original one, it was later simplified as it showed to be difficult to justify and collect data on these features, when studying the real life closer. One the other hand, the time was not introduced as a decision variable in the first version.

These last remarks are examples of the value of being able to test ideas of decision support tools in a simulated environment, while developing them. A simulation model like this serves as a laboratory, where experiments can be made without the costs of real life.

## 6. ANALYZING THE IMPACT OF INDIVIDUAL QUOTAS

In most fisheries of the world, methods for managing the fishing in one way or another have been implemented or are at least being discussed. One of many different management schemes is the individual quota system (IQ), i.e. each vessel is allocated (given or sold) an annual quota for each the most important species. In some cases, the quotas are transferrable (ITQ).

They can be leased or sold. Open access to the fisheries, possibly with a Total Allowable Catch (TAC), can be regarded as the special case of infinite IQ.

In Iceland, all fishing vessels have had IQs since 1984. Here, we will focus on the cod fishery, the most important species in terms of export value. Every year, a TAC is set for the cod stock. Then, if all vessels were alike, and there were N vessels, the individual quota would be

$$IQ = TAC / N$$

Of course, the vessels are different, and so are the IQs. However, if we consider the factory trawlers per se, we have a relatively homogeneous fleet. Then the question arises : Is it most economical to have as few trawlers as possible, with as high IQ as possible ? Most economists and other specialists have, implicitly or explicitly, said yes to this question. Some have stated that the number of vessels in the Icelandic fishing fleet should be cut down by 30 - 40 %.

This result would certainly be correct if the net revenue earned by a vessel would be a linear function of the IQ allocated. Then, a "bang-bang" type of solution would appear : Either full IQ or 0. In the literature of fisheries economics, this seems to be one of the basic assumptions, even though some practitioners in the fishing industry do not agree by intuition.

It is therefore of interest to study the linearity of the net revenue with respect to the IQ. We restrict ourselves to Icelandic factory trawlers fishing cod. In the following, we will see how the simulation model was used to provide answers to this and other fundamental questions regarding fisheries management.

In Table 1, the data for the model trawler is given, while Table 2 shows data for the onboard processing, i.e. the various products that the trawler can produce, as well as production capacity data. Data for the cod fishing and it's seasonal pattern is in Table 3.

The model was run 20 times for each value of IQ allocated, in order to get reliable results. Each run spanned a year, or less if all the quota was caught before the end of the year.

Net annual revenue is defined here as the sales value of all products produced in the year, minus variable costs, which are of two types :

(i) Costs associated with each trip (fuel for steaming to grounds etc.)

(ii) Costs associated with each day at sea.

The results are presented graphically in figures 1, 2, 3.

The simulations reveal that the revenue function is not linear with IQ. The reason can be seen in fig. 3 : The product mix changes as more IQ is given to the trawler. So does the average net price per kg of fish, see fig. 2.

The implications of these results are outside the scope of this paper. At present, the effects on fisheries economics and fisheries management theories are being studied. Suffice to point out here, that the state of the markets for fish products must be considered when deciding individual quotas. In case of one product, or all products having similar sales price per kg of fish (accounting for yield coverage), the revenue increases linearly with IQ. The more the products differ in this respect, the greater is the concavity of the revenue function, and the more erroneous are the theories and results, that are based on the linear form.

The results are useful for the fisheries managers, when analyzing the impacts of different quotas for the vessels. Also, the operators of the vessels can use the results for decision making. To take an example, the marginal price per kg of fish, fig. 2, tells them how much they could pay for additional quota.

## 7. CONCLUSIONS

As some readers may have concluded, a more analytical (optimization) approach could have been used to the problem presented in this paper, however at the risk of loosing some important aspects of this dynamic and stochastic reality. The product mix problem, with stochastic raw material quantity from each haul, may be regarded as a "Wait and see" problem (the "passive method") in Stochastic Programming, see Jensson 1975. It would, however, be difficult to grasp the essence of the decision behavior of the captains with such an approach. Also, our experience tells us that with a simulation model, it is easier to gain the confidence of the decision makers, as reality can be modelled more closely.

In the last section, we have seen an example of the possibilities of the simulation model. Following is an overview of the various potential users :

i) Naval architects and engineers, comparing alternative design of equipment and production facilities onboard.

ii) Operators of factory trawlers, planning the year or single trips, or deciding whether to invest in a certain processing line or not, or to buy more quota.

iii) Fisheries management authorities, evaluating the consequences of quotas or other management schemes for the firms and the sectors of the fisheries.

iv) Educators and trainees in fisheries operations management. By using simulators, principles of management can be taught and trained.

v) Researchers in fisheries management and economics, and developers of decision support systems for operators and captains.

Several additions to the model have been planned, like adding more fish species and fishing grounds, and introducing the decisions of choosing grounds. Also, more model runs are planned to study various important aspects of fisheries management, and to test ideas to decision tools. The model has shown it's value by serving as a laboratory, where ideas and methods can be tried out without the costs associated with making real life errors.

# The Nordic Fisheries Management Model - The model and the data for the Icelandic version

**Asgeir Danielsson**

National Economic Institute, Kalkofns vegw 1, 150 Reykjavik, Iceland

ABSTRACT

*The paper describes the main features of the Nordic Fisheries Management Model (NFMM). This model has been developed by P. Helgason, S. Olafsson,, S. Wallace, R. Arnason, A. Danielsson and others. The aim of the model is to simulate the economic and biological consequences of different methods for manging the fisheries. The model simulates the vessels choice of fishery, their catches the production decisiosn of the processing plants, the market for wet fish, and for catche-quotas, the profits of the firms and the biological consequences of their activity.*

*The paper describes also the collection/construction of data for the Icelandic version of the NFMM. As the basic unit in the model are actual firms it requires data on the production costs of the different products in the model, i.e.it needs input/output coefficients for every fishery and every boat as well as input/output coefficients for each production line in the processing plants of the firms.*

## 1. INTRODUCTION

In most countries fisheries management has changed radically during the last two decades. A variety of administrative controls have been introduced. In some countries efforts are being made to use market mechanisms to control the fisheries through individual transferable catch quotas. In the North Atlantic area Iceland has had from Jan. 1, 1991, a system where fishing of the 11 most important species is almost completely managed with individual, transferable catch quotas which are allocated to fishing vessels[1]. In Canada and Norway individual quota schemes have been used together with other systems for managing the fisheries. The European Community and its member states, on the other hand, rely on total quotas and technical controls.

1. There is no regulation of the fishing of other species than cod, haddock, saithe, redfish, greenland halibut, plaice, capelin, herring, shrimp, scallop and lobster.

In most countries the advantages and the disadvantages of the different management systems are intensively debated among the fishermen and their organizations and in the scientific community. The Nordic Fisheries Management Model is to be a tool for making comparisons of the different management systems. This model originates from efforts to develop a model to simulate the effects of different quota management schemes for the Norwegian demersal fisheries which started in 1988 at the Christian Michelsen Institute in Bergen, Norway. These efforts were a follow-up of a modelling of the pelagic fisheries done earlier at the same institute.[2] Some use was also made of the experience from a simulation model for the Icelandic demersal fisheries.[3] This modelling activity was carried out during 1988-1990 at the Haugesund Maritime College, Norway, and has been documented in several reports.[4]

From mid-1990 this modelling activity has been supported by a grant from the Nordic Council of Ministers under a special program on multi-species research. At the same time the main modelling activitiy has been transfered to the Fisheries Research Institute at the University of Iceland. The Icelandic Ministry of Fisheries is co-sponsoring the project, principally the data collection and the adaptation to the Icelandic case. This aspect of the project is also supported by the National Economic Institute and the Marine Research Institute in Iceland. The Nordic grant is to cover only those general aspects of the modelling work which will be useful for modelling fisheries in all Nordic countries. It is this Icelandic version of the Nordic Fisheries Management Model (NFMM for short) which will be discussed in this paper.

A number of researchers have been involved in the work on the NFMM. Those most involved in the construction of the model have been T. Helgason and S. Olafsson from the University of Iceland and S.W. Wallace from the Norwegian Institute of Technology, Trondheim. Others who have contributed include : R. Arnason and A. Einarsson from the University of Iceland, K. Skarphedinsson from the Ministry of Fisheries in Iceland, A. Danielsson from the National Economic Institute, G. Stefansson from the Marine Research Institute and Ö.D. Jónsson from the Fisheries Research Institute at the University of Iceland. E. Hvannberg from the University of Iceland has been in charge of the software design and data management. A. Danielsson has been responsible for the collection/construction of economic data for the model and G. Stefansson has been responsible for the collection/construction of the biological data, the selectivity of the gear and the catch per unit of effort of the fishing vessels in the model.

In the work on the NFMM the author of this paper was primarily responsible for the economic data for the model. This paper will therefore discuss the collection/construction of the economic data in some detail. But first it is necessary to give a summarized description of the model.

## 2. THE MODEL [5]

The NFMM is a simulation model which is designed to simulate the behaviour of an entire fishing fleet, the related processing and the exploited biological fish-stocks for a period of some years. The simulation encompasses both biological and economic behaviour. The model is designed to give maximum flexibility so that it can be adapted to the special conditions in individual countries. It allows that existing modules are changed and new one added as more information and experience is gathered. Much effort has been put into the design of a user-friendly software to run the model. This software makes it easy to use and allows visual respresentation of some standard output data from the model as well as giving the output data in tabular form in a spreadsheet.

The NFMM is intended as a practical tool to study the effects of different methods for managing the fisheries. The model is therefore designed to allow the user to define in the model the management rules which he wants to study. He can choose between effort quotas, common catch quotas for a group of vessels, individual vessel-quotas with unrestricted transferability, individual non-transferable vessel-quotas, or individual vessel quotas with limited transferability where

Helgason and S.W. Wallace : Nordic Fisheries Management Model - A short description, Science Institute, University of Iceland.

the limits are defined by the user who defines which vessels are allowed to engage in trade in quotas.[6] The model allows the user to choose whether some specific features which are used in the fisheries management in the nordic countries are included or not. The user can e.g. choose if half of the catch on longline during the period from November to February should not be counted as part of the quota of the vessel as is done in Iceland, or he can choose not to allow this. The user determines the TACs for each specie and each period [7] and it is allowed that he defines subsidies which are given to the firms to influence their financial and competitive positions. For each set-up which the user chooses the model will simulate the catches, the size and composition of the fleet, the cost of the fishing industry, the aggregate profits of the fishing industry, the size and the age-distribution of the fish-stocks, the regional development of the fishing industry etc.

The NFMM is a disaggregated model. The basic economic entities in the model are actual firms which own vessels and/or processing plants. It is believed that the model will be somewhat more realistic and more flexible through the modelling of the firms in the real world. The cost of this realism is that it is necessary to obtain, store and handle a large quantity of data in the simulations with the model. In the Icelandic version of the NFMM there are 389 firms involved in processing, each producing on the average 4.19 processed products. In the model there are more than 700 fishing vessels choosing on the average between 2.3 different options for gear and location.

In most cases it will be necessary to limit the size of the model in terms of number of firms and products by aggregating firms to some extend. In the Icelandic model some 1500-1700 small boats which are owned by independent fishermen have been aggregated into a few 'boats'. [8] It is assumed that each of these aggregated 'boats' are owned by one firm which operates it according to the rules of the model. These aggregate 'boats' are big in terms of number of vessels, but the catch of these vessels amounts to only 5-10 % of the total catch.

### *2.1 The biology*

The NFMM is developed under a Nordic program on multi-species research. It is, however, outside the scope of the work on the NFMM itself to develop a model for species interactions and other ecological effects. When such models are available they can be included in the NFMM, but as such a model is not available for the biological species in the sea around Iceland, the present version of the NFMM uses a single specie biology where the size of the stock at some period of time is a function of the size of the same stock in the previous period, recruitment figures, natural mortality rate and fishing mortality rate for this stock and the average weights to get the biomass in tonns from the numbers. This year the Marine Research Institute in Iceland started an ambitious project of multispecies research. When this project produces reliable results these will be included in the Icelandic version of the NFMM.

### *2.2 Technology*

The model assumes Leontief technology of fixed input-output coefficients for each product. From the economic point of view the level of aggregation used in the definition of the products in the model are arbitrary, but the biological part of the model requires that each specie which is included in the biological part of the model is treated as a separate entity. It follows that the maximum aggregation of products permissible in the processing part of the model is up to the point where all different products of each specie are aggregated into one product. So if cod and haddock are separate species in the biological part of the model the processing plants have to produce at least one cod-product and at least one haddock-product and there have to be input-output coefficients for each of these products. The typical freezing plant produces some cod-products, some haddock-products, some saith-products, etc., so there will therefore have to be input-output coefficients for each of these products. A salting plant will produce salted cod-products, etc.

Fishing is an activity which often produces many products at the same time. The input-output coefficents of the vessels therefore describe the volume of input needed for one unit of effort, e.g. per day at sea rather than per unit of output. As different gear and different location of the fishing activity produces different catches of different species it follows that

6. E.g. if quotas are to be transferable only within a region then the user will define a market in quotas which only allows vessels registered in this region to participate.
7. Or he specifies a rule for determining the TAC's on the basis of the size of the stock.
8. At least one such 'boat' will be operating in each region.

for each vessel the model requires data on the coefficients which show the use of input per day at sea for each gear/location available for that vessel. In this way it is possible to detemine the cost of each fishing trip. The catches and the income side of the fishing trip are determined through gear-selectivity coefficients for each vessel and coefficients which show the catch per unit of effort. The latter coefficients are defined as stochastic variables.

### *2.3 Behavioural assumptions*

It is assumed that the firms use their vessels and processing plants to maximize the firm's profit, possibly subject to some restrictions. The firms are assumed to decide on the basis of this maximization which fisheries open to their vessels they should engage in, where to sell the fish they catch or how to process the fish they catch (or buy wetfish from other firms for processing) and which quotas to buy and which quotas to sell. With the constant input-output coefficients and the constraints of production capacity being constants as well, this maximization is a problem for linear programming.

### *2.4 Markets*

The model assumes that the firms take the prices of their products as given on the market and that the wage rate and the prices of variable inputs other than wetfish are assumed given. Other prices, i.e. the prices of wetfish, the prices of quotas and the prices of vessels (or physical capital in general) are determined by the model itself. For these goods there are defined markets, which may be country-wide or regional (i.e. markets where only those firms located in certain region are allowed to trade). These markets are open on certain market days. The markets for wetfish are open most frequently, but the markets for physical capital are open once a year. These markets operate as Walrasian auction-markets. The market authority signals a vector of prices, the firms update their plans and calculate their net demand for each good on the market and send this information to the market authority. The market authority then adjusts the prices so as to reduce the excess demand for the goods. This interaction continues until the market authority has found a vector of prices which is tolerably close to the vector of market clearing prices. These prices will then be the effective prices for the trading in the market.

### *2.5 The balance sheets of the firms*

The model starts to simulate from a point in time when the value of the assets of the firms, their debt and therefore their net wealth is known from their balance sheets. [9] During the simulations the model will calculate a profit or loss each year which changes the net wealth of the firm. A firm is assumed to meet a loss by increasing their bank-debt which is the only form of financing in the model. It is assumed that the firm is able to borrow at an exogenously given rate of interest up the point where its net wealth as a percentage of its total debt is below a certain minimum. When this happens and the next period's outlook does not indicate any improvement, then the firm will go bankrupt and all its assets will be sold. A firm may also choose zero-activity or it may decide to sell all its assets and cease to exist in the model.

## 3. THE ECONOMIC DATA

The economic data for the NFMM can in principle be obtained through different routes. One method would be to send a questionnaire to each firm and ask them directly about the cost per unit of output of the different products in their sortiment and about their production capacity. At least some of the larger firms in processing have reliable data on at least some of the cost of production of the different products in their sortiment. It is, on the other hand, uncertain how reliable data could be obtained from the smaller firmst. And as for the fishing very little information is availale on the cost of different fishing methods. It was therefore decided to estimate the input-output coefficients through indirect methods, i.e.

9. As the balance sheets sometime reflect the tax law better than they reflect the value of the assets of the firms some revaluation of these assets have been made. This primarily concerns the value of the vessels and the value of the quota-rights of the vessels.

through some kind of regression analysis on the basis of information which had already been collected and stored in a computer. However, information on these input-output coefficients which could be obtained directly from the firms would be used where it was believed to improve the estimates.

### *3.1 Estimation of the input-output coefficients for processing*

The information which is used for estimating the input-output coefficients for the processing consists of two parts. Firstly there are the operating accounts of firms in fish-processing collected by the The National Economic Institute (NEI). These operating accounts are usually highly aggregate. Sometimes there is one operating account for freezing groundfish, one for freezing shrimp, one for salting groundfish and one for salting herring, etc., but sometimes there is only one operating account for the processing of a firm which produces frozen and salted groundfish, frozen shrimp and salted herring as well. Table 1 shows how well the operating accounts for 1990 in the sample of operating accounts of 142 processing firms [10] which the NEI collected are disaggregated into the seven main processing categories traditionally reported. The first column shows the percentage of income which is declared in the correct processing division. 98.2 % of all income from freezing groundfish is declared as a part of the income of divisions which are mainly involved in freezing groundfish. 1.8 % of the income for freezing groundfish is reported as a part of the income of divisions which are mainly involved in salting groundfish, freezing shrimp, etc. As much as 92.7 % of the income from drying is declared as a part of the income of divisions which are not mainly involved in drying, while only 7.3 % of the income is declared as a part of the income of divisions primarily involved in drying.

The second column in Table 1 shows the shares of the income of the processing divisions of the 142 firms in NEI's sample which come from the main product produced in these divisions. 84.6 % of the income of the divisions which were mainly concerned with producing frozen groundfish came from freezing groundfish etc.

Table 1 shows that even the limited disaggregation which is reported in the accounts of the firms is far from complete. Even when the processing of one specie is reported in a separate operating account (salting of herring and freezing of shrimp and scallop) this reporting is not complete. But most importantly, there are no separate accounts for the freezing of individual groundfish species, or for the salting of individual groundfish species which is what the NFMM needs. These accounts have to be constructed through the use of some additional information. This second set of information about the processing firms consists of data on the purchases of wetfish for processing by each firm which are collected by the Fisheries Association of Iceland (Fiskifélag Íslands). These data show for each processing firm the volume of each specie allocated to freezing, the volume of each specie allocated to salting, the volume of each specie allocated to drying and the volume of each specie allocated to the production of fishmeal and oil. These data possess the degree of disaggregation which the NFMM needs.

The idea now is to use regression analysis on the data to get estimates of the costs of production which are not available directly in the firms accounts. After some experimentation the following method was believed to be best.

Let $V_{jk}$ be the volume of wetfish which is allocated for the production of product j (frozen cod is product number 1, frozen haddock is product number 2, salted cod is product number 10, etc.) in firm k,

let $A_{jk}$ be the cost of a certain type [11] which is associated with product j in firm k,

let $a_j^2$ be the average cost per unit of wetfish of this type wich is associated with the production of product j and

let $C_k$ be the total cost of this type in the operatinal accounts of firm k.

We now assume that the firm-specific coefficients $A_{jk}/V_{jk}$ are square-root normal, i.e. if we assume that $(A_{jk}/V_{jk})^{.5}$ is normally distributed around $a_j$ with some standard deviation which is to be estimated from the data [12]. The estimates are then the solutions of the following optimization problem :

10. These 142 firms received 75.6 % of all wetfish which was allocated for processing in Iceland. The firms which are in the sample of the National Economic Institute are the biggest firms. The 247 firms which are not included in the sample received only 24.4 % of all wetfish allocated for processing in Iceland.
11. Or income of certain type or the volume of input or the volume of output.
12. By this assumption the distribution of the firm specific coefficients, $A_{jk}/V_{jk}$, is skewed to the right which seems reasonable. The estimation procedure described below gives estimates of $A_{jk}$ which are independent of the choice of units used for measuring the volume of wetfish ($V_{jk}$). It is therefore possible to use the volume of certain species measured in tons og kilos, while others are aggregated into a composite commodity and measured in kronas or cod-equivalent tons.

$$\underset{A_{jk},a_j}{\text{Min}} \quad \text{SUM(j,k)}\{V_{jk}[(A_{jk}/V_{jk})^{.5} - a_j]^2\},$$

$$\text{subject to SUM(j)}\{A_{jk}\} = C_k \text{ , } k=1,2,...,n_k \tag{1}$$

The Lagrange function for this problem is :

$$L = \text{SUM(j,k)}\{V_{jk}[(A_{jk}/V_{jk})^{.5} - a_j]^2\} + \text{SUM(k)}\{l_k[C_k - \text{SUM(j)}\{A_{jk}\}]\} \tag{2}$$

where $l_k$, $k=1,2,...,n_k$ are Lagrange multipliers.

Expanding the expression in (2), rearranging the terms and using the restrictions in (1) gives that :

$$L = \text{SUM(k)}\{C_k\} + \text{SUM(j)}\{a_j^{\,2}\text{Sum(k)}\{V_{jk}\}\} -$$

$$2\text{Sum(j)}\{a_j\text{Sum(k)}\{(V_{jk}\,A_{jk})^{.5}\}\} + \text{SUM(k)}\{l_k[C_k - \text{SUM(j)}\{A_{jk}\}]\} \tag{2'}$$

Differentiating (2) with respect to the unknown variables, $A_{jk}$, gives :

$$\frac{\delta L}{\delta A_{jk}} = -\,a_j\,(V_{jk}/A_{jk})^{.5} - \lambda_k = 0, \quad j = 1, 2, ..., n_j \quad \text{and} \quad k = 1, 2, ...,n_k \tag{3}$$

which implies that the ratio of the coefficients for cost (or income) per unit of wetfish allocated, specific to firm k ($A_{jk}/V_{jk}$, $j=1,2,...,n_j$) and the average for the industry ($a_j^2$) is the same for all products which the firm produces. This means that it is implicitly assumed in the estimation that the firm is equally efficient in the use of a certain input relative to the industrial average in the production of all the products in their sortiment.

(3) and the restrictions in (1) give that :

$$A_{jk} = [a_j^2 V_{jk}/\text{Sum(i)}\{a_i^2 V_{ik}\}]\,C_k \tag{4}$$

Differentiating (1) with respect to $a_j$ and solving for $a_j$ from the first order conditions gives :

$$a_j = \text{Sum(k)}\{(V_{jk}A_{jk})^{.5}\}/\text{Sum(k)}\{V_{jk}\} \tag{5}$$

Iterating between (4) and (5) gives a reasonably efficient algorithm for the solution of the optimization problem in (1).

In the estimation of the coefficients for the processing it was decided to allow for 20 products. These products are listed in table 2.

The 142 processing firms in the NEI's sample produced on the average 5.7 products so defined, so it was necessary to estimate 20 $a_j$ and 807 $A_{jk}$ coefficients for each cost/income item. For the NFMM three coefficients were estimated for each product : the coefficients for the income from each product, the labour cost and other variable cost associated with that product. In the estimation it was decided to include only those firms where all firm-specific coefficients $(A_{jk}/V_{jk})^{.5}$ deviate less than 3 standard deviations from the $a_j$. The justification for this procedure is that there are obvious errors in the data, especially in the data for the smaller firms. As it turned out this excluded very little of the processing in terms of volume (usually less than 1-2 % in unrestricted estimation) and somewhat more in terms of number of firms from the estimation.

The method above is most efficient in estimating input-output coefficients for those products which are largest in terms of volume and those which are relatively much produced in firms which produce only that one product. But for products like freezing of capelin and herring where the product is only a small part of the total production of the firms involved in this production and where there are no firms which specialize in this production, then the method above is not very efficient. The table 3 shows the differences between the estimates from the unrestricted estimation and the values which are believed to be the correct ones.

To improve these estimates it was decided to use direct information from the firms. In the estimation of the coefficients for income the relative values of 10 $a_j$ were fixed in advance and estimated together while the other 10 $a_j$ where estimated without restrictions. In the estimation of the coefficients for labour cost the relative values of 12 $a_j$ were fixed in advance and estimated together while the other 8 $a_j$ where estimated without restrictions. In the estimation of the coefficients for 'other variable cost' the relative values of 14 $a_j$ were fixed in advance and estimated together while the other 6 $a_j$ where estimated without restrictions.

In the estimation of the data for the NFMM which have been done up to now only data for 1990 have been used. Using data for more than one year in the estimation would probably improve the estimates.

It is rather difficult to get an idea about the efficiency of the estimates of the input-output coefficients as the correct figures are not known. One method was though close to hand, i.e. to estimate the division of the operating accounts which the firms reported from the aggregate account and compare the results with those reported by the firms. As the data for the shrimp allocated for processing are unreliable[13] operating accounts for the other 6 divisions were added into one aggregated operating account and then this aggregated account was divided into division-accounts with the aid of the wetfish data. The table 4 shows the results for those firms which reported operating accounts for more than one division.

The big errors in the estimation of the income and costs related to drying are mainly due to incorrect reporting of the volume of wetfish allocated to drying. The errors in the estimation of the income and costs related to salting herring are at least partly due to the fact that this production takes place during the winter months and there are large stocks at the end of the year. The errors in the estimation of the income and costs of a division of a specific firm are of course bigger than the errors in the estimation of the aggregates for a number of firms. The fact that there was only one firm which reported freezing of scallop together with some other activity in its operational accounts explains the errors in the estimation in that case.

This study showed two things : Firstly that the more important the division, the smaller is the error of estimation. And, secondly, the larger is the firm, the smaller is the error. For those firms which reported operating accounts for more than one division the average error in the estimation of the firm specific coefficients ( $_{jk}/V_{jk}$) for income from the largest product, freezing groundfish, was 2.1 % and for the largest firms which had together 50 % of the volume the average error was only 1.8 %. The average error in the estimation of coefficients for income from the second largest product, salting groundfish, was 10.4 % and for the largest firms which had together 48 % of the volume the average error was 4.4 %. The average error of estimation for the less important division of drying was very large. This indicates that much of the error in the estimation of the coefficients are due to errors in the data, rather than errors in the estimation. That firms often report incorrectly their internal allocation of the same specie between different methods of processing is an important source of error. Some of the error is also the result of a difference in the time period which is reported in the operational accounts and the time period for which is reported in the data on the allocation of wetfish for processing. These differences explain why the value of the wetfish which a firm puchased is not always the same in these two set of data and make it necessary to adjust the data on the allocation of wetfish for processing so that the value of the raw material used in the processing according to these reports are equal to the value of the raw material reported in the operational accounts before the estimation of the coefficients.

The errors in the estimation of the coefficients for labour cost and the coefficients for 'other variable cost' were larger than the errors in the coefficients for income. The average error for the labour cost per unit of wetfish in freezing was 8.5 % and in the case of other variable cost it was 8.1 %. In a factory with many divisions it is obviously much easier to record separately the income from the different divisions than it is to record separately all the costs which are specific to one division and not another. Labour can be moved from one division to another without anybody exactly recording it. Different firms have different policies in this respect. In the operational accounts of some firms the reported accounts for individual divisions are conscientiously done and reliable, but the cost side of the subdivision in the operational accounts of some other firms may be quite worthless [14]. It was therefore decided to use the information in reported subdivision of the operational accounts only in the estimation of the coefficients for income but to ignore it in the estimation of the cost items, except when there was a special account for the freezing of shrimps or for the production of fishmeal and oil. If the firms reported operational accounts for other divisions then the cost item in these accounts were summed up and the sum used in the estimation.

13. The figures do include raw shrimp bought directly from a fishing vessel in Icelandic harbour, but do not include imported raw shrimp.
14. This does not necessarily imply that the aggregate operational accounts of these firms are not accurate.

The data on capacity in the fish-processing were in most cases obtained through finding the maximum volume of production during 1988-1990.

### *3.2 Estimation of cost coefficients for fishing*

The income side of the fishing is closely related to the biology of the model and the selectivity of the gear which is used. This will not be dealt with in this paper. The cost side of fishing on the other hand is of pure economic nature and will be dealt with subsequently. The NFMM needs coefficients which show the use of different inputs (or cost items) per day at sea for each vessel, gear and location defined in the model. There is one such coefficient for the cost of oil, and one for the other variable cost, excluding the salaries of the fishermen which are detemined by the value of the catch according to a formula specified in the contracts between the federation of vessel-owners and the fishermen's unions.

Operating accounts of fishing vessels are collected by the NEI and the Fisheries Association of Iceland. Together these institutions collected operating accounts for 402 vessels in 1990. The value of the catch which these vessels landed was around 75 % of the value of all landings.

To estimate the cost coefficients for each gear/location it was decided to utilize data on days at sea collected by the Fisheries Associations of Iceland. In the estimation of the coeffcients for costs per days at sea it was decided to define 11 gear/location which the vessel can choose (see table 5).

It is obvious that these cost coefficients are usually larger for the larger vessels than for the smaller ones. It is therefore necessary to adjust for the size of the vessel. After some experimentation it was decided to estimate the cost per days at sea multiplied by the size of the vessels in GRT. This means that in the estimation procedure described above $V_{jk}$ becomes the number of days at sea when the vessels utilized gear j multiplied by the size of vessel k in GRT. The 402 vessels in the sample utilized 982 gear/location. This means that the estimation involved estimating 982 $A_{jk}$ and 11 $a_j$.

The average gear/location per vessel was 2.4 in 1990, which is much lower than the average number of products per processing firm. It is also not uncommon that a vessel utilizes only one gear/location. For these reasons it is to be expected that the estimates of the coefficients for fishing are better than the coefficients for processing. In the estimation of the coefficients for the NFMM only the $a_j$-coefficients for catching with bottom trawl were restricted. These coefficients were restricted so that their relative values were fixed and they estimated together while the other 8 coefficients were estimated without restrictions.

The data on capacity of a vessel in terms of the number of days at sea are easily obtainable. It is simply the total number of days in the year minus the days they have to be in harbour for landing the catch minus the days they have to be in harbour for maintenance minus the days they have to be in harbour because of the weather. Nowadays the last subtraction is relevant only for the smaller boats.

## 4. THE CONSTRUCTION OF DATA FOR MISSING DATA

Almost a quarter of the processing in Iceland takes place in firms which are not in the NEI's sample. Hopefully this number will decrease later, but there will always be some firms for whom there are no operational accounts and no balance sheets available. The only available information about the processing in these firms is the information about the volume of wetfish allocated for processing. To complete the set of data for the NFMM it was decided to generate the input-output coefficients for the processing in these firms with a random number generator assuming that the distribution of the $A_{jk}/V_{jk}$-coefficients is square-root normal with mean and standard deviation equal to the estimated values. In almost all cases the ratio of mean of $(A_{jk}/V_{jk})^{.5}$ to the standard deviation was so large that the probability of some $(A_{jk}/V_{jk})^{.5}$-coefficients becoming zero or negative is zero. In most cases this ratio was 30-40 for the coefficients of income in processing, 12-16 for labour cost and 8-10 for 'other variable cost'. For the cost of oil in fishing the ratio was in the 6-9 range, and for 'other variable cost' in fishing the ratio was in the 4-5 range.

The items on the balance sheets of these firms were constructed in a similar manner. The production capacity of these firms was determined in the same manner as the production capacity of the firms in NEI's sample.

The cost-coefficients for those vessels where there were no operational accounts were constructed in the same way as the missing input-output coefficients for the processing plants.

1. It should be kept in mind when one evaluates these errors in the estimation that the reported figures are not necessarily the correct ones. It is easy to point out examples of incorrect separation of costs between operational divisions of the firms in the operational accounts which are reported.

# Sources of Variance in the Economic Performance of New England Otter Trawl Vessels

**Iswanie J. Anwar[a], Philippe Lallemand[b] and John M. Gates[b]**

ABSTRACT

*This study updates and extends work initiated and described in working papers by Crutchfield and Gates (CG) (1983) and Gates et.al.(1984). The objective of the research was to monitor the economic performance of the fishing fleets ; an objective achieved by combining information from different sources. This paper is concerned with total revenue aspects of the research. The results are consistent with the CG results which found measurable, persistent differences between vessels. These disparities illustrate why it is rational for "highliners" to oppose, for example, an ITQ system based on mean performance. It would be of interest if such differences were diminishing, since such a trend might lessen antipathy toward policies widely regarded by economists as rational. Such a trend would also be consistent with weak versions of optimizing behavior based upon Darwinian survival. The results show persistent differences in revenue per vessel month which are not explained by measured variables.*

## 1. INTRODUCTION

The maximization of returns (MOR) hypothesis has a long and controversial history in economics (Friedman, 1953, pp.22-23), and Simon (1968). That two Nobel laureate economists disagree on this hypothesis is indicative of the periodic dispute about the universality and usefulness of the "maximization of returns"(MOR) hypothesis. This paper reports results which may be of interest for analysts of fishing industries and for the MOR dispute. We begin from observations of persistent differences in the performance of vessels which are not explained by measured inputs. The residual variance is hypothesized to be associated with suboptimizing behavior ; to "non-maximization of returns" or NMOR. With respect

to MOR, it must be noted that the hypothesis has a number of variants- long run versus short run, with or without risk aversion etc. This renders MOR particularly amenable to what Lakatos has termed "immunizing strategies" (Blaug, 1980, ch.1).

The existence of qualitative variables such as skill and experience of fishers are often asserted but never measured in fisheries economics (Gates, 1984). It is a conventional wisdom that these qualities strongly influence success in "fishing for dollars, not species". Loan officers of banks indicate that the captain's skill in landing dollars is the single most important question in loan evaluation. Such qualitative factors imply the existence of generalized Ricardian(qualitative) factor rents. The implications of such differentials for the "standard model" in fisheries management have been explored by Copes(1972).

In the New England Otter Trawl fleet the number of vessels increased by approximately 60 percent from 1976 to 1982. This investment in physical capital stock also required a commensurate increase in number of captains or "skippers". A good captain may have the benefit of years of experience which is a form of "human capital" and cannot be created overnight. Given these events as background, it would not be surprising to find differences in skill during the 1976-1981 period and that is what Crutchfield and Gates(CG) reported in 1984. This study updates their work. However, we have made several procedural changes and presently do not have the pre 1982 data.

## 2. THE DATA

The data were obtained from the National Marine Fisheries Service, Northeast Fisheries Center, and include only New England landings by vessels using a specific gear, which is otter trawl (gear code 050). During each year, "trip records" for vessels are obtained by the National Marine Fisheries Service(NMFS). A trip record includes information summarizing a specific trip by a specific vessel. It includes such pertinent data as days absent, catch, landed value, etc. The trip records are aggregated by NMFS staff by vessel and month which resulted in annual files with approximately 9000-12000 records per file. Measured variables include vessel home port, vessel characteristics and intensity of vessel use. The measured characteristics of vessels include length and gear type used. Intensity of vessel use is measured by days absent from port per vessel-month.

## 3. THE MODELS

Five categories of captain's skill were defined in descending order (following CG), viz., High Liner(HL), High Average (HA), Average (A), Low Average (LA), and Low Liner (LL). Skill can be considered as measurable performance differences between vessels in terms of (1) gross revenue, (2) catch, (3) price or (4) cost. This paper is concerned with (1). We estimated "skill" measures for revenue, catch and price but will report only on revenue skill in this paper, since it combines both quantity and price related skills. It was found that the data set in the post 1988 period will not support more than three clusters, which we label "Lowliner"(or LOW), "Average" (Ave) and "Highliner"(or HIGH).

A log-log model was fitted for each year from 1982 to 1990 using the form in equation 1,(initially without the RFOS) variables :

$$LY = \alpha_0 + \alpha_{pi}\, HOMEPORT_k + \alpha_{mi}\, DMONTH_n + \alpha_{si}\, LRFOS_l + \alpha_1\, LLENG + \alpha_2\, LQLENG + \alpha_3\, LDA + \alpha_4\, LQDA + u_t \quad (1)$$

All continuous variables are in Naperian logarithmic form, indicated by an "L" prefix :

Definition of variables :

Continuous variables :

Y ≡ LN(GROSS STOCK) in dollars /vessel-month

$RFOS_l$ ≡ relative frequency with which a given vessel is classified in SKILL category l=1,2,..,L.

LENG ≡ vessel length in feet ;ln ≡ Naperian logarithm.

DA ≡ days absent per vessel-month

LQLEN,LQDA ≡ squared values of LLENG and LDA, respectively

$u_t$ ≡ heteroscedastic, Gaussian error term.

Qualitative variables

$HOMEPORT_k$ ≡ Home port of vessel= qualitative variables ; k ≡ 14,

$DMONTH_n$ ≡ MONTH qualitative variables ; n ≡ 12,

SKILL ≡ qualitative variables ; may be TRCLUSTER, QCLUSTER or PCLUSTER, for revenue, catch and price, respectively.

The model stated by equation 1 was applied to 1982-1991 monthly data for the New England otter trawl fishery which is a multispecies, multijurisdictional fishery.

## 4. PROCEDURES

The estimation procedure we used had six stages. In the first stage, an unweighted general linear model regression procedure was used to estimate equation 1 without the RFOSS variables. In stage two, the residuals of stage 1 estimation were analyzed using Glejser procedures (Gujarati, 1988), to detect the presence of heteroscedasticity terms. Since the residuals were not homogeneous, output(predicted values of residuals) from the Glejser model was used as a weighting factor in a weighted OLS estimate of model 1. This was stage 3. Weighted least squares(WLS) is a special case of Generalized Least Squares(GLS). (Kmenta,1971, pp. 264-265). If the Glesjer procedure succeeded, the residuals from the stage 3 model would be Gaussian white noise having been purged of any variance patterns in stage 2. However, an analysis of the residuals from the stage 3 model showed a pattern of "fat tails" ; i.e. normality was violated.

One interpretation of such patterns is that the data is drawn from heterogeneous normal densities. Cluster analysis (PROC FASTCLUS in SAS) was used to partition the residuals into a user defined number of clusters. The stage 2 use of a Glesjer procedure reduces the chances of spurious clustering around heteroschedasticity induced by measured variables such as vessel size, port, month or intensity of vessel use. SAS clustering procedures can be used to cluster the observations or the variables in a data set. The cluster analysis uniquely allocates each residual to one of the clusters.

There are no fully satisfactory methods for determining the correct number of population clusters for any type of cluster analysis (Everitt 1979, 1980 ;Hartigan 1985 ; Bock 1985). That is partly because the notion of a "cluster" is itself vague. It was found that the data set in the post 1988 period did not consistently support five clusters. The marginal clusters either cannot be created by the clustering algorithm used or the marginal clusters which result become so sparse that numerical instabilities are induced. A minimum cluster size of 30 was imposed which caused the clustering algorithm to find only three clusters which we will call "Low", "Average" and "High". In 1982, only two clusters were found. This produces somewhat anomalous results for 1982 which we are still investigating.

The clusters were then used to construct the "Relative Frequency of Skill" (RFOS) variables. Construction of the RFOS variables entailed tabulation of the number of times the observations on a given vessel (FOS) were classified in SKILL category i by the FASTCLUS procedure. Because the value of FOS differs between vessels, use of RFOS variables may induce heteroschedasticity which will be addressed below in stage 5. The total number of observations on a given vessel was used as a denominator to calculate the RFOS variables by dividing the FOS variables by observations per vessel. Note that the RFOS variables are ratio variables which necessarily lie between zero and unity and which sum to unity for a given vessel.

In stage four, the stage three model is re-estimated exploiting information gleaned from the cluster analysis. CG created qualitative variables corresponding to the clusters. This has avoidable consequences. First, since the qualitative variables

are derived from the cluster analysis, which is, in turn, driven by the residuals from earlier stages, it is difficult to claim independence. Secondly, the structure does not address ambiguities associated with the fact that a given vessel's records may be spread across more than one cluster. To avoid these consequences, the relative frequencies(RFOS) with which a vessel is classified in each cluster were calculated. Because the number of vessel records varies considerably, the same relative frequency can result from widely different per vessel sample sizes. Because landings at different ports appear as different records, the number of monthly records is not bounded by twelve per vessel ; some vessels have as much as thirty-six records per year. This inequality of sample sizes may reintroduce heteroschedasticity to be addressed in Stage five, but should tend to reduce dependence.

In stage four, the stage one model is re-estimated but inclusive of the relative frequencies just described. The descriptive labels are assigned based on the relative magnitudes of the means of residuals by cluster.

In stage five, the Glejser procedure is re-applied to the residuals of the stage 4 model to detect whether heteroscedasticity has been reintroduced by the inclusion of frequency of skill variables. In model 6, the OLS model of stage 4 is re-estimated using weighted OLS with the Glejser estimator from stage five as weights.

## 5. RESULTS

A summary of the cluster analysis results appears in Table 1. In general, the clusters appear quite stable, but two caveats are noted. First, as noted earlier, PROC FASTCLUS was able to create only two clusters in 1982 given the restriction on minimum cluster size(30 records). There are small numbers of extremely skewed observations which, if too many clusters are requested, can cause numerical instabilities. There is some indication that the frequency of such outliers is less in recent years ; a point to be kept in mind in evaluating the MOR hypothesis.

On average, coefficient (elasticity) estimates for relative frequency of "skill" (RFOS) variables in all years were statistically significant at ≤1 % LOS ; the persistence in error terms has been quantified via these variables(Table 2).

On average the $R^2$ was about 80 percent. The goodness of fit results can be compared with goodness of fit for the Stage 1 or 3 gross stock models of 65 percent ; a forty percent reduction in residual variance through inclusion of the frequency of skill variables. This improvement in goodness of fit is not surprising ; otherwise the clustering algorithm would be expected to have difficulty converging on clusters which differ statistically from each other. However, including the RFOS variables in the model 6 regression recasts the results of the cluster analysis in a useful form as part of a general linear model.

Variables for which parameters were estimated include qualitative variables for month and home port and continuous variables for vessel length and days absent per month. We have not reported these results since it results in a much larger Table wich is mostly irrelevant to the focus of this paper. All conditional mean parameter estimates in model 6 showed better results in terms of narrower confidence intervals compared to models 1 and 4. Reductions in standard errors of estimation are of course the intent of GLS procedures so this result is not surprising.

From the summary of results in Table 2, it can be seen that significant differences existed between the highest and the lowest skill level for revenue. The RFOS variables are tautological in that they describe the expected effect on monthly revenue of a change in the relative frequency with which a given vessel is classified in a particular skill category. However, we think it better to be tautologous than to ignore the obvious.

## 6. DISCUSSION OF RESULTS

The existence of differences between managers is widely accepted by investigators who have a "managerial" or "business" orientation (Farrell, 1957 ; Seitz, 1970). Although economists have figured prominently in the above literature, other economists have disputed the relevance of such differences. The dissenting view asserts that MOR would erase such differences or, if MOR failed, that any empirical differences are irrelevant because they must be due to pursuit of other or conflicting objectives(Stigler, 1976). Simon's critique of Friedman's casual empiricism is consistent with his

research program on "bounded rationality". Since neither is at pains to define their terms, let us define what we presume is meant by MOR, in its various forms. We define MOR1 to mean that all producers are always maximizing profits. In this extreme form we doubt that many would believe the hypothesis. Simon believes that producers would like to maximize profits but may not know how to achieve such a complicated task. Friedman's weak ("survival") rationale for profit maximization would predict a tendency for disappearance of sub maximal skills. This weaker version we term MOR2. As far as we can tell, the MOR2 hypothesis says nothing about relative rates of convergence(whereas MOR1 denies that there are differences to disappear). The MOR2 hypothesis predicts an upward drift by the submaximal vessels as the experience of survivors grows and or the inexperience of non survivors is purged through attrition. There would be a tendency for the skill variables to become less significant with the passage of time and to become more "compressed" so that some skill categories would become statistically indistinguishable from one or more adjacent clusters.

A version(MOR3) even weaker than MOR2 would recognize learning by new entrants. This "stochastic process" version could, under stable conditions, lead to a stable *distribution* of skills due to equilibrium of entry and exit processes. This would be one way of rationalizing the logical structure proposed by Houthakker(1956) to derive aggregate production functions from micro premises. Of course, in a fluctuating, uncertain environment rates of entry and exit vary and the FOS variables may also vary over time. This weakest version of MOR is very difficult to test directly, since it "forbids" so little and is so easily immunized(by noting unanticipated environmental fluctuations, for example).

We stress that the skill variables measure *relative* differences between vessels in the same year ; not absolute differences or levels. We may regard the skill clusters as metaphorical "waves" while mean performance level is the "tide". In this metaphor, waves (skill differences) may persist or dissipate regardless of the level of the tide. MOR2 holds that the waves would diminish in amplitude due to learning and attrition (of the troughs) ; MOR1 deny the existence of waves. MOR3 acknowledges the waves but suggests that they "tend" toward a stable distribution. Note that the "tide" may rise(fall) due to a uniform rise(fall) in skill, price or stock abundances ; our real world counterparts of the tidal metaphor. MOR3 allows for the possibility that individual waves may dissipate but, if constantly replaced by new entrants, a stable population of waves may evolve and persist.

The skill clusters are measured from a reference point independent of aggregate stock or market dynamics. Thus, while stocks have declined during the study period, all captains had access to the same stocks(although not necessarily the same knowledge). The dissipation of heterogeneity says nothing about the background level ; for that we must examine the time trend of the regression intercepts.

Figure 1 addresses graphically the hypotheses of skill convergence by showing the "relative frequency of skill" (RFOS) coefficients by year and skill level for all skill levels. For category i=1,2,3, RFOS(i) indicates the proportion of times a given vessel is classified in category i. The associated coefficient indicates the elasticity of monthly vessel revenue with respect to RFOSS(i).

The zero reference point in Figure 1 is, ex hypothesis, what one would expect for an "average" vessel ; that is, an increase in the frequency of average performance would be expected to have no effect on the performance of an average vessel. The RFOS coefficient for the average category is statistically insignificant. The RFOS coefficients for Low and High categories are non-zero, have the expected signs(by construction) and show no evidence of convergence toward zero as implied by MOR2.

The non-convergence in Figure 1 is sufficiently clear and space is limited so we will not present statistical tests of nonconvergence, although we did construct them.

## 7. SUMMARY AND CONCLUSIONS

The gross stock model, yielded "good" estimates of gross revenue for the simulator. In this equation, month, homeport, and "skill", as qualitative variables were highly significant statistically and economically important for estimating monthly gross stock. Inclusion of these qualitative variables, along with such continuous variables as length of vessel and days absent from port narrowed substantially the confidence intervals for conditional predictions of individual fisher's gross stock (gross revenue) during 1982-1991. This result is consistent with CG. The results do not support either the MOR1 or MOR2 hypotheses. The results do not conflict with the MOR3 hypothesis but, as noted earlier, MOR3 is broadly compatible with almost any time series data.

The results of the dynamic analysis of skill levels suggest that profit maximization and/ or Darwinian survival have diminished the skill differences but have not eliminated them. Under the MOR3 hypothesis, we should not expect their elimination. Entry-exit can be viewed as a stochastic process. If we presume that entrants will be skewed toward the low skill end of the spectrum, and a 20-30 year life cycle, then very simple stochastic processes imply a steady state which is heterogeneous with respect to skill.

In our interpretation, MOR is another relevant characteristic of (some) vessel operators and is a component of "skill". If two individuals have available the same resource opportunities, markets and technology but one makes better product mix decisions (for example), is this not part of "good management" ? This interpretation has the advantage of suggesting that differences are not immutable ; that data, information and communication can improve the status quo and, by implication, can contribute to the demise of such differences.

Also of interest are the effects of these skill variables on cost equations. There could be underlying differences in engine horsepower, electronic equipment or fishing time per day absent ; differences which would have some effects on costs. Another set of compensatory mechanisms exists in the lay system. Differences may exist between skill level and the lay system employed and in the opportunity costs of labor and management.

Do the skill levels matter to economists ? We would certainly not suggest that all analyses attempt such detail. There are contexts where the detail may be useful ; perhaps essential. It matters in advising individuals ; the Marshallian fiction of a "representative firm" is potentially disserving when the question at hand is individual and specific rather than generalized and abstract. Also, in fisheries management there are many contexts(e.g. individual catch rights) in which distributional issues are very important and skill differences are one dimension of such issues.

Another set of issues may arise in estimation. A good introduction to regression analysis will include a fallacious example in which a regression curve is fitted to two distinct clusters of data. The results will often indicate a non-zero slope when the nature of the problem is merely one of differing, discontinuous means. Under such circumstances, analysis of variance (use of qualitative variables) is a more appropriate tool because it eschews the assumption of continuity.

The interpretation of cluster differences as "skill" is debatable since managerial skill is approached via residuals ; whatever cannot be explained via measured inputs is attributed to "management" or "skill". It seems likely that some, if not all of the observed differences are explainable via product mix decisions in response to relative prices and abundances. That is a premise of duality approaches (Squires, *op cit.* ; Kirkley and Strand, *op cit.*).

Statistical estimation is ideal if all follow the same behavioral rule and observation units are technically homogeneous. As a matter of logic, however, if it is admitted that some follow NMOR, then there is no compelling reason to suppose( which duality does), that suboptimal units are technically efficient but allocatively inefficient. The converse is equally possible and a mixture of inefficiencies seems (to us) a more plausible characterization of humanity ; there is an infinity of ways to suboptimize. An allocatively inefficient, technically efficient solution is always equivalent in terms of net income, to (many) technically inefficient solutions. It would be interesting, therefore, to examine the stability of duality estimations across clusters and time periods. We have no desire to criticize duality theory per se. However, we do wish to note that regression analysis in the presence of clusters *could* give results which are spurious in part or in total. Possible pathologies could include violation of second order necessary conditions etc. Recognition of skill differences may alleviate such problems but at a price of acknowledging that some fishers operate on the interior of the revenue possibilities set rather than at different points on the frontier.

* MEAN VALUE USED

# A General Bioeconomic Simulation Model of the catching Sector of a Multispecies Fishery

**Philip Rodgers**

S.F.I.A., 10, Young Street, Edinburgh EH2 4JQ, United Kingdom

ABSTRACT

*This paper describes a general bioeconomic simulation model for the catching sector of a multispecies fishery. The objective of the model is to set out the economics of a fishery so that the final figure measured is the nett discounted present value of future value added from the fishery.*

*The model is comprehensive and is applicable to a fishery prosecuted by a number of countries with fleets using a variety of fishing methods. It accommodates multiple species fisheries over a multi-cohort span which permits landings by size category of fish to be simulated.*

*The model assumes that there is no more than one stock of a species since the intention was to concentrate on the economics of the fishery, but little extra programming would be required to allow for separate stocks of a species.*

*The model has two purposes. First, to act as a test bed for the mathematical structure of the system of equations used, so that a suitable optimisation method can be developed. Secondly, to offer a means by which fisheries managers can examine the impact of proposed measures on the different participants in a fishery.*

## 1. INTRODUCTION

Until now almost all economic models of fisheries have limited themselves to an examination of some aspect within the context of a single species fishery. This assumption has been necessary because of the need to understand the complex bioeconomic system on which the essentially economically-driven fishing activity takes place. While there are many such single species fisheries to be found, such models make no attempt to describe the complex interrelationships which exist where, because of the behaviour of the fish, only multi-species catches are possible, or where there are alternative fishing opportunities.

It has become apparent that there is now a need for a thorough-going model of a multi-species fishery that accommodates the variety of interactions between economic behaviour and biological factors.

## 2. THE OBJECTIVES OF THE MODEL

In planning the construction of any economic model the first question to determine is what task the model is required to perform. There are three functions a thoroughgoing bio-economic model can be asked to perform.

First, it can be asked to simulate the history of a fishery. The main purpose of this exercise is to test the specification of the model and validate the coefficients used.

The second is to predict ex ante the behaviour of the fishery and each of the variables included in the model. The model can be used to assess the impact of a range of events on the fishery. These events may be controllable, such as a change in regulatory limitations to fishing effort, or uncontrollable, such as failures in the recruitment of young fish to the stocks.

The third is to predict the level of activity which will maximise a variable such as profitability, value-added, or the size of stocks.

These functions are not mutually exclusive, and while the third of them requires different software from the first two in order to obtain a solution, the fundamental mathematical and economic structure of the model remains the same for all three tasks. Thus, my aim has been to describe a detailed general model of a fishery subject to exploitation by a number of countries by a variety of different methods aimed at a differing mix of the species available.

## 3. A GENERAL SCHEMATIC ANALYSIS OF THE DYNAMICS OF A FISHERY

The schematics of the model described in this paper are set out in Figure 1.

The relationships on the right hand side of most of the equations discussed below are almost wholly unknown. The mathematical specification of the equations has often merely been assumed in order to facilitate development of the strucure of the model. The functional form of the equations, the variables to be included and their dynamics, remain to be discovered.

In the formulation below all variables should be read as at time t unless otherwise specified. I have omitted the subscript t to avoid the formulae becoming unnecessarily cluttered. Given that the mathematical specification of the formulae remains to be discovered the philosophy of the systemic approach is more important than precise but possibly spurious specification. Similarly, I have omitted a number of identities which are merely summations necessary to move with mathematical exactitude between equations. This should not cause the reader any difficulty, but again has been done to avoid overcomplication. For the reader who wishes to check the detail, the computer program shows the exact summations needed.

The subscript c represents country, g fishing method, f species, a age cohort of fish, and s market size category of fish.

## 4. THE INVESTMENT FUNCTIONS

Thus for the purposes of the model it is postulated that investment is a function of injections and profitability, such that

$$I_{cg} = i0_{cg} + (i1_{cg} * PY_{cg}) \tag{1}$$

where I is investment, i0 is injected capital, and PY is profitability.

Profitability is the proportion of revenue accruing to profits, such that

$$PY_{cg} = \frac{PI_{cg}}{TR_{cg}} \tag{2}$$

where PI is the absolute level of profits and TR is the Total Revenue.

## 5. THE CAPACITY CONSTRAINTS

The capacity of the fleet is here defined as the maximum number of days fishing the fleet is capable of achieving. In the United Kingdom this normally means that a vessel is limited to about 200 days fishing a year. It would be possible for a vessel to be used much more heavily, subject to the mechanical wear and tear, by double or even triple crewing. It is necessary, therefore, that it is assumed in the model that there is no change to the pattern of crewing.

Capacity is here postulated to be a function of previous capacity, and investment such that

$$K_{cg} = K_{cgt-1}^{k1_{cg}} + (k2 * PI_{cgt-2}^{k3_{cg}}) \tag{3}$$

where K is capacity. The parameter k1 represents decay and

$$0 < k1_{cg} < 1 \tag{3a}$$

but k3 includes technological growth. The two period lag postulated for the impact of investment relates to the fact that it takes a considerable amount of time between earning profits and the launch of a new vessel. Usually commissioning the building of a new vessel involves staged payments as the work progresses. Further, there are other ways of investing such as the addition of a new piece of machinery to a vessel. Both these make the formulation postulated in equation 3 insufficient to describe accurately the true specification of capacity functions.

Capacity, however, need not be fully used. It is therefore a constraint on effort. Thus

$$E_{cg} = < K_{cg} \tag{4}$$

The formulation given in equation 3 assumes a given limit to capacity for each country and method. The model does not permit switching between methods which would increase the capacity available for one method at the expense of another. At this stage I do not believe this to be a significant weakness, though it is undoubtedly unrealistic. To over come the problem a series of constraints limiting the sums of capacity by country and method is needed. As these are specific to a given fishery I see no advantage in including them in the general model at this stage.

## 6. THE EFFORT EQUATIONS

Subject to the constraint expressed in equation 4, fishing effort expended may depend upon a number of factors.

Nominal fishing effort is postulated to be a function of a constant and the level of profitability of the method in that country in the previous time period

$$E_{cg} = e0_{cg} + (e1_{cg} * PY_{cgt-1}) \tag{5}$$

The adjustment period must remain a matter of conjecture until the hypothesis can be tested empirically. A one year lag was chosen because it seems unlikely that the reaction to a downturn would be immediate. There is little empirical evidence on which to base a postulation and an added advantage of a lag of some degree is that it facilitates computation by making the system recursive.

The question of switching effort from one method to another is similar in concept to that outlined in capacity above. Here it is perhaps more important but again because the structure of effort is specific to a fishery there is little to be gained in including effort switching inequalities at this stage.

## 7. THE STOCK EQUATIONS

The size of stock is fundamental to the viability of the economic activity based on it, and is a function in part of that activity. In the model there is assumed to be a single stock of each species. The stock equation used in the model calculates the numbers of fish in each age cohort and is

$$S_{fa} = (S_{f,\,a-1,\,t-1} * \exp(-M_{f,\,a-1} - F_{f,\,a-1,\,t-1})) + IM_{fa} - EM_{fa} \qquad (6)$$

for a > 1, assuming recruitment takes place at age 1.

where S is the stock, M is natural mortality, and F is fishing mortality.

Equation 6a is the standard Beverton-Holt model with the simple addition of terms for immigrants, IM, and emigrants, EM, to the stocks.

Fishing mortality is defined as :

$$F_{fa} = \ln\left(1 - \frac{CA_{fa}}{S_{fa}}\right) \qquad (7)$$

where CA is the catch in numbers, and

$$CA_{cgfa} = \frac{Q_{cgfa}}{MW_{fa} * D_{cgfa}} \qquad (12a)$$

Q is the quantity of landings by weight, MW the mean weight-at-age of a fish, and D the percentage rates of discard.

## 8. THE RECRUITMENT FUNCTIONS

It is assumed that recruitment is a constant. This has been done more for the potential use of the model in predicting the impact of management measures than to model the effect of fishing on the spawning stock and ultimately on stock size.

In some degree, this is unfortunate as the link between fishing and recruitment to the stocks is at the heart of fisheries management. The relationship appears to be so dependent upon a range of environmental factors, about the influence of which little is known, that models specifically designed to simulate the relationship have not yet been developed.

It is however possible to include actual recruitment data for the ex-post simulations. This overcomes the difficulty of including what must inevitably be a questionable functional form for the recruitment function and avoids also the problem of determining multi-species effects on recruitment.

The advantage in using a constant for recruitment is that a whole range of scenarios may be tried, and the effects of a single management measure determined given the unpredictability of future natural events. Thus

$$R_f = \bar{R}_f \qquad (8)$$

where R is recruitment. R is either mean, given, or actual recruitment depending on whether the model is running ex-post or ex-ante.

Where recruitment of young fish to all stocks is given as the mean historic level or some other constant, it should be noted that this model, and any which uses a similar assumption, is unable truly to replicate the extinction of a stock through overfishing. In the limiting case of their being no spawning stock there can of course be no subsequent recruitment. Any model using some form where recruitment is not a function of the spawning stock cannot replicate extinction.

A better alternative, which is not attempted for the reasons given above would be

$$R_f = R\left(SSB_{ft-1}, \sum_{i=1}^{f} Stock_i, ECC\right) \tag{8a}$$

where SSB is the spawning stock biomass. ECC is the environmental carrying capacity of the sea.

## 9. THE SPAWNING STOCK BIOMASS

Spawning in fish is related to size rather than age. Size is a function of food and space available. There would be no great difficulty in making the model accommodate fish by size but since the relationship of size as a function of food and space is unknown it has to be assumed constant. This leaves size as a function of age and simple substitution means that spawning can be treated directly also as a function of age.

Thus functions of the form

$$SSB_f = \sum_{i=4}^{a} S_{fi} \tag{9}$$

will suffice. Note that I have made no attempt to deduct those fish caught in each time period before they spawn. This leaves each time period split into three discrete sections ; recruitment, spawning, fishing.

## 10. THE CATCH EQUATIONS

Effort, given by equation 5, applied to the stocks results in the catch.

The Beverton-Holt model for catches is derived by substituting equation 6 into 7 and rearranging. This arithmetic manipulation gives

$$CA_{fa} = S_{fa} * (1 - \exp(-F_{fa} - M_{fa})) * \frac{F_{fa}}{F_{fa} + M_{fa}} \tag{10}$$

and

$$F_{fa} = E_{cg} * q0_{cgfa} \tag{11}$$

where q0 is a catchability parameter. Note that equation 10 contains no parameter representing stock density, and equation 11 has no parameter for diminishing returns to effort.

## 11. THE LANDINGS FUNCTIONS

Information about the levels of discarding is extremely limited and so given percentages are assumed to be discarded from each catch.

Those fish remaining after the unwanted fish in the catch are discarded provide the landings,

$$Q_{cgfa} = CA_{cgfa} * D_{cgfa} * MW_{fa} \quad (12)$$

The application of mean weights, MW, at this stage converts landings from numbers of fish to weights of fish.

To compute the quantity landed of each market size category it is necessary to multiply equation 12 by a matrix of mean size-at-age. Thus

$$Q_{cgfs} = Q_{cgfa} * SXA \quad (13)$$

where SXA is the mean size-at-age matrix.

## 12. THE PRICE FUNCTIONS

Quayside demand for fish is a derived demanded filtered by the needs of retailers, caterers, and processors who add value to the fish before it reaches the consumer. The model requires the demand schedule to be rearranged to form a price function.

The price function used is of the form :

$$P_{cfs} = p0_{cfs} + (p1_{cfs} * Q_{cfs}) + (p2_{cu} * Q_{cu}) \quad (14)$$

where P is price. u refers to the vector of substitute species for the one whose price is currently being estimated. The constant term p0 has subsumed within it the ceteris paribus assumptions relating to the vector of explanatory variables not determined endogenously.

It might have been preferable to include the prices of substitute species as explanatory variables instead of quantity but the use of price avoids the necessity to calculate prices simultaneously.

## 13. REVENUE

Revenue is calculated simply by multiplying the quantities by price :

$$TR_{cgfs} = P_{cfs} * Q_{cgfs} \quad (15)$$

where TR is total revenue.

## 14. THE COST EQUATIONS

Costs here relate to the costs of the whole fleet disaggregated by country and method. They include all costs including the cost of capital provided other than by the shareholders but excluding profits and wages.

Costs may be divided into fixed and variable costs. Fixed costs are a function of the size of the fleet. Variable costs are a function of the cost of fishing. In addition, many charges, such as harbour dues and salesman's commission are a percentage of the value of the catch landed.

The cost function used is therefore :

$$C_{cg} = (c1_{cg} * E_{cg}) + (c2_{cg} * TR_{cg}) + (c3_{cg} * K_{cg}) \quad (16)$$

where C is costs.

## 15. THE WAGE EQUATIONS

In the fishing industry in the UK crew remuneration is normally by one of two methods.
It may by proportionate to the value of the catch nett of running costs. The usual alternative to this means of payment is for the crew to be paid a basic wage, and some form of bonus as a proportion, w1, of the value of landings, so

$$W_{cg} = w0_{cg} + (w1_{cg} * TR_{cg}) \quad (17)$$

where b is a constant which represents the sum of basic wages by country and method, and

$$0 < w1_{cg} < 1 \quad (17a)$$

If any vessel at all for the country and method pays its crew a basic wage independent of the revenue from landings then the function for the country and method will include a non-zero intercept term.

## 16. THE PROFIT IDENTITIES

Profits are defined as

$$PI_{cg} = TR_{cg} - C_{cg} - W_{cg} \quad (18)$$

where PI represents profits.

## 17. VALUE ADDED AND THE DISCOUNTED VALUE ADDED

It is assumed in the model that the ultimate objective of society in having a fishing industry is to maximise value-added to society. In the catching sector of fishing the discounted value added from each method is

$$DVA_{cg} = (PI_{cg} + W_{cg}) * (1 - r)^t \quad (19)$$

where DVA is the nett discounted present value of value added, and r is the discount rate.
This completes the model.

## 18. THE SIMULATION MODEL

The structural model detailed above has been incorporated into a simulation model. The program is written in BASIC. BASIC is much derided by computer buffs but the flexibility it offers while one's thinking is developing in parallel with

the work has been an immense asset. The program is now some 7500 lines in length and as the importance of new factors has come to be understood it has been relatively easy to add sections to cope with their influence. At no stage have I felt constrained by the software in what I have wanted to model.

One limitation has been that the TurboBasic package used has insufficient memory to store all the calculated variables for output at the end of the simulation run. This constrains the output to be by time period, so that the memory can be overwritten, rather than by variable. It is less than ideal as it prevents ready access to the variables without needing to re-run the model in order to provide a particular set of results in time series format, but it is a question of presentation of output and not whether the output can be produced. The difficulty could easily be overcome by repeatedly running the model and retaining the values of one group of variables at each run for output at the end of the run. This is already done in the current program with Discounted Value Added.

However, the main objective of setting up the conceptual structure to answer the question of who gains and who loses has been achieved and transfer to a larger computer would enable all the output to be stored till the end with only minor changes to the program.

BASIC may prove unwieldy at some stage in the future if simultaneous solution of some of the equations is sort. At present, this limitation is negligible when set against the advantages the language's flexibility offers.

## 19. USE OF THE SIMULATION MODEL

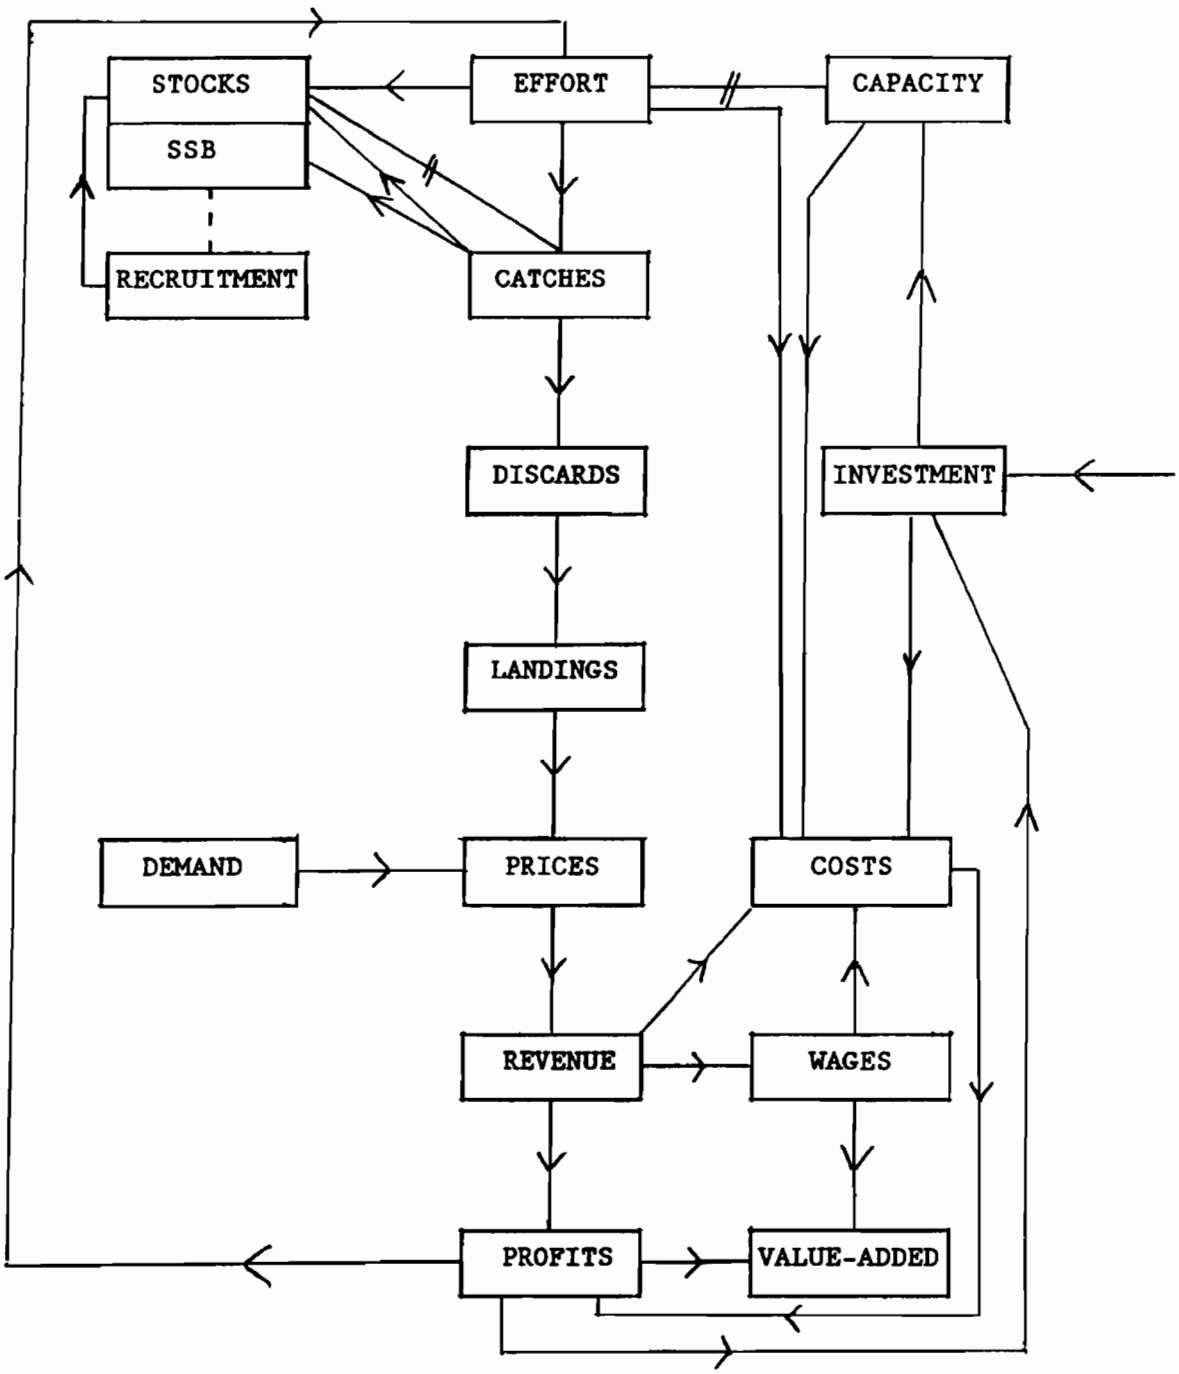
The model can be used in a number of ways.

First, it can be used to test the correctness of functional forms. By examining the closeness of the simulation results to those historically observed the user will be able to develop a better understanding of the economic relationships existing in fisheries. In addition the user, by making small changes to the values of the coefficients, will be able to test the sensitivity of the economic system to a variable.

Secondly, it will be possible to run the model to determine what the effect of a suggested regulatory measure will be, including identifying the gainers and the losers, and the impact on the contribution of fisheries to the economy as a whole.

Thirdly, it will be possible to examine the vulnerability of the catching sector of the fishing industry to external factors, such as demand for fish, or the cost of fuel oil.

There are throughout the model assumptions which have had to be made. The decision criteria for these has been to select those which pull the model closer to reality so long as the basic theoretical framework of the model is not compromised.



Even if we had perfect knowledge of all the economic parameters, there remains the problem of the apparently stochastic nature of recruitment.

This seems to me to be so fundamental a problem that any attempt to use this or any other bioeconomic model which includes it is bound to conclude with a series of "if... then..." comments.

## 20. CONCLUSION

What I have achieved here is twofold. First I have identified the conceptual structure of a thoroughgoing bioeconomic model. Secondly, I have shown what data is needed for such a model. The schematics show the true position of the stocks as constraints on economic activity and not an end in themselves. Capacity is also shown to be a constraint on effort and not causal.

ABSTRACT

*The paper provides a summary of the elements and structure of a bio-economic model of fish harvesting and processing. BEAM 4 is the fourth in a series of bio-economic analytical models issued by the FAO Fisheries Department. The model allows to predict yield and a range of economic performance indicators as a function of fishery management measures such as fishing effort control, closed season, closed area and minimum mesh size regulation. BEAM 4 can deal with a fishery system of several stocks, several fleets, several areas (fishing grounds) and several processing plants, and can account for migration of the animals as well as seasonality in recruitment. The model behind BEAM 4 is an age-structured cohort-based fish stock assessment model combined with an economic model of both harvesting and processing.*

## 1. INTRODUCTION

This paper provides a summary description of BEAM 4 (Sparre and Willmann, 1992), the latest in a series of bio-economic analytical models issued by the FAO Fisheries Department [1]. BEAM 4 is a versatile tool for the analysis of space-structured multi-fleet and multi-species fisheries and can account for migration of the animals as well as seasonality in recruitment. The model behind BEAM 4 is an age-structured cohort-based fish stock assessment model combined with an economic model of both harvesting and processing sectors.

1. BEAM I and II by Coppola, Garcia and Willmann (1992), and BEAM III, the stochastic simulation model by Cochet and Gilly (1990).

The objective of BEAM 4 is to predict yield, value and a series of measures of economic performance as a function of fishery management measures such as fishing effort control, closed season, closed areas and minimum mesh size regulation. The measures of economic performance include profit, profitability, gross value added, net value added, national net value added, resource rent, employment, costs in foreign exchange and foreign exchange earnings.

BEAM 4 is primarily designed for the analysis of tropical mixed fisheries with penaeid shrimps as the target and finfish as the by-catch. It is, however, general, and in principle may be used to analyse any fishery. It is suitable for the analysis of resources shared between artisanal and industrial fisheries. It is a simulation model and has no routine for optimization.

BEAM 4 is implemented in TURBO PASCAL for IBM micro-computers. The system is user-friendly and menu-driven. It contains extensive data entry, file handling and output facilities as well as graphical presentation of results.

BEAM 4 consists of a biological/technical and an economic model which are described below.

## 2. THE BIOLOGICAL/TECHNICAL MODEL

Models used for fish stock assessment either deal with the analysis of historical data such as the Virtual Population Analysis, VPA, (Fry, 1949) or they deal with prediction of catches and stock sizes such as the Thompson and Bell model (1934). The series of BEAM models is of the latter type but their biological input parameters are usually estimated with VPA or similar methods. BEAM 4 works with numbers of fish/shellfish by age group as described by, for example, Beverton and Holt (1956).

There are two kinds of input data into the biological/technical model. The first kind include data on growth, migration and mortality by species which need to be obtained on the basis of stock assessment techniques such as VPA. The second kind are data on observed fish catches and fishing efforts by species, fleets and fishing grounds which are used to tune the model.

### *2.1 Number of Survivors*

The number of survivors of a cohort belonging to a stock is designated, N. With indices, the number of survivors reads :

N[s,t,ar,a] = Number of survivors of stock (species) s, at the beginning of time period t, in area ar, belonging to age group a.

Let NoS, NoT and NoA designate the numbers of species, time periods and areas, respectively : s = 1,2,..,NoS ; t = 1,2,..,NoT ; ar = 1,2,..,NoA. The number of survivors in area ar at the beginning of time period t is :

N[s,t,ar,a] = (The number at the beginning of previous time period in area ar, i.e. N[s,t-1,ar,a-1])
- (The number which died from fishing during period t-1)
- (The number which died from natural causes during period t-1)
- (The number which migrated out of area ar)
+ (The number which migrated into area ar)

### *2.2 The time step and the age group concepts of BEAM 4*

The smallest time step considered in BEAM 4 is called the "basic time step", and is designated "dt". BEAM 4 allows for the following options for the basic time step, dt : 1, 2, 3, 4, 6 or 12 months. The length of an age group may take the same values as the basic time step (but must be larger than or equal to the basic time step). The length of the age group of species s is designated DT[s].

The life span is, for the sake of simplification, assumed to be equal to the length of 12 time periods, or some multiplicity of 12 (that is 24, 36, 48,...). In the following it is assumed, for simplicity, that there are 12 age groups of each species.

*2.3 Recruitment*

"Recruitment" refers to the number of juvenile animals which enter the stock, i.e., the "incoming cohorts". That is, the numbers in the first age group. They are also called the "0-group" and assigned the index zero. N[s,t,ar,0], is the number of recruits to stock s in area ar at the beginning of time period t, t = 1,2,...,NoT. As an approximation to reality, the recruitment in BEAM 4 takes place at the beginning of the time period.

The number of recruitment batches per year is determined by the time step applied to model the different stocks. If a stock has a time step of 3 months it can have from 1 to 4 recruitment batches (or incoming cohort parts) per year. If a time step of one year is applied only one recruitment season per year can be considered. Thus, for short-lived species like penaeid shrimps, BEAM 4 can account for seasonality in recruitment, whereas seasonality is ignored for species with a life span of 12 (or more) years. The recruitment may occur in any sea area.

In BEAM 4, the number of recruits is an input parameter. As the number of specimens which can be caught by the fishery is proportional to the number of recruits, the simulation results are highly sensitive to this parameter. Many attempts have been made to find the relationship between the size of the parent stock (the so-called spawning stock biomass) and the subsequent recruitment. However, none of them appears to have much prediction power, and consequently, no stock and recruitment relationship is modelled in BEAM 4.

*2.4 The growth of a single animal*

Mean body length of species s as a function of the age group a, is given by the von Bertalanffy growth model (von Bertalanffy, 1934) :

$$LGT[s,a] = L_{\infty}[s]*\{1 - \exp( -K[s]*\{DT[s]*(a + 0.5)- T_0 [s]\})\}$$

where $L_{\infty}[s]$ is the asymptotic body length of species s, K[s] (per year) is the curvature parameter of species s, $T_0[s]$ (year) is the initial condition parameter of species s, DT[s] is the length of an age group (years) of species s. These four variables are input parameters.

The body weight is given by the equation :

$$W[s,a] = CF[s] * LGT[s,a]^{CE[s]}$$

where CF[s] is the condition factor and CE[s] is the condition exponent for species s ; these are input parameters to BEAM 4. The asymptotic body weight, $W_{\infty}$, of species s is derived from $L_{\infty}$ using the above equation.

*2.5 The area-based exponential decay model*

BEAM 4 assumes the sea area to be partitioned into a number of sub-areas (or fishing grounds). To begin with, however, the partitioning of the sea into areas is ignored and only the total number of the entire stock in all areas combined is considered :

$$N[s, t, . , a] = \sum_{ar = 1}^{NoA} N[s, t, ar, a]$$

i.e. the number of species, s, of age group a at the beginning of time period t. Note that the dot "." is used to indicate summation over an index.

The death process of BEAM 4 is modelled by the usual exponential decay model (see for example Sparre *et al.*, 1989) :

$$N[s,t+1,.,a+1] = N[s,t,.,a] * \exp( - Z_{stock}[s,t,a]*DT[s]), \text{ for } a = 0,1,2,...,10,$$

and where $Z_{stock}[s,t,a]$ (per year) is the total instantaneous mortality coefficient for the entire stock of species s.

The oldest age group, a = $A_{max}$ -1 is a plus-group, so after age $A_{max}$ - 1 the animals stay in age group $A_{max}$ - 1. For age group $A_{max}$ - 1 the model takes the form, in the case $A_{max}$ = 12 :

$$N[s,t+1,.,11] = N[s,t,.,10] * \exp( - Z_{stock}[s,t,10]*DT[s]) + N[s,t,.,11] * \exp( - Z_{stock}[s,t,11]*DT[s])$$

The total mortality is composed of fishing mortality, $F_{stock}$, and natural mortality, M, referring to the entire stock :

$$Z_{stock}[s,t,a] = F_{stock}[s,t,a] + M[s,a]$$

$F_{stock}$ is composed of the fishing mortalities created by each fishing fleet in each area. The non-aggregated fishing mortality, F[s,t,ar,fl,a] has five indices, where fl, is index of fleet and ar is index of area. $F_{stock}$ is related to the non-aggregated F in a rather complex way. As $Z_{stock}$ is composed of M and F, these features are similar for $F_{stock}$ and $Z_{stock}$.

The model of the death process for a single area is similar to that of the entire stock (as an example is used $A_{max}$ = 12) :

$$N[s,t+1,ar,a+1] = N[s,t,ar,a] * \exp( - Z[s,t,ar,a]*DT[s]), \text{ for } a = 0,1,2,...,10$$

$$N[s,t+1,ar,11] = N[s,t,ar,10] * \exp( - Z[s,t,ar,10]*DT[s]) + N[s,t,ar,11] * \exp( - Z[s,t,ar,11]*DT[s])$$

Here Z is the total mortality of the part of the stock which is in area ar. Z depends on the number of fishing boats which fish in area ar in addition to M. It should be noticed that the relationship between $Z_{stock}[s,t,a]$ and Z[s,t,ar,a] is not as simple as the relationship between N[s,t,.,a] and N[s,t,ar,a]. $Z_{stock}[s,t,a]$ can be derived from Z[a,t,ar,a] and the Ns :

$$Z_{stock}[s,\ t,\ a]*DT[s] = -\ln\left(\sum_{ar=1}^{NoA} \frac{\exp(-Z[s,\ t,\ ar,\ a]*DT[s])*N[s,\ t,\ ar,\ a]}{N[s,\ t,\ .\ ,\ a]}\right)$$

where "ln" stands for "natural logarithm".

This equation follows from the fact that total mortality for the entire stock is defined by the inverse exponential decay equation :

$$Z_{stock}[s,t,a] * DT[s] = - \ln( N[s,t+1,.,a+1]/N[s,t,.,a] )$$

The sum over areas gives number of survivors at the end of the period (if migration is ignored) :

$$N[s,\ t+1,\ .\ ,\ a+1] = \sum_{ar=1}^{NoA} \exp(-Z[s,\ t,\ ar,\ a]*DT[s])*N[s,\ t,\ ar,\ a]$$

The mean number of survivors in area ar during time period t is defined :

$$\overline{N}[s,t,ar,a] = (N[s,t,ar,a] - N[s,t+1,ar,a+1]) / Z[s,t,ar,a]*DT[s]$$

For an explanation of this formula, see for example, Sparre *etal.* (1989).

The mean number of survivors in the stock is calculated similarly :

$$\overline{N}[s,t,.,a] = (N[s,t,.,a] - N[s,t+1,.,a+1]) / Z_{stock}[s,t,a]*DT[s]$$

Notice that if the Zs vary between areas then :

$$\bar{N}[s, t, . , a] \text{ is different from } \sum_{ar=1}^{NoA} \bar{N}[s, t, ar, a]$$

Only if the Zs are equal in all areas will there be equality.

In BEAM 4, natural mortality, M[s,a] (per year), is a function of species s, and age group, a. Natural mortality is input to BEAM 4. Often, M is assumed to remain constant from age group to age group. The reason for this assumption is not that it represents a good approximation to reality. The reason rather reflects the lack of knowledge about M. The available knowledge suggests that M is a function of age indicating that there is in fact a very pronounced size dependency. One obvious explanation is that small specimens are more exposed to predation mortality than large specimens. BEAM 4, however, does not attempt to model natural mortality, or predation mortality along the lines of the so-called Multi-Species Virtual Population models and their prediction counterparts (see for example, Sparre, 1991).

BEAM 4 contains an option for a simple age dependent model of M, which reflects some of the findings from multi-species VPA :

$$M[s,a] = M_A[s] + 1/(a + M_B[s]),$$

where $M_A[s]$ and $M_B[s]$ are parameters. This is a reformulation of the model of Caddy (1991).

*2.6 Gear selectivity*

The number of fleets is designated NoF and fl is the index of fleet. E[fl,t,ar] denotes the effort of fleet fl exerted in area ar during basic time period t. Gear selectivity is modelled by the mathematical function :

$$f(x) = \frac{1}{1 + \exp(a - bx)}$$

where a and b are positive constants. It approaches zero when x takes high negative values and it approaches 1.0 when x takes high positive values. This mathematical function is called the "logistic" curve. It has been used to model the probability that a fish is retained by the meshes of a gear (notably codends of trawls) as a function of its body length. The probability that a fish if it enters the gear multiplied by the probability that the fish is available to the fishery (the so-called resultant selection curve) is in BEAM 4 given by the logistic function, the "selection ogive" (see for example Kimura, 1977) :

$$SO[s, fl, ar, a] = \frac{1}{1 + \exp(SP1[fl, ar, s] + SP2[fl, ar, s] * LGT[s, a])}, \quad \text{where}$$

$$SP1[fl, ar, s] = \frac{\ln(3) * L_{50\%}[fl, ar, s]}{L_{75\%}[fl, ar, s] - L_{50\%}[fl, ar, s]}, \quad \text{and}$$

$$SP2[fl, ar, s] = - SP1[fl, ar, s] / L_{50\%}[fl,ar,s]$$

These two parameters are derived from the input parameters $L_{50\%}[fl,ar,s]$ and $L_{75\%}[fl,ar,s]$ : 50 % and 75 % availability/retention length for species s in area ar caught by fleet fl.

### *2.7 Effort and fishing mortality*

The fishing mortality of fleet fl exerted in area ar on age group a of species s during time period t is designated F[s,t,ar,fl,a]. F is assumed to be proportional to the effort, E[fl,t,ar], and the factor of proportionality is the "catchability coefficient", Q[fl,s,ar].

BEAM 4 can use different measures for the effort of different fleets. Within a fleet, it is assumed that boats are identical. If a fleet contains a number of different boat types a unit such as "boat day" cannot be used if the boat types have different fishing power. Effort may then be expressed in "standard boat units" if estimates of fishing power are available. BEAM 4 allows for area-specific allocation of fishing effort in each time period considered.

The model for fishing mortality for species s, age group a, during time period t, caused by fleet fl in area ar is :

$$F[s,fl,t,ar,a] = Q[fl,s,ar] * E[fl,t,ar] * SO[s,fl,ar,a]$$

The tacit assumption behind this model is that the fish and the fishing vessels, irrespective of their numbers, are evenly distributed within the area. The area (the fishing ground) is assumed to be homogenous in all respects.

The total fishing mortality in area ar by all fleets is :

$$F[s, . , t, ar, a] = \sum_{fl=1}^{NoF} F[s, fl, t, ar, a]$$

Within an area, simple sums of fishing mortalities can be made, because of the homogeneity assumption. However, the overall fishing mortality by all fleets for the entire stock is not defined as a simple sum, but has to be calculated as a weighted sum as was the case for $Z_{stock}$ :

$$F_{stock}[s, t, a] = \sum_{ar=1}^{NoA} F[s, . , t, ar, a] * \bar{N}[s, t, ar, a] / \bar{N}[s, t, . , a]$$

The total mortality used to calculate number of survivors is the area-based mortality, the mortality for the part of the stock which is in area ar :

$$Z[s,t,ar,a] = M[s,a] + F[s,.,t,ar,a]$$

Fish caught may be either landed or discarded (returned to the sea). BEAM 4 assumes that all discarded fish die. Therefore, the fishing mortality can be separated into two components :

$$F[s,fl,t,ar,a] = F_{discards}[s,fl,t,ar,a] + F_{landings}[s,fl,t,ar,a]$$

### *2.8 Migration*

Inclusion of migration in age-based fish stock assessment has been suggested for many years, but there are few examples of practical use of the methodology. For a theoretical discussion of migration in connection with age based fish stock assessment the reader is referred to Quinn II *etal* (1990). These authors also discuss the estimation of migration parameters. In principle their model is the approach used in BEAM 4.

The types of migrations accounted for in BEAM 4 are only horizontal movements, i.e., along the coast, inshore and offshore or even between rivers/lagoons and marine areas.

BEAM 4 can deal with any number of areas (fishing grounds) and any migration route between the areas (within the limits of the memory capacity of the micro-computer). Migration is modelled in a time discrete manner and takes place at the end of each (species dependent) time period. The process of migration takes zero time. During a time period the fish/shrimps are assumed to be homogeneously distributed within the area (fishing grounds).

The "Migration Coefficient", MC, from area A to area B is defined as the fraction of the animals in area A which moves to area B. In this definition, migration includes the "movement" from area A to area A, i.e., the event that the animal does not migrate. The migration coefficient depends on (or has the indices) : ar (starting area) ; j (destination area) ; s (species) and a (age group). The sum of migration coefficients over destination areas always becomes 1.0, as the starting area is also considered a destination area :

$$C[s, fl, t, . , a] = \sum_{ar=1}^{NoA} F[s, fl, t, ar, a]* DT[s]* \bar{N}[s, t, ar, a]$$

*2.9 Number caught and yield*

The number caught of species s, age group a in area ar during time period t by fleet fl is given by the Baranov model (Baranov, 1918) used for only that part of the stock which is in area ar :

$$C[s,fl,t,ar,a] = F[s,fl,t,ar,a] * DT[s] * \bar{N}[s,t,ar,a]$$

The total catch in all areas by fleet fl is the sum :

$$C[s, fl, t, . , a] = \sum_{ar=1}^{NoA} F[s, fl, t, ar, a]* DT[s]* \bar{N}[s, t, ar, a]$$

The total catch from the stock by all fleets in all areas is

$$C[s, . , t, . , a] = F_{stock}[s, t, a]* DT[s]* \bar{N}[s, t, . , a]$$
$$= \sum_{fl=1}^{NoF} C[s, fl, t, . , a]$$

This is in accordance with the definition of overall fishing mortality by all fleets for the entire stock, $F_{stock}$.

The catch in weight, the yield, for fleet fl in area ar is :

$$Y[s,fl,t,ar,a] = C[s,fl,t,ar,a] * W[s,a]$$

The yield of species s age group a of fleet fl in all areas is :

$$Y[s, fl, t, . , a] = C[s, fl, t, . , a]* W[s, a] = \sum_{ar=1}^{NoA} Y[s, fl, t, ar, a]$$

and the total yield caught by fleet fl during the year becomes

$$Y[s, fl, . , . , a] = \sum_{t=1}^{12} Y[s, fl, t, . , a]$$

The last two equations form the basis for the calculation of the value of the yield which in turn produces the input for the economic analysis of the fishery.

The total yield of all age groups caught by all fleets during one year becomes

$$Y[s, ., ., ., ., ., .] = \sum_{fl=1}^{NoF} \sum_{a=0}^{11} Y[s, fl, t, ., a]$$

The yield of species s, caught by fleet fl in area ar during time period t summed over age groups is :

$$Y[s, fl, t, ar, .] = \sum_{a=0}^{11} C[s, fl, t, ar, a] * W[s, a]$$

These quantities will be used for comparisons of observed yields to simulated yields (predicted by the computer program).

### *2.10 Commercial size categories*

For many species, unit prices differ with the size of the animals whereby small fish or shrimps fetch lower prices in the market than larger ones. Prices are often quoted by commercial categories that have been defined in the market according to the specific nature of the product (species). For example, in shrimp fisheries, commercial size categories (counts) are defined as number of tails or animals per pound or kg.

As the biological model of BEAM 4 works on the basis of age groups, there is the need to convert commercial categories (or sizes) into the corresponding age groups and vice versa. The computer program BEAM 4 has a built-in facility to do this conversion.

### *2.11 Prices and value of yield*

For computational reasons, the value of the yield is calculated within the biological/technical part of BEAM IV. The value of the yield, Y[s,fl,t,.,a], of species s, age group a, taken by fleet fl during time period t, is expressed in terms of "ex-vessel value" and "wholesale value". The ex-vessel value is the gross revenue of the harvesting sector from selling the yield to the processing sector. The wholesale value is the gross revenue of the processing sector from sale of the processed yield.

The values are based on the prices :

PE[s,fl,a] : Ex-vessel price per weight unit of species s, age group a, caught by fleet fl

PW[s,fl,a] : Wholesale price per weight unit of species s, age group a, caught by fleet fl

Different species and sizes of fish generally fetch different prices in the market. In addition, fish of the same species and size may realize different prices because of differences in product qualities. The latter is often related to the handling and storage facilities on board of the vessels. In BEAM 4, price differentials may be due to species, size and/or technical characteristics of the fleets.

Wholesale prices are those received by the processing plant when selling the processed fish/shrimps to either the domestic or export market. Fish/shrimps of the same sizes and species are assumed to realize the same wholesale price in either the domestic or export market. However, fish/shrimps sold for export will earn foreign exchange.

The BEAM 4 model operates with constant fish prices because originally it was designed for shrimp fisheries where there are many suppliers and buyers in the international market and where no single shrimp fishery would have a significant impact on prices.

Combining all age groups gives the total ex-vessel value of species s caught by fleet fl during time period t :

$$VEF[s, fl, t] = \sum_{a=0}^{11} Y[s, fl, t, . , a]* PE[s, fl, a]$$

and the corresponding wholesale value becomes :

$$VWF[s, fl, t] = \sum_{a=0}^{11} Y[s, fl, t, . , a]* PW[s, fl, a]$$

In case discarding takes place, the discarded amounts are subtracted before the sum of products are calculated.

Summed over species and time periods the total value of the yield caught by fleet fl, VWF[.,fl,.,], is obtained. This, together with the effort figures are inputs into the economic analysis of fleet fl.

### *2.12 The links between the biological/technical sub-model and the economic sub-model*

For the economic analysis of each fleet and the entire harvesting sector, the following data are produced by the biological/technical sub-model : (i) annual landings ; (ii) ex-vessel value of the annual landings ; and (iii) effort per year and number of boats. To avoid any misunderstandings, the term "landings" has been introduced to account for the fact that the yield also includes discards. Landings are, therefore, defined as the yield minus discards.

For the economic analysis of the processing sector, the following data are produced by the biological/technical sub-model for each plant and for the entire processing sector : (i) annual landings delivered by each fleet ; (ii) ex-vessel and wholesale values of the annual landings delivered by each fleet ; and (iii) the share of the annual landings sold in the export and in the local markets.

## 3. THE ECONOMIC MODEL

The economic model of BEAM 4 calculates a range of economic performance criteria. Its principal input variables are cost data for the fishing fleets and processing plants plus aggregated results from the biological/technical model as described above.

### *3.1 Costs of fish harvesting*

In BEAM 4, there are three different types of harvesting costs, namely

(i) costs depending on fishing effort ;
(ii) costs depending on the number of fishing vessels ; and
(iii) costs depending on the value of the landings (i.e., ex-vessel value).

The first category of costs, also referred to as variable costs, is assumed to be linearly related to fishing effort and comprises fuel and lubrication, repairs and maintenance, ice, habour/landing fees, crew wages (independent of the ex-vessel value of the landings), and miscellanous costs. For a particular fleet the total of this cost category is calculated by multiplying the total number of units of effort expended per year with the total costs per unit of effort.

The costs depending on the number of boats refer to those costs which arise even though the vessels may not go out for fishing. They are also referred to as "fixed costs" and comprise depreciation of hull, engine and gear, insurance, interest, overheads and fixed licence fees. In BEAM 4, these costs are given on an annual basis. The total costs of this category for a certain fleet is given by multiplying the number of boats with the average total fixed costs per boat per year.

The third category of harvesting costs in BEAM 4 are those costs which depend on the ex-vessel value of the landings ; they comprise two elements, namely (i) crew remuneration and (ii) fish auctioning/marketing fees.

The common system of labour remuneration in fishing is different from that of other occupations. In fishing, crews are often paid a share of the value of the landings. Usually, certain variable or effort dependent costs such as fuel or repair and maintenance costs, etc., are deducted from the ex-vessel value prior to sharing the proceeds between the crew and the owner of the fishing vessel. In BEAM 4, the user can specify which costs are deducted before sharing.

Auctioning fees are determined as a share of the ex-vessel value of the landings (without prior deduction of costs).

The total harvesting costs of a particular fleet are obtained as the sum over all three cost categories. Obviously, total harvesting costs will not increase linearly with fishing effort because some costs depend on the value of the landings produced by that effort which changes with the intensity of exploiting the fishery resource. The total costs of the entire harvesting sector are given as sum over the costs of each fleet.

### *3.2 Processing costs*

The BEAM 4 model is constructed in such a way that all fish caught is also processed, although it may be processed in different plants and in different ways, i.e., drying, freezing or canning, etc., (including discarding in a pseudo processing plant). Different processing techniques (and plants) are reflected by differences in processing costs. The case of no processing can be modelled by putting all processing cost items to zero. The user is free to determine for each fleet and for each age class or commercial size category of each species the type of desired processing.

Processing cost items include power and water, packaging, wages, depreciation, insurance, interest, etc. They also include the ex-vessel value of the landings. Costs are given per ton of raw material processed. This implies that processing costs are independent of the intensity of utilization as processing capacities are automatically adjusted to the amount of fish harvested by the fishing fleet(s).

### *3.3 Foreign exchange costs*

Each of the cost elements and items presented above may entirely or partially be incurred in hard currency. Fuel, for example, needs often to be imported and paid for in foreign exchange. Similarly, equipment such as engines, hulls, echosounders, etc., frequently have to be imported.

In joint-venture fisheries, crew remuneration may occur in hard currency because the vessels may be manned by foreign fishermen. Further, interest and insurance payments may need to be settled in foreign exchange. In these cases, the respective foreign exchange costs are entered in a separate category in the BEAM 4 model that is referred to as "transfers abroad". Profits can also be transferred.

### *3.4 Opportunity costs*

The opportunity cost concept is used to better reflect the costs to the economy of using a production input in one activity rather than in another one. In fisheries, remuneration of labour is often based on a sharing system. It is unlikely that the system results in a "price" of labour that is equal to its opportunity cost. Therefore, BEAM 4 allows the user to adjust crew remuneration so as to reflect better the cost to the economy of using labour in fishing rather than in its next best alternative occupation.

The other important production factor that may need to be adjusted through opportunity cost is capital. In the definition of Gittinger (1982 :490) it is "The opportunity cost of using investment resources in a project rather than in their next best alternative use, usually expressed in the form of an interest rate." In BEAM 4, two kinds of opportunity cost of capital are considered. One type is as described above by Gittinger.

The second type of opportunity cost of capital refers to depreciation of capital equipment. Once a fishery has expanded to the point where economic and possibly biological over-fishing occurs, the fleet size may be reduced and vessels retired.

If there is no other alternative use for the vessels in other fisheries or in other activities such as transportation, the costs of using them in the fishery are low or zero. Adjustments to costs of depreciation may also be called for if the initial capital investment was subsidized (or taxed) by the government.

### *3.5 Taxes and subsidies*

Taxes are payments from private individuals or companies to the government. Subsidies are negative taxes, i.e., tax rebates or payments from government to private individuals or companies. Therefore, both taxes and subsidies are transfers of income rather than costs to the economy.

In BEAM 4, taxes and subsidies are considered explicitly only in the case of fuel and lubricants (harvesting), power and water (processing) and of repair and maintenance (harvesting and processing). Taxes will increase the costs of these inputs to the entrepreneur while subsidies will reduce them. In both cases, the real cost to the economy of using these inputs may be distorted.

### *3.6 Economic performance criteria*

BEAM 4 uses a number of different criteria to evaluate (or predict) the economic performance of an unregulated fishery or of a fishery under a certain management regime. These include resource rent, profit, profitability, value added and net foreign exchange earnings.

Resource rent is calculated by adjusting private profit of the harvesting sector with the relevant opportunity costs, as discussed above, and by adjusting for taxes and subsidies. Private profit is defined as the difference between ex-vessel value of the catch and total harvesting costs. Resource rent is only considered for the harvesting sector.

In the short and medium-term, maximizing resource rent may result in socially undesirable effects including increased unemployment and undesirable income distribution. BEAM 4 allows to assess the income distribution and employment effects of alternative management regimes.

Income comprises of several components including (i) wages and salaries to crew, processing workers, shore staff and administrative personnel ; (ii) interest payments on capital ; (iii) profits to private investors ; (iv) taxes net of subsidies, and licence fees accruing to the government treasury. The summation over all these income elements is called the net value added. Adding depreciation of equipment gives the gross value added.

Not all income generated in a fishery may accrue to the national economy because some of it may be transferred abroad. Except for taxes and licence fees, all other elements of income may partially or entirely be transferred to other economies. In BEAM 4, the user can give the income shares (percentages) that are being transferred. The sum of the incomes that stay in the country are referred to as national net value added.

For many developing countries, foreign exchange earnings are of particular importance for economic growth because they allow the importation of essential production inputs. The BEAM 4 model allows the assessment of foreign exchange costs and earnings, so that the net contribution of the fishery can be assessed.

Employment is an important criterion for assessing the relative benefits of alternative management regimes. In BEAM 4, employment is measured in two ways : (i) numbers of people and (ii) numbers of person-years.

The integrated analysis of BEAM 4 simply consists of adding the various economic performance criteria for the harvesting and processing sectors (except for the resource rent). It is of great importance in the case of those fisheries where substantial onshore processing activities take place.

# Gérez Vos Pêcheries *

**Claude de Verdelhan**

IFREMER, 7, place du Séminaire - BP 7 - L'houmeau - 17137 Nieul Sur Mer, France

RÉSUMÉ

*GEREZ VOS PECHERIES est un logiciel à vocation pédagogique permettant une compréhension rapide des mécanismes de base qui régissent la gestion des ressources halieutiques. Ce modèle basé sur les techniques d'analyses de cohortes sur compositions en âges des captures permet de voir sous une forme graphique claire :*

- *l'évolution des résultats globaux (production, chiffre d'affaires, bénéfices ou pertes) d'année en année ; les mêmes résultats par "métier" ;*
- *les évolutions dans le temps, par espèce, des compositions en nombre d'individus ou en poids par classe d'âge, des stocks et des captures ;*
- *les évolutions des biomasses totales et des biomasses fécondes.*

*A chaque instant, l'opérateur peut interrompre le processus de calcul afin d'imposer une modification des conditions d'exploitation (par métier : nombre de navires, nombre de jours de mer, maillage). Ceci permet donc d'expérimenter les conséquences à court terme et à long terme de ces changements. Une option permet d'avoir un recrutement aléatoire (loi log-normale).*

*Enfin un bilan systématique après 60 ans permet d'organiser des concours et de donner à ce logiciel un caractère ludique qui en facilite l'usage pédagogique. Un utilisateur connaissant bien une pêcherie particulière pourra créer un jeu de données spécifiques.*

## 1. LES RAISONS DU DÉVELOPPEMENT DE CE LOGICIEL PAR L'IFREMER

La lecture des journaux spécialisés du monde de la pêche montre que les mécanismes de base qui régissent l'évolution des ressources halieutiques soumises à une exploitation sont souvent mal compris. Il en résulte des difficultés

* Conditions de vente et d'utilisation

*"GÉREZ VOS PÊCHERIES"* est vendu ; il suffit de le commander à l'IFREMER, Laboratoire RH, place du Séminaire, BP n° 7, 17137 Nieul Sur Mer - France, en précisant le format de la disquette.

Son prix est de 500 FF. La licence d'utilisation donne droit d'installer le logiciel sur tous les ordinateurs du licencié (un seul site) afin de permettre son utilisation par des groupes disposant de plusieurs ordinateurs. Pour un bon fonctionnement, il faut un PC sous MSDOS, une carte graphique couleur EGA, ou VGA ou SVGA et une souris (non indispensable mais très utile).

Il existe une version en anglais mais la notice et l'aide en ligne ne sont pas traduites pour l'instant.

considérables dans l'élaboration des règles de gestion de ces ressources et plus encore dans leur mise en oeuvre. C'est pourquoi l'IFREMER a considéré qu'il était aussi de sa mission de mettre au point un logiciel pédagogique afin que toutes les personnes concernées par ce secteur d'activité puissent comprendre quels sont les facteurs principaux qui déterminent l'évolution économique d'une pêcherie.

## 2. ORIGINE DU LOGICIEL

Ce logiciel est déjà la troisième version d'une idée qui remonte à 1985.

La version 1, écrite en Basic par Claude de Verdelhan en 1988, ne permettait de simuler que l'exploitation d'une espèce par un engin. Cette version a été commercialisée par le CRDP de Poitiers (Centre Régional de Documentation Pédagogique).

La version 2 a été écrite par Olivier Le Pape dans le cadre de son diplôme d'Agronomie Approfondie en 1991 (Ecole Nationale Supérieure d'Agronomie de Rennes ENSAR). Elle permet des simulations plus complexes multi-métiers et multi-espèces pouvant utiliser des jeux de données très variés. Elle a été écrite en TURBO PASCAL (BORLAND) et bénéficie des avantages de la programmation orientée objet.

La version 3 reprend tous les acquis de la version 2 et l'enrichit d'une aide informatique, de graphiques supplémentaires, d'améliorations dans la présentation des graphiques (visionneuses graphiques et visionneuses graphiques animées), et dans les menus. Elle introduit aussi une option permettant de calculer le rendement actuariel brut d'une décision d'aménagement (réduction du nombre de jours de mer ou augmentation du maillage).

## 3. OBJECTIFS DU LOGICIEL

*"GÉREZ VOS PÊCHERIES"* est un logiciel qui permet de simuler une pêcherie composée d'un ou plusieurs métiers (type de navires et d'engins) exploitant une ressource composée d'une ou plusieurs espèces. Les résultats de cette simulation sont un graphique montrant, année par année, les résultats économiques de la pêcherie (chiffre d'affaires, bénéfices, coût).

A chaque instant le déroulement de la simulation peut être interrompu pour modifier les conditions d'exploitation en faisant varier :

(i) le nombre de navires,

(ii) le nombre de jours de mer par navire et par an,

(iii) le maillage utilisé,

par l'un ou l'autre des métiers.

Il est aussi possible de suspendre le déroulement de la simulation pour accéder très facilement à de très nombreux graphiques donnant des résultats détaillés pour chaque métier ou pour chaque espèce ainsi que de nombreux autres graphiques permettant de comprendre les raisons de ces évolutions. Parmi ceux-ci, on retiendra les graphiques donnant l'évolution des biomasses et biomasses fécondes par espèce et surtout les graphiques animés permettant de visualiser les structures en âge des populations et des captures (nombre d'individus par classe d'âge ou biomasse par classe d'âge) d'année en année, et de les comparer avec les structures des populations vierges. Ces graphiques sont animés car ils sont une succession d'images apparaissant automatiquement (une par année) et permettant de voir l'évolution des structures de la première année de la simulation à la dernière. De plus, l'usage des touches avec des flèches permet de revenir en arrière pour "rejouer" des périodes déterminantes (année de l'augmentation des maillages). Cette représentation permet de très bien voir la conséquence d'une augmentation du maillage ou d'une réduction d'effort de pêche.

*"GÉREZ VOS PÊCHERIES"* n'est pas un logiciel de plus pour les groupes de travail et les réunions d'experts. Ce n'est pas non plus un programme d'analyse de population ou de statistiques économiques. Son ambition est d'être un outil

pédagogique pour assurer une formation de base aux professionnels de la mer ou même à un public plus général (élèves des lycées..) et un moyen très agréable et efficace pour présenter des résultats d'une étude sur une pêcherie particulière, même complexe.

L'utilisation à des fins pédagogiques fait l'objet d'une publication dans le "EC Fischeries Cooperation - Bulletin - CE Coopération Pêche" de Septembre 1993.

## 4. LES BASES DU MODÈLE

Ayant été conçu par des biologistes et des halieutes, le modèle de *"GÉREZ VOS PÊCHERIES"* est très développé au niveau biologique et beaucoup plus simple au niveau économique.

### *4.1 Modèle biologique*

Les données de base du modèle sont lues dans un fichier. Pour chaque espèce elles consistent en :

- pour chaque âge la longueur, le poids et la mortalité naturelle,
- le recrutement moyen en nombre d'individus,
- le multiplicateur, diviseur maximum du recrutement moyen qui permet de limiter les valeurs maximales et minimales en cas de recrutement aléatoire (loi log-normale),
- le niveau de la biomasse (exprimé en pourcentage de la biomasse féconde moyenne du stock vierge) en dessous duquel il y a une relation stock-recrutement,
- l'écart-type de la loi log-normale de recrutement aléatoire,
- l'âge de maturité sexuelle,
- pour chaque métier et pour chaque âge, un coefficient de capturabilité,
- pour chaque métier, les coefficients de sélectivité $\alpha$ et $\beta$

$$\alpha = L50/D \qquad \text{et} \qquad \beta = \frac{L75 - L25}{L50}$$

ou D est le maillage exprimé en mm et L25, L50 et L75 sont les longueurs correspondant au taux de retenue de 25, 50 ou 75 %) qui permettent de calculer le taux de retenue pour chaque âge en fonction de la longueur correspondante du poisson.

Les équations de base sont tout-à-fait classiques :

– l'effectif $N_{i,\,j,\,k}$ de la cohorte d'âge j, de l'espèce i, au début de l'année k est calculé à partir de $N_{i,\,j-1,\,k-1}$ en fonction de l'équation de survie :

$$N_{i,j,k} = N_{i,j-1,k-1}\, e^{-\left(\sum_m F_{i,j-1,k-1,m} + M_{i,j-1}\right)}$$

avec $N_{i,1,k} = R_{i,k}$ (recrutement)

Le recrutement $R_{i,k}$ ne dépend pas du niveau de la biomasse féconde si celle-ci dépasse un niveau minimum (exprimé en % de la biomasse féconde d'un stock vierge). Il peut fluctuer par rapport au recrutement moyen en fonction d'une loi de distribution log-normale si l'option recrutement déterministe n'a pas été choisie.

$F_{i,j,k,m}$ est égal au coefficient de capturabilité multiplié par le taux de retenue (sélectivité), par le nombre de navires et par le nombre de jours de mer, pour chaque métier, âge, espèce, année.

Le changement des conditions d'exploitation modifie les valeurs de $F_{i,j,k,m}$ et par conséquent les taux de survie. Au contraire, $F_{i,j,k,m}$ ne dépend pas de l'abondance du stock. Ceci veut dire que ce modèle biologique est bien adapté à des espèces dont la capturabilité ne dépend pas de l'abondance. Cette condition est assez bien respectée pour les espèces démersales mais irréaliste pour les espèces pélagiques dont la capturabilité augmente souvent quand l'abondance diminue en raison de l'effet de bancs.

- Les captures en nombre réalisées par le métier m sur cette espèce au cours de l'année k se calculent :

$$C_{i,j,k,m} = \frac{F_{i,j,k,m}}{\left(\sum_m F_{i,j,k,m} + M_{i,j}\right)} N_{i,j,k}\left(1 - e^{-\left(\sum_m F_{i,j,k,m} + M_{i,j}\right)}\right)$$

(Laurec et Le Guen, 1981)
(Mesnil, 1988)

- On en déduit les captures en tonnage :

$Y_{i,j,k,m} = C_{i,j,k,m} P_{i,j}$ où $P_{i,j}$ est le poids moyen d'un individu de l'espèce i et d'âge j.

*4.2 Modèle économique*

Le modèle économique est alimenté par des données, pour chaque métier, lues dans le même fichier :

- coût fixe annuel d'un navire (amortissement, assurance, salaires minimums garantis),
- coûts d'opération par jour de mer (combustibles engins, suppléments de salaires),
- pour chaque espèce et par âge, prix au kilo du poisson pêché $PK_{i,j,m}$ (si le poisson est rejeté, son prix au kg est nul, si la moitié des poissons d'une classe d'âge est vendu en criée à 20 F au kg et que l'autre moitié est rejetée, le prix au kg du poisson pêché n'est que de 10 F).
- nombre de marins embarqués par navire et par an,
- taux de réduction annuel de la masse des chômeurs par transfert vers d'autres activités.

*4.3 Liaison des modèles biologiques et économiques*

La liaison entre le modèle biologique et le modèle économique est donc très simple. La valeur des captures $V_{i,j,k,m}$ est calculée de la manière suivante :

$$V_{i,j,k,m} = Y^*_{i,j,k,m} PK_{i,j,m}$$

Le coût annuel des opérations $D_{k,m}$ pour un métier est donc :

$$D_{k,m} = NbN_{k,m}(CF_m + NbJM_{k,m} \times CP_m) \quad \text{où}$$

$NbN_{k,m}$ est le nombre de navires du métier m pour l'année k

$NbJM_{k,m}$ le nombre de jours de mer par navire des métiers m pour l'année k.

$CF_m$ le coût annuel par navire pour le métier m

$CP_m$ le coût journalier par navire pour le métier m

Ainsi, ayant le coût des opérations et le chiffre d'affaires, il est possible de calculer les bénéfices et/ou pertes annuelles, globalement et par métier.

## 5. L'OPTION "ETUDES"

Tous ceux qui tentent d'expliquer qu'une augmentation de maillage ou une réduction d'effort de pêche présente un intérêt à long terme se trouvent confrontés au problème des pertes à court terme. Comment expliquer que le bénéfice attendu à long terme est à la hauteur des pertes à subir à court terme. C'est pour pouvoir chiffrer l'intérêt de ce type d'arbitrage qu'a été introduite l'option "Etudes". Elle permet de calculer le rendement actuariel brut d'une augmentation du maillage et/ou d'une réduction de l'effort de pêche et ainsi d'exprimer d'une façon synthétique l'intérêt d'une telle option. Deux types de résultats sont proposés :

(i) les résultats "Biologiques" ne prennent en compte que les réductions puis les augmentations à long terme du chiffre d'affaires. Ce qui revient à ne prendre en compte que les valeurs des captures perdues puis gagnées : ils correspondent donc au rendement de l'épargne biologique (réduction des captures) qui a été faite. La biomasse épargnée et les captures supplémentaires qui en résultent plus tard sont valorisées en tenant compte du prix de débarquement ;

(ii) les résultats "Economiques" prennent en compte l'évolution des bénéfices et/ou les pertes de la flottille. C'est-à-dire qu'ils ne s'intéressent pas seulement aux captures mais aussi aux coûts d'exploitation. Il faut cependant interpréter avec prudence ces résultats, en particulier dans le cas d'une réduction du nombre de navires de la flottille. Une diminution de 20 % du nombre de navires entraîne une réduction des coûts d'exploitation du même ordre pour la flottille, ce qui est pris en compte par le logiciel, mais en même temps, il y aura des charges exceptionnelles de restructuration (primes de licenciement pour les marins, pertes de valeur des navires, etc...) et des "recettes" correspondantes (ventes des navires à d'autres flottilles, primes et indemnités diverses) qui n'interviennent pas dans le modèle.

Il n'y a de différence entre les résultats biologiques et économiques que si les changements de conditions d'exploitation de la flottille ont amené des réductions des coûts d'exploitation (réduction du nombre de navires ou du nombre de jours de mer par navire et par an).

Dans les deux cas, les pertes (de chiffre d'affaires ou de bénéfice) à court terme sont considérées comme des investissements étalés dans le temps, qui donnent à long terme une rente qui est la différence entre le résultat (chiffre d'affaires ou bénéfice) qui sera réalisé et celui qui aurait été réalisé s'il n'y avait pas eu de changement des conditions d'exploitation. La somme de ces investissements est appelée "Investissement (sci)" (sci signifie sans capitalisation des intérêts). Le programme calcule par itérations l'"investissement (aci) " (aci signifie : avec capitalisation des intérêts) et le rendement de cet investissement

$$\left( \frac{Rente}{Investissement(aci)} - 1 \right) \times 100 .$$

Cette option n'est opérationnelle que dans le cas d'une pêcherie simple (une espèce exploitée par un seul métier).

## 6. SIMULATION DE L'ÉVOLUTION DE LA TAILLE DES ENGINS

Nous avons vu au cours des récentes années apparaître des nouveaux métiers qui ont évolué très rapidement. Ainsi par exemple est apparue la pêche de la sole au filet droit et les navires ont très vite (pour compenser une baisse du rendement) augmenté la longueur totale de leurs filets.

Actuellement, la dimension des engins n'est pas l'un des paramètres des conditions d'exploitation ; il semble donc impossible de simuler une évolution de ce type.

Il avait été envisagé pendant un moment d'ajouter cette option mais cette idée a été abandonnée afin de garder au logiciel un niveau de simplicité compatible avec un objectif pédagogique et de le rendre utilisable par des enseignants non spécialisés dans les problèmes de la pêche.

Comme *"GÉREZ VOS PÊCHERIES"* est un modèle multi-métiers, il est possible de contourner cette difficulté en créant par exemple 4 métiers de fileyeurs ayant respectivement des longueurs de filets de 5, 10, 15, 20 km. Cette manière de procéder permettra de changer les coûts fixes et proportionnels, mais aussi le prix du poisson (on a constaté que les navires ayant de grandes longueurs de filet débarquent plus de produits de qualité inférieure et vendent à un prix moyen inférieur). Pour simuler une augmentation de la taille des filets, il suffit donc de faire glisser la flottille d'un métier dans un autre.

# Aquaculture enterprise management by M. Antona and P. Paquotte

L'histoire de l'aquaculture et en particulier l'encadrement de son développement contribuent à l'hétérogénéité des structures des entreprises de ce secteur. Ainsi, dans les pays où la ressource en eau était déjà destinée à des usages agricoles (riziculture) complétés ou non par un usage aquacole extensif, plusieurs formes d'entreprises coexistent de la plus artisanale à la plus industrielle. L'aquaculture de crevettes en Asie et du catfish dans les états du sud des USA en sont une illustration.

A l'inverse, lorsqu'aucune tradition n'existe et que les entreprises du secteur sont issues de transferts de technologie assortis d'incitations publiques, leurs structures et leurs modes de fonctionnement sont industriels, comme on peut le constater en Amérique latine (crevettes, saumon). Entre ces deux extrêmes, les situations intermédiaires sont très diverses (saumon en Norvège, bar et daurade en Europe méditerranéenne) et dépendent de l'encadrement institutionnel du secteur.

Néanmoins, les entreprises de ce secteur ont en commun d'être confrontées à des marchés de plus en plus internationalisés et à de fortes disparités de coûts des facteurs. Elles sont aussi dépendantes de leur environnement naturel, dépendance renforcée par le cadre institutionnel qui définit les conditions d'accès, d'utilisation et de protection des espaces côtiers.

La gestion des entreprises d'aquaculture apparaît comme une gestion sous contraintes multiples. Parmi les contraintes les plus vives, on peut citer celles afférentes à la recherche de facteurs de compétitivité, à la réduction des externalités liées à l'usage intensif de la ressource naturelle, au financement du capital technique et de l'innovation ou encore propres aux espèces élevées. Les possibilités d'accroître la densité d'élevage ou la capacité de stockage des produits vivants sans une forte augmentation des coûts et des risques de l'activité, varient ainsi fortement selon les espèces.

Le thème de la gestion des entreprises aquacoles est relativement récent par comparaison au démarrage de

The history of aquaculture and, in particular, the management of its development has contributed to the heterogeneity of business structures in the sector. In countries where water resources were already used for agriculture (rice growing) whether or not complemented by extensive aquaculture, several kinds of businesses have co-existed from the most artisanal to the most industrial. Prawn aquaculture in Asia and catfish in the Southern States of the USA are such examples.

On the other hand, where there is no tradition and businesses in the sector have resulted from technology transfer accompanied by government incentives, their structures and their ways of operating are industrial, as can be seen in Latin America (prawns, salmon). Between these two extremes, there are many intermediate situations (salmon in Norway, bass and sea bream in Mediterranean Europe) which depend upon the sector's institutional management.

However, all businesses in the sector are confronted by increasingly globalised markets and by great variability in input cost. They also depend upon their natural environment, a dependence which is reinforced by the institutional framework defining the conditions of access, of use and protection of coastal zones.

The management of aquaculture businesses appears to operate under many constraints. Among the most important ones are those related to the search for competitive advantage, the reduction in externalities linked to the intensive use of the natural resource, the funding of technical capital and innovation as well as those constraints peculiar to the cultivated species. The possibilities of increasing the culture density or the stocking capacity of living products without drastically increasing costs and risks vary a lot according to the species considered.

The management of aquaculture businesses is a relatively recent theme when compared to the beginning of

recherches analogues en agriculture dès les années 60. Les analyses ont pour objectif de faciliter la prise de décision de l'entrepreneur ou de l'aménageur public en matière de système de production. La détermination de la taille optimale et la mesure des économies d'échelle ont été les premières questions soulevées en aquaculture. Ces interrogations correspondaient à la phase de démarrage de l'activité. Comme l'illustrent les communications présentées dans cette session, les problématiques s'orientent maintenant davantage vers l'identification des contraintes de fonctionnement et leur impact sur la gestion des entreprises, les outils d'analyse restant inchangés et les approches peu influencées par des caractères spécifiques à une espèce ou une zone.

Plusieurs questions sont abordées dans cette session, qui confortent cette évolution :

(i) le premier type concerne le choix de l'affectation des facteurs ou le mode de valorisation du produit sous contrainte de disponibilité de ressources (Pomeroy et Martin) ou sous contrainte biologique (Wright, Rizzo). La fonction objectif de l'entreprise est déterminée *a priori* : dans tous les cas il s'agit de maximiser le revenu. Les notions de revenu minimum et d'aversion au risque sont prises en compte par un seul auteur dans un modèle MOTAD (Pomeroy). Tous les modèles sont normatifs. A l'exception du modèle de Rizzo, ils font appel à la Programmation Linéaire (Pomeroy, Wright, Martin).

La contrainte d'affectation de l'espace introduite par Pomeroy renvoie à la question plus générale de diversification de l'agriculture et de choix entre plusieurs spéculations dont l'aquaculture. Dans ce cas, la programmation linéaire constitue un outil d'aide à la décision.

En ce qui concerne les choix techniques dans la conduite des élevages (fréquence des tris, durée d'élevage, taille à la vente), ce type d'approche a plus une vertu pédagogique. La confrontation des résultats de ces modèles à la réalité de l'entreprise révèle d'autres contraintes à prendre en compte (pénibilité des tâches, faisabilité des schémas d'élevage proposés, effets de seuil dans l'utilisation des facteurs).

(ii) le second type de question concerne les interdépendances entre facteurs pour évaluer l'impact sur le revenu d'une modification d'un des facteurs. Spratt présente un modèle descriptif qui retrace les liaisons entre variables physiques et financières et permet de simuler le fonctionnement d'une entreprise de bar en Méditerranée.

(iii) le troisième type de questions abordé dans cette session s'intéresse à la viabilité des entreprises

similar research in agriculture dating as far back as the sixties. The purpose of such studies is to help decision-making by the businessman or the public planner regarding productive systems. The first questions raised in aquaculture related to determining optimal size and measuring scale economies. These questions related to the start-up phase of the industry. As the papers presented in this session indicate, the main questions now concern identifying operational constraints and their effect on business management, although the analytical tools remain unchanged and approaches are not really influenced by the particular characteristics of a species or a zone.

Several issues are tackled in this session confirming this evolution:

(i) The first issue concerns the input choices or the mode of valorization of the product constrained by resource availability (Pomeroy and Martin) or by biological factors (Wright, Rizzo). The business objective is determined *a priori*: in every case, it is about maximizing revenue. The concepts of minimum revenue and risk aversion are taken into account by only one author in the MOTAD model (Pomeroy). All the models are normative and except for the Rizzo model, they are all based on linear programming (Pomeroy, Wright, Martin).

The constraint concerning spatial use introduced by Pomeroy is reminiscent of the more general question of agricultural diversification and the choice between several possibilities including aquaculture. In this case, linear programming is a tool helping decision-making. Such an approach is more educational when it concerns technical choices in culture management (sorting rate, culture time, marketable size). The results of such models when confronted to the business reality reveal other constraints that need to be taken into account (unpleasantness of the work, feasibility of the proposed culture plans, threshold effects in factor use).

(ii) the second issue concerns factor interdependence when evaluating the revenue impact of the change in any one factor. Spratt presents a descriptive model which shows the links between physical and financial variables and simulates the operation of a bass business in the Mediterranean.

(iii) the third issue dealt with in this session concerns the viability of businesses taking into account ecological, social and economic conditions. Mudiantonio illustrates this problem with monographs based on a sample of more than 200 businesses in three Indonesian regions. He identi-

compte-tenu des conditions écologiques, sociales et économiques. Mudiantonio illustre cette question au moyen de monographies basées sur un échantillon de plus de 200 entreprises dans trois régions d'Indonésie. Il identifie les contraintes à l'intensification en comparant les résultats comptables de différentes techniques -intensive, semi-intensive et extensive- et de divers modes de gestion -artisanal ou industriel. Cette recherche met en évidence les contraintes d'appropriation de l'espace, d'accès au crédit, de disponibilité en juvéniles d'écloserie et de capacité à maîtriser les techniques d'intensification. La rentabilité des entreprises n'apparaît pas directement liée à la taille ni à un système technique donné.

Plusieurs communications de cette session montrent que les réponses aux questions de gestion de l'entreprise ne se trouvent pas uniquement dans un modèle ou une simulation de paramètres propres à l'entreprise mais dans la prise en compte des variables externes saisies à un niveau méso-économique. Le cas de l'aquaculture en Europe illustre l'incidence des modes de financement et des conditions d'accès aux sites sur la viabilité des entreprises. Les conditions de financement alliées à la baisse actuelle des cours des produits d'aquaculture limitent l'entrée dans l'activité aux Industries agro-alimentaires qui disposent d'une surface financière leur permettant de couvrir les risques d'exploitation.

Cependant, des contraintes dont l'influence est croissante, sont encore peu traitées dans le cas de l'aquaculture. Issues du débat actuel protection des milieux naturels versus développement des activités économiques, les contraintes de préservation de l'environnement posent la question des modes de prise en compte des externalités et de leur impact sur la gestion des entreprises et les formes de compétitivité des activités.

fies the constraints to intensification by comparing the accounting results of different techniques - intensive, semi-intensive and extensive - and different managements schemes - artisanal or industrial. This research demonstrates the constraints related to space appropriation, credit opportunity, the availability of hatchery reared juveniles and the potential to master intensification techniques. Business profitability does not appear to be directly linked to a given size or technical system.

Several papers in this session show that the answers to business management questions cannot be found in a single model or in a simulation of the business's own parameters but by taking into account external variables at a meso-economic level. The aquaculture case in Europe illustrates the effects that funding procedures and accessibility to sites have on business viability. Funding conditions together with the present decrease in the prices of aquaculture products restrict entry into the activity to those agro-alimentary industries that have enough financial back-up to cover the operating risks.

However, some constraints of increasing importance are still not really dealt with in the case of aquaculture. Originating from the present debate on protection of the natural environment versus the development of economic activities, constraints imposed by environmental conservation raise the question of how to take into account externalities and their impact on business management in the competitive framework in which they operate.

# Profitability of Catfish on a Representative Multiple Enterprise Farm in the Southeastern United States Under Conditions of Risk

**Robert S. Pomeroy[a], Stephane M. Carlier[b] and Charles E. Curtis, Jr.[c]**

ABSTRACT

*Farmers in many parts of the world are looking toward agricultural enterprise diversification to provide an additional and stable revenue. Aquaculture has been presented as a viable alternative for farmers and as a profitable enterprise. However, aquaculture can be a high risk agricultural practice. Disease, predators, and poor water quality can be potential threats to the fish crop. The fluctuating price of feed and fish prices can significantly impact profit margins. The capital investment can be high and land use is committed to aquaculture for a long term.*

*The objective of this study is to investigate the potential of aquaculture as an alternative enterprise on a typical row crop farm in the Southeastern United States. Farmers may hesitate to include an aquaculture enterprise into their farming system because of the risk associated with this type of enterprise and the constraints inherent in the U.S. government farm bill. A comparison of traditional row crops with and without aquaculture will be conducted on a risk-return basis under the 1990 Farm Bill. A sensitivity analysis will also be conducted with different expected catfish yields. The Target MOTAD method is used for the analysis. Risk is defined as the absolute deviation from five target incomes.*

## 1. INTRODUCTION

The restructuring of United States agriculture in the 1980s was a difficult process for many farmers. The farm population decreased by 29 percent and the number of farms decreased by 11 percent during the decade. Both financial and climatic

conditions were causes of the problems. The elimination of some Federal government subsidy programs put additional pressure on farmers to adjust their farming practices. This restructuring was felt especially hard in the Southern United States, where, because of environmental constraints, much of the region is considered as marginal for producing major agronomic crops. During this period, and after, Southern farmers began to look toward enterprise diversification from traditional row crops (soybean, corn, wheat, cotton) to provide additional and stable income.

In the Southern United States, especially, aquaculture was developed as a viable alternative for farmers and as a potentially profitable investment. One fish species in particular, channel catfish, developed as a strong commercial alternative. However, catfish farming is a high risk agricultural practice. Disease, predators and poor water quality management can be potential threats to the fish crop. The price of feed, as well as fish prices, fluctuates and can significantly affect profits. The capital investment is high and land use is committed to aquaculture for a long term (Pomeroy and Rathwell, 1988).

In addition to aquaculture, vegetable production was also viewed as a potentially profitable alternative enterprise. This includes a variety of vegetable types such as bell pepper, cantaloupe, cucumber, snap bean and tomato. Risk is also an inherent part of vegetable production. Yields are susceptible to climate change, diseases and insects. Prices can vary during the growing season depending upon growing conditions in other production regions.

The economic viability of an alternative enterprise depends upon existing financial, marketing and managerial conditions. In addition, external parameters such as government programs can affect farmer decisions to diversify and their choice of crop. This is especially apparent under the 1990 U.S. Farm Bill which, due to restrictions on the number of acres eligible for deficiency payments, restricts the acreage and non-program crops which can be utilized (USDA, 1990).

The purpose of this paper is to compare opportunities for enterprise diversification on a representative multi-enterprise farm in the Southeastern United States under the 1990 U.S. Farm Bill. The specific objectives of the study are (1) to determine the best combination of agronomic crops on the base program acreage, and (2) to compare catfish, vegetable and row crop production on a risk return basis, including them in the total acreage of the farm. The Target MOTAD method is used to analyze the risk associated with enterprise diversification.

## 2. GOVERNMENT FARM POLICY

The Food, Agricultural, Conservation and Trade Act of 1990, commonly referred to as the "Farm Bill", provides a 5-year framework for agriculture and food programs in the United States. The primary goals of the Farm Bill are reducing the federal deficit, improving agricultural competitiveness, and enhancing the environment (USDA 1990, House 1991). The basic mechanisms brought into play are reducing deficiency and diversion payment acres, permitting crop planting flexibility, maintaining market-oriented loan rates, and implementing agricultural resources conservation program. Under the first mechanism, called the acreage reduction program (ARP), farmers are obliged to remove some acreage from crop production to qualify for program benefits and are restricted in the amount of acreage they can plant in any one crop and still collect subsidy payments. Each row crop has a different ARP value ; not less than 15 percent for wheat, 7.5 percent for corn and 5 percent for cotton.

Under the second mechanism, referred to as triple-base, farmers are given greater flexibility to produce non-program crops and still receive deficiency payments. In comparison to the 1985 Farm Bill, deficiency payments on 15 percent of base acreage are eliminated. However, these acres can be flexed (normal flex acreage, NFA). Under the new flexibility provision, farmers can plant the crop of their choice, except fruits and vegetables. Farmers are allowed to remove voluntarily an additional 10 percent of the base acreage program crop production under the same stipulation (optional flex acreage, OFA). If they choose to plant a crop other than their original program crop, they will be eligible for nonrecourse and marketing loans, but not for deficiency payments. The portion of the crop base left is the permitted planting acreage (PPA) on which the program crop can grow. Farmers have two options : planting the eligible crop (and receive subsidy payment) or participating in the 0/92 program (for feed grains) or 50/92 (for cotton). The -/92 program is an acreage diversion in which farmers devote all or a portion of their permitted planting acreage (in excess of 8 percent of required acreage) to conservation uses. Thus, under the 1990 Farm Bill, farmers have greater flexibility for using their land to produce alternative crops and still retain government payments than under the 1985 Farm Bill.

## 3. METHODOLOGY

### *3.1 Target MOTAD*

Risk is an inherent part of agriculture. The Target MOTAD methodology was chosen for this study because it includes risk in a linear programming framework that is easy to implement. Hazell (1971) developed the MOTAD model (Minimum Absolute Deviation from the Mean) as a linear substitute for quadratic programming in deriving an E-V frontier. Hazell's model can be formulated as the minimization of the total absolute deviation from the mean income for each activity, subject to technical constraints and to a parametric constraint on expected total net revenue. The decisionmaker can identify the combination of enterprises that maximize expected returns. Revenues above as well as below the mean are considered as elements of risk.

The concept of a target level which the decisionmaker wishes to exceed is similar in concept to the "focus loss" concept presented by Boussard and Petit (1967). They presented a linear optimization model in which they enforce the requirement that there is only a "negligible possibility of ruin". It is assumed that farmers will not select a production plan in which their income is below a minimum sufficient level to cover "unavoidable expenses", comprised of variable and fixed costs, a minimum amount for family consumption, and repayment of short-term loans.

Target MOTAD is a modification of MOTAD that can be used to optimize revenues subject to pursuit of a minimum target (Tauer 1983). Tauer assumed that decisionmakers are risk averse to only those revenues below their "target" (income level necessary for firm survival) and risk-neutral to revenues above. The utility function of income z is assumed as :

$$\begin{aligned} U(z) &= a + bz + c(z-t) && \text{if } z \leq T, \\ &= a + bz && \text{if } z \geq T, \end{aligned}$$

where T is the target income and a, b and c are constant.

The objective of the Target MOTAD model is to maximize expected revenues subject to technical constraints, and risk constraints defined as deviations below a fixed target (Hatch and Attwood 1988). The model is formulated as :

$$\text{Maximize } E(z) = \Sigma c_j \, x_j \text{ for } j = 1,..., n$$

$$\begin{aligned} \text{subject to } & \Sigma a_{ij} \, x_j \leq b_i \text{ for } i = 1,..., m \\ & \Sigma c_{rj} \, x_j - t_r + y_r \geq 0 \text{ for } r = 1,..., s \\ & \Sigma p_r \, y_r = \lambda \\ & x_j, \, y_r \geq 0 \end{aligned}$$

where

$n$ = number of activities,

$m$ = number of constraints,

$s$ = number of observations (usual years),

$a_{ij}$ = use of resource i by one unit of activity j,

$b_j$ = total availability of resource j

$c_j$ = expected revenue for activity j,

$c_{rj}$ = actual revenue for activity j in year r,

$x_j$ = level of activity j,

$T_r$ = the fixed target income for year r,

$y_r$ = absolute value of negative revenue deviation from the target income

$p_r$ = probability of year r,

$\lambda$ = maximum total negative deviations from the target.

For each specified target income, an "income target deviation" frontier is developed by varying $\lambda$ from 0 to unbounded. When $\lambda$ increases, the expected income increases and tends to approach the LP maximizing return solution.

In a comparative study, Watts et al. (1984) stated that Target MOTAD solutions will always yield higher income than MOTAD for a given level of risk. The authors state that "if only negative deviations from a correctly selected target are a source of risk, the Target MOTAD solutions are clearly superior."

For a large value of the risk parameter $\lambda$ (which is the allowable absolute deviation below the Target income), the model selects the mix of activities that maximize the income. In order to find the hypothetical risk efficient frontier of the programming model, the risk l is then minimized subject to an income change. By varying the risk level between these two extremes, several points of the risk frontier are determined.

### *3.2 The Representative Farm*

A typical commercial crop farm of the South Carolina Coastal Plain was selected for study (Boring, 1991). The representative farm used in the model consists of 1069 acres and produces 979 acres under the government program. The proportion of acreage in commercial production are assumed to be 117 acres of cotton, 604 acres of corn and 258 acres of wheat (including soybeans double cropped with wheat). The farm is considered to have in its possession all machinery and equipment for producing the row crops. One manager and two full-time persons work (600 hours/month) on the farm. The financial situation is assumed to be adequate to support diversification without interfering with the total farm financial conditions.

The addition of catfish farming as an enterprise requires significant investment, especially with the construction of the ponds and purchase of specialized equipment. Size of the operation affects yield, cost structure and profitability because of the managerial abilities and the economies of scale (Pomeroy and Rathwell 1988). Some producers, due to risk management, financial and/or marketing constraints, prefer to start small. For this reason, three sizes of catfish operations were considered in this study : 20 acres (two-ten acre ponds), 40 acres (four-ten acre ponds), and 80 acres (eight-ten acre ponds). It is assumed that the farmer has experience and knowledge of catfish farming.

Vegetable crops can be produced without special additional investment with the exception of irrigation machinery. The wells required by the catfish farming can be used for vegetable irrigation. The selected vegetables are fresh cabbage, fresh cucumber, turnip green, pickle cucumber, and watermelon. These vegetables were chosen because of their potential for high gross revenues and because the high labor requirement period is often in the slack time of the row crop enterprises. The production of vegetables is both labor intensive and requires high levels of managerial skills. It is assumed that the vegetable acreage cannot be more than 50 acres in spring and fall, because of the difficulties of management. It is assumed that the farmer has experience and knowledge of vegetable farming.

The farmer/farm manager is assumed to choose the best combination between these alternatives in order to obtain the highest return to land, labor, risk and management. Table 1 presents the Target MOTAD model. It includes the following activities : agronomic crop, aquaculture, spring vegetable crop, fall vegetable crop, monthly hired labor, risk deviation transfer, and target income transfer.

The objective function to be maximized is expressed as :

$$\text{Max } \Sigma c_j \, x_j - 4.25 \, h_m - 10sa \, ;$$

where

$x_j$ = level of activity (acres) ;

$h_m$ = monthly machinery labor hired (hours) ; its cost is \$4.25/hour ;

sa = set aside acres ; its cost is \$10/acre ;

$c_j$ = per acre average gross revenue return minus total variable costs for activity j ; representing the return to unpaid fixed resources including machinery, equipment and land debt, property taxes, insurance and labor available on the farm.

Yield and price data were obtained from records kept by members of the Central South Carolina Farm Management Association (FMA) (Boring, 1991). This data was supplemented by county yield and price data for agronomic crops in

two South Carolina counties, Sumter and Orangeburg, for the period 1983-1990 (S.C. Agricultural Statistics, 1991). Deficiency payments are added to receipts. Program yields for wheat, corn and cotton are set at the historic yields (based on the last five years) for the FMA. Annual deficiency payment rates were calculated by the difference between the 1990 target prices and the market prices of each year. Thus, these deficiency payment values deflated by the GNP price deflator, are thought to better capture risk under the new Farm Bill.

Costs and revenues for catfish farming were estimated based on the enterprise budgets developed by the Clemson University Cooperative Extension Service (Pomeroy, Schwedler and Luke 1988). The biological assumptions of production are reported in that report. As risk is minimized in the objective function, a variability of the catfish yield is required. Since no data currently exist in the United States on average commercial catfish yields, a random determination of yields for eight years was done. Three stocking rates of 3275, 3600 and 4500 fish per acre were used. The price of catfish were obtained from the U.S. Department of Agriculture monthly catfish report.

Costs and revenues for vegetables were estimated using 1983-1990 costs, yields and prices received by farmers in Sumter and Orangeburg counties and from enterprise budgets developed by the Clemson University Cooperative Extension Service (Rathwell, 1990).

### *3.3 Constraints : Technical, Risk and Policy*

Land and labor are the resources assumed to limit the maximization of the objective function. The labor is divided into two categories - labor for working with machinery and catfish management and labor for harvesting vegetable crops by hand. The labor on the farm is comprised of three full-time workers who provide 600 total hours of labor each month. Two workers can be hired during peak periods to provide 400 hours of additional labor per month. Other labor requirements for particular enterprises are reported in the respective enterprise budgets.

Capital is assumed not to be a limiting resource because of the availability of borrowed capital. The total 1069 land acreage of the representative farm is divided into two time periods because fresh cucumbers and pickle cucumbers can be produced during the spring and/or fall seasons. Soybeans and wheat and/or canola can also be double-cropped.

Prices, yields and costs for the years 1983-1990 are used to measure the variability of gross revenues over time. It is assumed that each of the eight annual observations of outcomes has the same probability of occurrence. The risk transfer rows contain the annual gross returns over the variable costs per acre for each activity. When the sum of the revenues is below the target income in a given year, the deviation is transferred into the risk constraints. By varying the risk-aversion parameter l, the model estimates farm plans corresponding to various degrees of risk aversion. The parameter l is defined as the average of the yearly deviations from the target income which is acceptable.

Farmers are assumed to be willing to participate in the government programs and, therefore, to agree to fulfill the requirements. Consequently, constraints are added to the model. Farmers cannot plant more than the permitted acreage in program crops to be eligible for program payments. Moreover, if they underplant their program crops, their future base acreage will be reduced.

Flexibility is the highlight of the 1990 Farm Bill. Crop acreage is henceforth divided into three categories : ARP (acreage reduction program), flexible acreage, and permitted acreage. The acreage constraints are shown in Figure 1.

Since the program crop of the farm is 979 acres, the producers have set aside 90 acres but it is allowed to flex at least 148 acres (up to 246 acres). The total planting of cotton, corn and wheat with deficiency payments can not exceed 743 acres. Catfish, vegetables and oilseeds are added to the model on the non-program acreage (90 acres).

The Target MOTAD model includes the suitable percentages of each Farm Bill constraint. Thus, the model can be adapted very quickly to another farm acreage (Tables 2 and 3).

The Target can be any goal that is important to the decisionmaker. In this study, the Target income represents the amount of money that can assure the long-run survival of the representative farm. Five Target incomes were selected as a function of different fixed costs between alternatives. The computation was conducted in two parts : (1) a base Target income, and (2) a specific additional cost for each scenario.

The base Target income included a minimum annual farm family income of $32,417 ; an annual full-time hired laborer income of $8,840 ; and the cash fixed costs for insurance, rent and property taxes. The base Target income is $124,390. It is applied to the representative farm without diversification.

Additional target incomes include :

Target 2 - $140,227 (20 acre catfish ponds)
Target 3 - $149,062 (40 acre catfish ponds)
Target 4 - $169,956 (80 acre catfish ponds)
Target 5 - $127,890 (no ponds, vegetables)

## 4. ANALYSIS AND RESULTS

The profitability of five combinations of row crops, aquaculture and vegetable enterprises are analyzed for the representative farm under the 1990 Farm Bill. For each Target, a comparison with three different catfish yields (5,000, 4,000 and 3,640 lbs. per acre, scenario 1,2 and 3, respectively) will be studied.

### *4.1 Target 1. ($124,390)*

The farm is first studied with the typical row crops (Target baseline) under the 1990 Farm Bill (Table 4). The program acreage is 979 acres and the non-program acreage is 90 acres. The most profitable plan ($116,806 Plan C) is approximately $8,000 smaller than the target income of $124,390. Interpreting the dual activity, it can be concluded that adding one acre of land in spring increases the income by $63 while adding one acre in the fall increases income by $12. The farmer chooses canola/soybean and corn on the NFA ; corn, cotton and wheat on the OFA ; corn, cotton and wheat on the PPA ; and canola/soybean on the 90 acres of non-program acreage.

The most profitable plan (C) is only $2,700 higher than the less risky plan (A). That means that South Carolina farmers do not have a lot of choices with their rotation. Even if farmers can make their decisions according to the market prices, they flex only the acreage that they are obliged to flex, and are not interested in the optimal flex acreage.

Thus, during a period of eight years, the expected income was below the Target for all three plans. Moreover, the risk deviation is high (near $30,000). Such a farmer is assumed to look for an alternative in order to increase his gross revenue and decrease the risk. Diversification seems to be the best way to obtain these goals in South Carolina.

### *4.2 Target 2. ($140,227)*

The farmer has the opportunity to raise catfish on a two ten-acre pond system and/or to plant vegetables on the 90 acres of non-program acreage. These 90 acres can also be planted in soybeans, canola, or canola/soybeans. Vegetable acreage is assumed to be less than or equal to 50 acres.

The most profitable plan (1C) produces a gross revenue of $205,229 (Table 5). Risk deviation is relatively low ($16,810).

Under plan 1C, the program acreage includes 147 acres of canola/soybean is planted on the N.F.A. acreage ; 60 acres of corn, 12 acres of canola/soybean and 26 acres of wheat are planted on the O.F.A. acreage ; 408 acres of corn, 82 acres of cotton and 155 acres of wheat are planted on the P.P.A. acreage. The remaining 90 acres of non-program acreage contains the 20 acres of catfish ponds, 17 acres of canola/soybean, 50 acres of spring cucumber and 50 acres of fall cucumber. Greens, spring cabbage and watermelon were not able to compete with spring cucumbers because the yield incomes were too low.

The comparison of the coefficients of variation (Table 6) shows that the production of fall pickles (C.V. = 74 percent) is less variable than the production of fall cucumbers (C.V. = 116 percent). This is due to the fact that pickles are sold under contract (where prices are less volatile), whereas fresh cucumbers are sold on the fresh market.

Under the remaining two catfish yield scenarios, plan 1C is the most profitable plan, although gross revenue decreases and risk increases. All other crops on both program and non-program acreage remain the same.

*4.3 Target 3. ($149,062)*

Catfish farming is conducted on four ten-acre ponds and the production of vegetables on 45 acres. The maximum gross revenue (plan 2C) obtainable in this scenario is equal to $219,944 (Table 7). It is higher than for Target 2 by $14,700 because the supplementary 20 acres of catfish ponds adds $23,700, although the reduction of the vegetable acreage by 5 acres decreases profits by $9,000. Catfish farming is still profitable. The risk associated with the expected incomes is lower than with the Target 2 because catfish provides additional revenue for the year 1990, resulting in a lower deviation from the target ($10,000 less).

On the program acreage, the evolution of the rotation is almost the same. On the NFA, soybean and canola/soybean share the acreage on the less risky plan (2A) ; canola/soybean is the only crop in the most profitable plan (2C). On the OFA, corn, canola/soybean and wheat share the 98 acres. The base corn, cotton and wheat share the PPA.

As with Target 2, fall pickles replace fall cucumbers when the risk parameter decreases. Spring cucumbers are included under all three plans. As fall cucumbers require more labor, corn is not flexed on the OFA.

Under the lower catfish yield scenarios, the profit maximizing plan stays the same (plan 2C). All program acreage crop mixes stay the same. Risk increases under each scenario and plan.

*4.4 Target 4. ($169,956)*

The farmer has the choice between eight, ten-acre ponds of catfish or non-program crops for the remaining 90 acres. With a catfish yield of 5,000 lbs per acre, both solutions are very close and the catfish ponds are selected in both cases (Table 8). The maximum gross revenue ($202,227, Plan 3B) is smaller than for the two previous Targets. This is because there is no production of vegetable, especially spring cucumbers, and 10 acres of land used for pond levees are not available for crops. The spring cucumbers are a highly profitable alternative.

The risk deviation is high since catfish farming on 80 acres is more risky than vegetable farming. The program acreage is almost the same as previous Targets. As catfish requires less management labor than vegetables, it is possible to plant canola/soybean on 45 acres of the OFA for the corn base in the most profitable solution (plan 3B).

With the other two yield scenarios, there is only one solution for the 4000 lb/acre and risk is high. No aquaculture enterprise enters the solution for the 3,640 lb/acre scenario.

*4.5 Target 5. ($127,890)*

In this case the vegetable enterprise is the only alternative analyzed. The maximum acreage of vegetable is 50 acres.

The most profitable plan (4C) produces $184,074 of gross revenue (about $56,000 above the Target). The risk deviation is $18,566.

Canola/soybean is planted on the NFA for each case. On the OFA, the program crops of corn,cotton and wheat replace soybeans in previous plans. Flexing optional acreage by soybean involves a low income but also a smaller risk (C.V. = 79 percent). The C.V. of cotton is relatively high (110 percent).

On the non-program acreage, canola/soybean is planted on 40 acres. As for previous plans, fall and spring cucumbers are planted.

*4.6 Return-Risk Target Comparison*

The return-risk target comparison evaluates the risk-efficient frontiers of the four Target levels for the three catfish yields (Figs. 1, 2, and 3). On each risk-efficient curve, the furthest point from the origin represents the most profitable but most risky farm plan. A risk-preferrer decisionmaker would maximize utility with such plans.

The efficient frontiers for the four Targets in scenario 1 are illustrated in Figure 1. With the exception of Target 4, the risk-efficient frontiers lie in descending order for the three other Target incomes, and indicate a lower level of utility. the

slope of the frontiers are the same. The marginal risk per additional dollar of revenue is similar for the three Targets. Higher Targets are associated with better return-risk trade-offs. Target 3 is clearly superior to Targets 2 and 5. The risk-efficient frontier for the Target 4 is reduced to a small segment with the highest risk deviation. With such a catfish yield, the more you diversify, the more you earn.

Under scenario 2 (Figure 2), strong changes appear. On the one hand, the risk level is higher. On the other hand, it is now lower Targets which are associated with better return-risk trade-offs. The slope of Target 2, 3 and 5 are still the same. Higher Target levels are associated with shifts of the efficient-frontiers to the right. The risk-efficient curve for Target 4 is reduced to one point. A combination of vegetable and catfish enterprises is not the most profitable solution anymore.

Figure 3 illustrates the scenario 3. The Target 4 has been retired. The risk-efficient frontiers are well separated. The higher the Target, the higher the risk deviation. The expected income for Target 3 is lower than for Target 2. The shift in the slope of the efficient-frontier for Target 2 and 3 corresponds to the substitution of catfish for canola/soybean.

## 5. SUMMARY AND CONCLUSIONS

A Target MOTAD model was used in this analysis to identify optimal farm plans under a strategy of enterprise diversification. When making production decisions, the farmer was assumed to be facing technical constraints (land and machinery were limited), risk constraints (deviations from the target incomes were parametrically decreased to reflect various risk-aversion degrees), and policy constraints (the farmer was assumed to be willing to benefit from farm programs and meet the required conditions for the 1990 Farm Bill).

The model was limited by the length of time used in the risk constraint data set ; capital was assumed to be borrowed without constraint ; no marketing constraints exist ; and the farmer was assumed to have knowledge and experience in producing the alternative enterprises.

# The Management Schemes for Brackishwater Pond Production

**Mudiantono**

Faculty of Economics, Diponegoro University, Jalan Erlangga Tengah 17, Semarang 50241, Indonesia

ABSTRACT

*Tambak production is a relatively new trend of business in Indonesia, since Indonesia has some experiences in the over exploitation of marine resources during 1970s. Many programs are set to develop the tambak in Indonesia. Most of those programs are in management system. This study has main objective to recommend alternative management schemes for tambak operation, basically for tambak operation in north coast of Java, and west coast of South Sulawesi as the leading areas for tambak production in Indonesia using 300 tambak operators as the samples.*

*The results of this study indicate that the tambak management in north coast of Java and west coast of South Sulawesi vary from region to another and levels of management. This variation may have generated differences in cultured species performance i.e. milkfish and shrimp. It seems that environmental variables such as temperature, salinity, soil texture and quality, and water control structure are to be significant roles in determining the cultured species performance. This is obviously, in turn, influencing the production level in each tambak culture systems.*

*The other husbandry parameters that also affecting the economic efficiency of tambak management are stocking density, and food and feeding practices. The study indicates that with increasing stocking density, the variable cost will also increase and in turn reduce the ratio of net profit to total costs.*

*In order to optimize tambak production and economic efficiency, it can be proposed that zonation of tambak areas according to ecological condition and supporting infrastructures in the sites is necessary to be done. It is especially important to tambak investors to determine the selected sites.*

## 1. BACKGROUND

The total shrimp production of the world has increased steadily since 1960s. It was recorded to increase in about 70 % during a decade of 1972 to 1982 amounted for 1.2 to 1.7 million tons. During the last five years, the world production

stayed at about 1.7 million tons. Out of these, according to the 1983 FAO yearbook of Fishery Statistics, the developing countries produced about 70 % with four leading producing countries from Asia i.e. India, China, Thailand and Indonesia.

The demand for shrimp in the world market is generally following an upward trend. This continous increase of the demand for shrimp has put an over increasing pressure to the producing countries to increase their supply. This has caused a sharp increase of the size and amount of trawler and small vessels which engage in shrimp capture fisheries. There is the danger of over exploitation of marine resources, because most of the major shrimp fisheries are at present being fully exploited to maximum sustainable yield.

Indonesia has some experiences in the over exploitation of marine resources during 1970s. In 1971, for example, the number of vessels harboured on Cilacap area alone was only 13 compared to 200 in 1976 with corresponding total catch was increased from 171.5 tons in 1971 to 3.055 tons in 1976. In 1980, there were 161 larger trawling vessels with 121 shrimp trawlers concentrating in the Maluku and Irian Jaya Areas. On the other hand, more than 13,000 vessels with inboard engines were concentrated in the Malacca Strait, East Sumatra and the northern of Java. This resulted the growth of Indonesia's fishery product exports from US$ 7 million in 1970 to US$ 253.6 million in 1982. Shrimp export constituted 71.5 % of the total revenue, 28.8 % of the volume and 28 % of the value of fishery products in that year. These activities placed the Indonesian shrimp industry in trouble especially of over exploitation of shrimp stocks (Palomares, 1985).

Although the over exploitation can be prevented through the better stock assessment and management, but there is no real hope for capture to give higher yields. To solve this problem, Indonesia has chosen to ban the trawler operation in Indonesian waters since 1980 and is looking primarily to its brackish water ponds (tambak) for further development of shrimp culture, in order to substitute shrimp cought from the sea.

North coast of Java is the leading tambak area in Indonesia. There is at present about 92,000 ha of tambak in Java. These tambak are generally cultivated for either shrimp or milkfish. The culture systems which are being practiced by the tambak operators are the traditional culture system for shrimp or milkfish as monoculture, and shrimp and milkfish in polyculture, the semi intensive culture system for shrimp in monoculture, and intensive culture system for shrimp in monoculture :

(i) the traditional culture system depends completely on natural food propagated in the pond with or without fertilization and on tidal water replenishment. In this system, the management practices depend mainly on the natural condition without any assistance from human. The stocking density ranges from 2,000 to 10,000 fry of shrimp and 500 to 3,000 fry of milkfish per ha.

(ii) the semi-intensive culture system is a higher level of the system than the traditional one. In this system requires the supplementary feed such as trashfish, mussel meat and artificial feed, and the use of water pumps in addition to tidal exchange. Stocking density is as higher as 10,000 to 40,000 fry/ha.

(iii) the intensive culture system is almost completely independent of the nature. This system usually stocks 40,000 to 200,000 fry/ha. Such high density can be supported only through major inputs of formulated feed mostly in the form of pellets and water exchange through the pumps and aeration facilities (e.g., paddle wheels). The size of ponds is smaller ranged between 3,000 and 6,000 m square. This system is usually characterized by capital intensive.

Some programs are set to develop tambak in Indonesia. One of the programs is tambak intensification. This program is aiming to improve and increase the production of tambak for exports and domestic consumption purposes, to increase the income of tambak operators by improving their business production and productivity, and to provide and to enlarge the employment opportunities. Meanwhile, to stimulate shrimp culture industry by private sectors, the government is also giving business fresh-atmospheres such as deregulations and debureaucratic policy in order to drive non-oil export commodities. To make this program successful, the government also provides a special facilities package such as special credit scheme with soft requirements, technical assistances, and input facilities. Up to now, the program has not been so successful in term of the target area. It was only about 9 % of the target come to the reality. It is generally due to the technical bank conditions which are still being employed by the executive banks, eventhough the bank requirements in this program have alternatively been reduced. The main problem faced by the most traditional tambak operators to join the program run by the government was to show their certificates of tambak ownership as a collateral to the bank. Most of them do not have it, so that the bank is not able to approve its credit scheme. It was one of the constraints in improving

the traditional tambak productivity. On the other hand, the self-financed shrimp culture industry run by private sectors have rapidly been growing. For the last four years, the number of intensive tambak financed by private sector has increased almost 200 %. It has mainly been operated by the investors who are often not necessarily come from the fisheries/aquaculture sector. The rapid growth of shrimp hatcheries in Java makes the shrimp fry be easily available. It has stimulated the investors to invest their money in tambak business (shrimp culture industry).

In most regions, there is a strong tendency that the traditional tambak are converted into the intensive cultured ones. For instance, in Tugu District Semarang Regency, Central Java nearly a half of the tambak area available has been used intensively by private investors. In the site selection, they are often ignoring the needs of other tambak operators. The conflicts among the tambak operators may arise from this situation. These investors occupied their tambak either by buying or renting from traditional tambak owners.

The texture of soils, water sources, accesebility and infrastructure facilities in surrounding tambak areas are usually used to be the considerations in the site selection. Pre-observations showed that the texture of soils and other facilities as mentioned above are not the same for the north coast of Java. Not all locations of existing tambak areas are suitable for intensive shrimp culture purposes. There are some investors that select the unsuitable locations for their intensive tambak sites. Since they are not able technically to select the suitable sites, they are mostly using trial and error method to find out the optimum use of inputs. Consequently, the maximum profit cannot be achieved by them. It is because they have to invest too much in tambak preparations and operating costs. It might be worthwhile to keep some certain locations of tambak area available to be operated by the extensive shrimp culture system in order to achieve the optimum production in certain level.

Eventhough shrimp culture has been becoming more popular, milkfish is still widely cultured. The market for milkfish is still large and the management operation of that culture is quite easy such that many tambak operators are interested to culture milkfish beside the lack of fund needed to convert their tambak for shrimp cultivation. However, the milkfish culture is still to be an important part of tambak culture system.

In this research, the identifications of tambak conditions based on the location, technological adaptation, species cultured and ownership should be conducted in order to get the initial descriptions of existing tambak operations. The various existing conditions as mentioned earlier on tambak could be used to analyze the conflicts which might be arise in the tambak resource allocations. So, the rational tambak utilization should be investigated. To achieve it, the economic and social considerations would be in the high priority in addition to the technical considerations.

## 2. OBJECTIVES

Generally, this study is aimed to recommend the alternative management schemes for tambak operation. This objective will be reached through some specific objectives such as :

(i) to describe the existing tambak operation based on the level of management and technology adaptation ;

(ii) to evaluate the performance of tambak enterprise management, and to find out the parameters affecting theeconomic efficiency of tambak management ;

(iii) to identify the critical externalities in intensive tambak development ;

(iv) to analyze the existing aquaculture systems in order to identify the appropriate (and economically sustainable) technological mix of enterprises in different environments.

## 3. METHODOLOGY

### *3.1 Data Collection*

The tambak location as study area is mainly on north coast of Java. The data collection activities are started by collecting the secondary data showing the locations of existing tambak with level of management adopted by tambak operators.

Some regions with strong tendencies of tambak traditional, semi-intensive or intensive are selected. The selection of culture systems of tambak uses the general description of existing tambak condition in those regions. To make the general description and to find out the major problems in the regions, the method of Rapid Rural Appraisal (RRA) is used. This method gives the researchers the simple and efficient ways to decide the sampling areas and the samples of tambak operators to be monitored in order to analyze the performance of tambak operations. The tambak operators who are to be the samples consist of operators operating traditional culture system for shrimp and milkfish in monoculture and polyculture of shrimp and milkfish, semi-intensive system for shrimp and intensive system for shrimp.

The sample area of this study consists of three provinces namely West Java, Central Java, and East Java. The total sample is 223 which can be divided into : 73 samples of West Java, 75 samples of Central Java and 75 samples of East Java.

The data were collected from those tambak for three seasons through one shot and monitoring data collections. One shot data collection was done for the first season in August 1989 (for the season which harvested around August 1989) by interviewing to the tambak operators. The monitoring was done for the two seasons after that season.

### *3.2 Data Analysis*

Some computer programs such as DBase III, ENFIN, and Lotus are used in this study to find out the optimum allocation of tambak resources. The data from the field are stored first in the computers using DBase III, so that they can be further processed easier through making the worksheet. ENFIN and Lotus programs are used to measure the returns and costs using certain level of management. The level of management employed by the tambak operators and natural conditions such as soil textures and the existing conditions of tambak infrastructures may be the constraints in developing the tambak. So, they will be analyzed first before the analysis of costs and return. The results of the analysis will recommend the alternative management schemes for tambak production.

### *3.3 Limitations of Study*

The monitoring could not be done smoothly because of the cropping season of each study sites was not started in the same time. When in one site has begun the season, in the other sites still waited the harvest time. This situation made the data collection from monitoring could not be done in the same time, while the researchers had the limit time. So, the data from monitoring came late to be analyzed. It made the research schedules could not be followed.

## 4. TAMBAK MANAGEMENT

### *4.1 Land and water supply*

Location of pond should be considered in the tambak system. Some factors which significantly influence the production process of tambak system are as below :

(i) water supply and water quality
The suitable water salinity ranges between 15 % and 25 % therefore in dry season, fresh-water should be available to maintain the optimal water salinity. Beside that, the water should be unpolluted by industrial, agriculture or water transportation activities.

(ii) tidal range
Tidal range related to the pond water management system would influence the pond construction as a whole. How strong the dykes, watergates, and canals should be built depend on the tidal movement.

(iii) Soil quality
Claysoil, sandy clay or loamy soil with pH around 7.5 and more or less 2 % organic materials contains are favourable conditions for pond.

Transport accessability, unflooded area, extended possibility and security aspect are other important factors of pond locations.

In this study, the distance of pond location to the fry sources varies among intensive, semi-intensive and traditional tambak systems. However there are two different patterns of West Java and Central Java in one side and East Java in other side. In West Java and Central Java, more than half of the pond are located in more than 50 Km from fry source. Meanwhile in East Java the distance of pond location to fry sources are more various.

Water supply, especially its quality, will stimulate sloughing and lead to high survival and growth rates in the pond. In contrary, poor water quality is one of the factors that caused mortality rate. In East Java the semi-intensive tambak system faces relatively higher problem of water quality than the other regions or other culture systems.

Related to the location of pond, this study found two problems which influence the tambak system, namely flood and physical-natural capacity conditions. Data indicate that the flood and physical-natural capacity conditions still become a problem in the tambak system not only for traditional and semi-intensive systems, but also for intensive culture system. It is also true that the problem is beyond the farmer control.

### *4.2 Fertilization and Pesticide Application*

Drying, cleaning, plowing and leveling of pond, application of lime and fertilizer are among the activities in pond preparation. These activities are done primarily to eradicate pests and predators, to reduce acidity and to enhance fertility of the soil. For old ponds, plowing to remove the surface soil comprising of accumulated unused feed during earlier rearing period is also an important activity in pond preparation. This is to prevent the soil and water pollution in the next rearing cycle.

This study found that all tambak operators practiced fertilizer and pesticide application into their ponds during pond preparation. However the frequency of fertilizer and pesticide applications are different and vary to the regions or culture systems.

In West Java and Central Java none of the tambak operators practicing fertilizer application three times during pond preparation. All traditional, semi-intensive and intensive tambak operators in East Java were practicing once, twice and three times fertilizer, respectively.

Eradicating pests and predators during pond preparation can be done by pesticide application. This study found that the frequency of pesticide application varies either to regions or to culture systems.

### *4.3 Acclimatization of Fry*

Water has many physical and chemical properties. There are some physical and chemical factors affecting water which are very important from the point of view of aquaculture, e.g. temperature, salinity, DO2, ammonia, nitrite, time and weather. Physical factors within and among the fish pond vary with space and time. No two ponds are exactly the same. Due to those factors, it is important to acclimatize the fry to the new condition when they are going to be stocked into rearing ponds.

To avoid high mortality of fry when they are stocked into the ponds, the tambak operators commonly do some treatments. Acclimatization of fry to the temperature and salinity of the water in ponds is done by the following manners :

(i) Replace water from the plastic bag as shrimp fry ( *benur*) container with that of the nursery pond water. This is usually done within an hour's time.

(ii) First stock the *benur* in the nursery pond before they are gradually released into the rearing pond.c.The stocking of fry are usually done early in the morning or late in the afternoon and night.

It is interesting to note that some traditional tambak operators in West Java stocked the fry into the pond at noon, although it is not theoritically suggested. This is, therefore, will be affecting to the mortality rate of shrimp during culture period.

### *4.4 Stocking of Fry*

Stocking the pond with shrimp fry involves two main activities, namely seed procurement and the practice of stocking. In the latter two factors are important, these are stocking rate and stocking time.

### 4.4.1 Seed Procurement

The main sources of shrimp fry for stocking are the hatchery and the nature. The first one is mostly applied for shrimp fry and the latter either for shrimp or milkfish fry. The shrimp hatchery supplies approximately 54 to 70 % of tambak in 3 provinces studied. The study revealed that the shrimp hatchery supplies approximately 63.01 %, 65.33 %, aand 70.76 % of tambak in West Java, Central Java and East Java, respectively. The rest of the tambak obtain the fry (shrimp or milkfish) from nature through the middlemen/suppliers. The fry is not always locally available, but some of them are supplied from other places at the a distance of more than 50 kilometers from the tambak location. Those are about 65 % for West Java, 58 % for Central Java and 38 % for East Java.

To some extent the distance affects the mortality rate or quality of fry. Without good transportation facilities, the more longer the distance the higher mortality rate will be. Therefore, the tambak operators usually prefer to buy the fry from the nearby shrimp hatchery or suppliers. But for some reasons, the shrimp fry supplied by those nearby hatchery or suppliers sometimes are inadequate. It forces the tambak operators to get fry from other places. The latter is also happened for other reasons, such as to get better quality and lower price. By experiences or local information sometimes they are able to get good quality of fry at low price. There is also a fact that even at the same location the tambak operators paid different prices for fry. So far the price of shrimp fry vary from one hatchery to the others and from one region to the others. The study indicated that the most intensive farmer have paid lower price than the traditional farmer (see Table 6).

### 4.4.2 Practice of Stocking

The level of technology adopted by the tambak operators can be classified into intensive, semi intensive and traditional systems. For each level of technology, the tambak operators tend to use different culture systems. The traditional tambak operators usually prefer to practicing polyculture and the intensive tambak operators tend to use monoculture systems. Meanwhile the semi-intensive tambak operators tend to do both culture systems, either monoculture or polyculture systems depending on their financial condition.

### 4.4.3 Stocking Rate

Stocking rate ranges from less than 50.000 to more than 100.000 shrimp fry per hectare. For the traditional systems, generally the stocking rate is less than 50.000 shrimp fry/ha, and the intensive systems stocked more than 100.000 shrimp fry/ha. According to the extension service officer the stocking rate adopted by most intensives tambak in Java is about 30 to 40 shrimp fry per square metre or 300,000 to 400,000 shrimp fry/ha. This is not for traditional tambak operators who are usually lack of capital.

### 4.4.4 Stocking Season

The stocking seasons are usually in October and April. These seasons are usually practiced by milkfish culture which has been done in Indonesia for a long time ago.

Compared to milkfish fry where their stocking depend on the fry season, shrimp fry can be obtained any time, especially from hatchery. Due to the field condition, however, the traditional operators still assume that October and April is also the stocking season for shrimp culture. This stocking season is not necessarily applied for the intensive operators since they can stock any time according to their own schedule of harvest. They do not fully depending on nature condition because they are able to manage the production process.

The frequency of stocking, however, is commonly practiced no more than twice a year per unit of pond. Most of tambak operators from different level of management stocked the shrimp fry only once throughout the year, even in the intensive systems (except in Central Java). It was happened for some reasons, such as : the availability of shrimp fry, current price (for shrimp and fry), capital availability, optimum production, etc.

### *4.5 Feeding Practice*

The extensive or traditional culture system of shrimp relies almost completely on natural foods in the pond. Occasionally, supplementary feeding e.g. trashfish, ricebran, and trashfish and ricebran mixed, may be needed when the availability of

*klekap* (natural food) is very limited. To generate the growth of natural food, the tambak operators applied fertilizer into the pond. They use different kinds of fertilizer and methods. In addition that, they are also using and buying fertilizer in different number and prices, even though they are in the same location.It is,therefore, affecting the operational cost of the tambak and its profitability. The field study indicated that the differences in using fertilizer to grow natural food is mainly due to the lack of technological information among them. There are several sources of technological information being used by the operators. There is no any single information acts as a dominant source.

As the stocking rate of biomass increases (more than 5,000 fry/ha) and the cultured species is, obviously the natural food will be limited. It is, therefore, the supplementary feeding needed. The supplementary feeds applied by traditional tambak operators are generally home made (e.g. trashfish, ricebran) rather than manufactured feed (pellet). In practice it is not necessarily like that since they used many kinds of supplementary feeding. In term of the feeding rate per ha, it can be identified that the traditional system is mostly applied it for less than the intensive one. In addition, the most traditional farmer tend to use the low price of supplementary feeding which is usually related to the low quality of feed.

The feeding frequency and the way of feeding practiced by tambak operators are varied from region to region. In general, the feeding frequency is given three times a day : in the morning, noon and evening. During morning and noon times, the feed is usually given at once, except in West Java. In the evening, however, the frequency of given ranged from one to three times. The feeding method adopted by the tambak operators are varied from one level of management to the others depending on their experience and background of technological information. The methods such as spreading or broadcasting the feed into the pond and 'tray' method.

### *4.6 Pest Control*

Saponin and Teodan are mostly applied by of intensive operators to eradicate wild fishes and other undesirable animals. In addition, there are still two other pesticides that mostly applied by traditional and semi-intensive operators (especially in West Java), namely Tridion and others. The intensive operators applied more pesticide in their ponds than the traditional systems except for those in Central Java, since the intensive operators in Central Java using the least pesticides. They only applied pesticide of less than 100 kg/ha. The most dominant pesticide users are tambak operators (i.e. intensive and semi intensive) in West Java, in which more than 47 % of them applied more than 100 kg/ha. Meanwhile, the majority of traditional operators can be considered as the low users of pesticide (less than 50 kg/ha). The price of pesticide varyto the regions. The traditional operators in East Java are mostly bought pesticide at price of more than Rp 700.00/kg.

In other places, meanwhile, the traditional operators have been paying the pesticide at low price (less than Rp 500.00/kg). The low price is normally related to the low quality of pesticide which in turn will affect its effectiveness as a means of controlling pest. This might due to different sources of information in practicing pest control or due to the low purchasing power. It seems that the role of experience and the extension service officer as source of information in South Sulawesi and East Java are more predominant than those in Central and West Java. In the latter provinces books and others seems to be more predominant as source of information in using pesticide. The different sources of information clearly will influencing the operators in determining : the kinds, number of pesticide, and the method of utilization. There is a variation frequency in using pesticide per season which is ranging from one to four times per season. They used pesticide either in dry or wet season without any preference.

## 5. HARVESTING

The cultured species in tambak system can reach marketable size within 4 to 5 months for shrimp and 5 to 6 months for milkfish after stocking. The frequency of harvesting varies either between regions or level of management. In East Java and South Sulawesi (especially for intensive culture systems) harvesting time is practiced twice a year by means of selective method using net, the small (non marketable) size is returned to the ponds for further rearing. While 70 % of traditional culture system in all regions (except East Java), are harvesting their products at once.

There are several reasons to harvest the tambak products. In West Java and Central Java, especially for intensive and semi intensive culture systems, more than 50 percent of the tambak harvest their products when the optimum production has been reached. The reason "Cash money need" has been answered by traditional operators in Central Java and East Java, with percentage of 3.5 and 3.7, respectively.

Draining the ponds or using net are two common methods of harvesting used by the tambak operators. However, there is no specific indication of harvesting method, it varies between regions or between culture systems.

## 6. COST AND RETURN ANALYSIS

### *6.1 Cost Structure*

In operating tambak, intensive culture system required the highest cost as compared to semi intensive and traditional ones. This is so since intensive system almost completely independent of the nature. By stocking relatively high density of fry, it uses not only artificial (formulated) feed, but also the pumps and aeration facilities. On the other hand, traditional system which are largely depended upon natural food propagated in the pond absorbed the lowest cost. However, tambak operators in Central Java who practiced this system still giving feed the shrimp by using artificial feed (such as trasfish, ricebran etc.).

In West Java, the traditional tambak system is completely depending on natural food, since the tambak operators do not applied supplementary feeding to the milkfish. As a consequence, variable costs as well as total costs of this culture system is the lowest as compared to intensive and semi intensive systems. Table IV.20. shows that the absolute amount of total costs for an average one ha tambak per season for intensive, semi intensive and traditional systems amounted to Rp 22,804,912, Rp 7,762,031 and Rp 639,093, respectively.

Variable costs dominated the cost structure in all management culture systems. As much as 96.43 %, 86.56 % and 53.91 % of total costs are absorbed by variable costs in intensive, semi intensive and traditional systems respectively. Unlike in intensive system, hired labour cost in semi intensive and traditional systems dominate variable costs comprising 48.76 % and 35.62 %, respectively. Feed cost in intensive system is the major cost accounting for 69.29 % of total costs.

Proportion of fixed costs and opportunity costs in cost structure for intensive as well as semi intensive systems are quite the same, i.e. about 3.25 % for intensive and less than 7 % for semi intensive. Whereas in traditional system, fixed costs and opportunity costs absorbed 31.24 % and 14.85 % of total costs respectively.

The total costs of tambak operation in Central Java on average one ha tambak per season for intensive, semi intensive and traditional systems amounted to Rp 11,252,683, Rp 4,258,745 and Rp 610,523, respectively. These figures indicate that the more intensive system or the less independency on nature practiced by taambak operators, the higher cost should be paid.

Proportion of variable costs in tambak operation in Central Java is the highest than fixed and opportunity costs. As percentage of total costs, variable costs absorb more than 90 % in intensive and traditional systems, and as much as 82.56 % in semi intensive system. Out of this, about 25 % is spent on purchasing fry. The major component of variable costs is cost of feed accounted for 62.06 %, 54.37 % and 48.04 % for intensive, semi intensive and traditional system respectively. It is interesting to note that proportion of fertilizer cost in cost structure of traditional system is relatively higher than the other two systems. As this culture system relied on natural feed produced in the ponds, it require more fertilizer to grow *klekap*. According to Slamet Suseno (1983), traditional or traditional culture system depends mainly on the natural condition without any assistance from human. In Central Java, however, the practice of tambak operation in this system employes labour as many as intensive and semi intensive systems. The proportion of hired labour cost accounting for 3.33 % is higher than intensive and semi intensive systems.

Fixed costs make up 8.72 %, 16.70 % and 2.75 % of total costs for intensive, semi intensive and traditional systems respectively. For all culture systems, proportion of opportunity costs is very low, accounting for less than 1.00 %.

Like West Java, the tambak operators in East Java who practice traditional system do not feed the milkfish using artificial feeding. The milkfish solely depends on natural food available in the ponds. The total costs on an average one ha tambak per season for intensive, semi intensive and traditional system amounted to Rp 11,584,090, Rp 2,733,785 and Rp 345,230, respectively.

In East Java, management intensity in operating tambak affected not only absolute amount of total costs, but also absolute amount of each cost component. In other words, the absolute amount of each component of cost structure increases as the more intensive management culture practiced.

More than three-fourth of total costs in all management systems is dominated by variable costs. As component of variable costs, purchased fry absorb the highest cost for intensive and traditional systems i.e. 57.80 % and 56.02 %, respectively, while only 27.79 % in semi intensive system. Thehighest proportion in semi intensive system is feed cost accounting for 47.48 %.

Fixed costs consisting of depreciation and land tax are higher for traditional system (16.69 % of total cots) than for semi intensive and intensive systems (16.56 % and 11.03 % of total costs respectively). Proportion of opportunity costs for traditional system is also higher as compared to semi intensive and intensive systems (5.50 % as compared to 3.87 % and 2.51 %, respectively).

### *6.2 Profitability*

The tambak farmers in three provinces observed are able to generate positive operating profit as well as net profit. It means that tambak operation is viable not only in the short-run, but also in the long-run. Furthermore, the tables above show that more intensive system applied, it can generate higher profit. Thus, culture system practiced for tambak operation affects total costs as well as profit earned by farmers.

By practicing intensive system, tambak operators in West Java earn the highest profitability. The calculation in terms of operating profit, net income and net profit, it amounts to Rp 21,000,267, Rp 20,259,589 and Rp 20,186,919 respectively. Although in absolute amount the net profit received by traditional tambak operators is the lowest, the ratio of net profit to gross revenues and to variable costs of this culture system is the highest i.e. 79.56 % and 722.10 %, respectively, as compared to intensive and semi intesive systems. The former indicated that for every Rp 100 received from the sale of the milkfish, tambak operators can obtain a net profit of Rp 79.56. And the latter indicates that for every Rp 100.00 spent on variable costs, the net profit is Rp 722.10. Then, its followed by intensive and semi intensive systems.

The tambak operators in Central Java earn net profits of Rp 26,739,446 (intensive system), Rp 12,374,876 (semi intensive system) and Rp 1,411,548 (traditional system). However, the highest ratio of net profit to gross revenues and to variable costs is generated by practicing semi intensive system, accounting for 74.40 % and 351.97 % respectively.

In East Java, net profit amounted to Rp 41,884,192, Rp 12,222,049 and Rp 422,275 are received by tambak operators who operate intensive, semi intensive and traditional systems, respectively. As like the tambak operators in Central Java, the practice of semi intensive system in East

Java generates the highest ratio of net profit to gross revenues and to variable costs accounting for 81.72 % and 561.85 % respectively. It indicates that farmers who practice this culture system is the most efficient in using inputs. It is followed by intensive and traditional systems.

The comparison among provinces under the culture systems is also carried out in this study. It shows that although tambak operators in East Java who practice intensive system uses the lowest inputs, which is represented by the lowest variable costs, they are superior in generating profit as compared to other provinces. Thus, rate of return of this province is also the highest. It indicates that productivity per unit input in this province is the highest.

By selling the shrimp and milkfish, tambak operators who practice semi intensive system in Central Java receive the highest profitability on an average one ha tambak per season. The rank is then East Java, West Java. However, the highest rate of return in terms of ratio of net profit to gross revenues, to variable costs, to fixed costs and to total costs, is received by tambak operators in East Java. It means that as compared to other provinces observed, tambak operators in East Java use inputs more efficiently.

In practicing traditional system, farmers in West Java and East Java do not feed the milkfish using artificial feed, as mentioned before. In calculating profit, however, there is an interesting information as farmers in West Java are able to generate the highest net profit of Rp 2,488,090 while tambak operators in East Java earn the lowest net profit amounting to Rp 422,275. Furthermore, tambak operators in West Java are also superior in generating the highest ratio of net profit to gross revenues and to variable costs accounting for 79.56 % and 722.10 %, respectively.

## 7. GENERAL DISCUSSIONS

### *7.1 Level of Management and Technology Adaptation*

During the past few years, there have been rapid development in tambak management in most tambak areas of Indonesia. One of the main reasons is the increase of international demand for shrimp production. Many tambak for milkfish are converted into tambak for shrimp, especially of *Penaeus monodon*. The government also persuades tambak operators to increase their productivity through some policies e.g. loan scheme for tambak operation (*TIR = Tambak Inti Rakyat*), training and information aids. Due to the promising price of shrimp in international market, many investors are interested in looking for tambak to be used for shrimp cultivation. This tendency in the short time rises new rich people from tambak operation. But this situation does not last for longer time. Some new comers in tambak operation fall in bankruptcy, since their experience is very limited besides there is sharp fluctuations in the price of shrimp. Shrimp hatcheries shortly became a new promising industry too. And due to the excess supply of benur (shrimp fry) the price of benur dropped. Due to the high demand for shrimp feed, the price of that feed increases sharply. This situation drives investors to set-up shrimp feed factories. Fortunately, these shrimp feed factories commonly are still survive.

The strong or big investors are usually more successful in operating shrimp tambak intensively. They may invest large money in tambak infrastructures and working capital as well. For newly built tambak, their productivity is increasing for the first two or three years, but decreasing again afterwards.

It seems that there is no serius problem in intensive tambak operaration, running hatcheries and shrimp feed factories as well, since in the beginning many of them employed foreign technicians such as from Taiwan and the Philippines. But for small tambak holders the absorption of this new technology does not rapidly happen. They could not afford employing technicians due to the lack of capital and the level of education. Up to now, the extensive or traditional tambak operation is still going on. Commonly, these traditional tambaks are used to cultivate milkfish ( *Bandeng*) as monoculture or as polyculture in combination with shrimp at low stocking density.

### *7.2 Externalities of Tambak Operation*

The rapid conversion of milkfish tambak to intensive shrimp tambak causes some main problems for local (former) tambak operators, social and ecological balances, as well as unexperienced new tambak investors. During the dry season, the water temperature may increase, especially in the shallower part of the pond. For instance, it can be seen in the conversion pond of intensive systems in Java (Brebes region). Providing a deeper pond bottom in this systems remedies the situation and serves as a hiding place for shrimp during a critical pond condition. When necessary, each pond compartment in intensive shrimp culture should have individual water supply and drainage outlets to make them independently from each other and therefore ecological balance in the systems can be sustained. Here, again, the strong aor big investors may much more easily make such adaptation than small tambak holders.

The raid of urban investors to buy or longterm rent for tambak may increase the proportion of landless people in the rural tambak areas. In the short period the former tambak owners become rich which drive their consumeristic consumption pattern. Many of the suddenly rich people could not used their money economically, such that they became poor again. On the other side, still many rural people did not get these windfall profit and were in poor condition. This social imbalance is not easily solved within the short time.

Some types of criminality tends to increase. The robbery of shrimp while in the ponds by force harvesting are more frequently happened. Most of intensive tambak operations have some guards to prevent the robbery or theft, but it may increase the cost of tmabak operation.

The burden of natural environment is becoming heavier. Some mangrove forests are spoilt to provide more land for tambak cultivations or other usages. The rest of shrimp feed and pesticides may deteriorate the quality of water in the surrounding areas. The low condition of the rural roads become worse due the heavier traffic in connection with activities in tambak operations.

### *7.3 Alternatives of Tambak Operation System*

The widely spread of intensive tambak in nearly all main tambak regions combined by the high stocking density of benur on the one hand is able to increase the profitability of tambak operation through the increase of production, but on the

others hand they have some diseconomies. The disturbance to the ecological balance of tambak systems is heavily predominated in some areas. Recent experience in the failure of shrimp cultivation due to the 'virus' epidemy can be exposed as a good example.

The growth of intensive tambak operation should be consistently controlled, especially for densely populated areas like in Java. However, there is natural power helping to do this job, i.e. through the decrease in benur stocking density because of the need to reduce the cost of feed and benur as well. Nowadays, many intensive tambak operation have reduced the high stocking density to the medium level in accordance with adopting most appropriate technology. Eventhough, there is a fall in their profit, many intensive tambak operators are forced to do so to avoid bigger losses by the high fixed cost.

By the reduction in stocking density, in terms of the number of shrimp fry (benur) planted, the management level tambak production would be regarded as semi-intensivesystems. The use of feed and pesticides are not so abundance such that the impact to the natural environment is not so heavy. It sounds that this level of technology adoption becoming the more appropriate technology for most shrimp tambaks in Java and South Sulawesi.

The profitability of semi-intensive tambak is not so high, but usually the risk of failure is also low. And, due to the lower working capital needed, this level of technology adoption is not beyond the reach of local people. These local people are badly needed for protection, otherwise the social turmulence or chaos may occur.

The intensive tambak operation with the main goal to reach high productivity of tambak per se, is still very needed in some selected tambak areas. It seems that the size or scale of intensive tambak operation do not have strong influence to the profitability of those tambak. The large scale tambak operation is rarely met. Most intensive tambak operation can be classified as small to medium scale of operation.

## 8. SUMMARY AND POLICY IMPLICATIONS

The results of this present study indicate that the husbandry management of tambak operation in north coast of Java vary from one region to another and levels of management (traditional, semi-intensive and intensive). This variation may have generated differences in cultured species performance i.e. milkfish and shrimp. It is, however, appreciated that a major limitation of the field study conducted is that the starting materials (inputs) to the systems e.g. stocking density, food and feeding practice, water quality management, pest control and harvesting method for the reaaring cycles recorded will have been very heterogenous from one region to another. These differences, therefore, make strict comparisons impossible and only generalizations can be made.

In general, environmental rearing conditions e.g. temperature, salinity, pH, DO in each level of tambak system (traditional, semi-intensive and intensive) varied. Among observed environmental variables, temperature, salinity, soil texture, and quality and water control structure seem to have a significant role in determining cultured species performance. This is obviously, in turn, influencing the production level in each tambak culture systems during field study.

In most tambak systems in Java no attempt has been made to maintain constant rearing temperatures and salinities. Tambak systems are allowed to remain at the temperature and salinity of the incoming sea water. The field study indicates that temperatures and salinities of tambak systems in Java vary considerably depending upon the season of the year. They can drop as low as 24 - 26 centigrades and 22 - 24 ppt during the peak rainy season and rise to 30 - 32 centigrades and 33 - 34 ppt in the peak dry season. This fluctuation is largely reflected by temperature and salinities in the traditional tambak system. It is, therefore, believed that these environmental variables, together with others such as the husbandry management adopted by tambak operators in each culture systems to have significant roles in determining economic efficiency in tambak enterprise management. These factors, however, are investigated in detail in an attempt to determine economic efficiency for tambak systems in Java.

A key variable suspected of affecting cultured species performance (shrimp) in semi-intensive and intensive tambak systems during the present study is water exchange rate, Most semi-intensive and intensive tambak in Java have adopted so-called "Taiwanese Technique" which is characterized by limited water exchange (10 % - 20 %/day) without disturbing the ecological balanced between larvae, algae, microorganism and organic materials in the systems. Such exchange rate are very low compared to those practiced in the Philippines or Taiwan (30 %/day). Waste products are allowed to

accumulate and decompose in a layer on the tambak bottom. This will obviously generate water quality problems such as increasing levels of ammonia-N and Nitrite-N in the systems as indeed seemed the case in Brebes and Pemalang Counties which is recently invaded by bacterial and viral diseases.

The tolerance of shrimp to ammonia-N-Nitrite-N in tambak systems has not been estimated in Indonesia. Such knowledge might contribute greatly to successful shrimpculture industry in Indonesia. Realizing the importance of this aspect, especially its role in economic efficiency of tambak operation further studies are needed to be done.

The other husbandry parameters that also affecting the economic efficiency of tambak management are stocking density and food and feeding practice. Stocking density is an important faactor that can influence survival aand growth performance of cultured species in tambak systems. The results of this study indicate that with increasing stocking density for intensive culture system, the variable cost will also increase and in turn reduce the ratio of net profit to total costs. It is particularly for the cases in West Java. There is a strong need to determine appropriate stocking density in each management level of tambak systems in Indonesia according to its carrying capacity and productivity level.

As indicated earlier, food and feeding strategies are also one of the parameters that affecting the economic efficiency of tambak management. Food and feeding strategies employed by tambak operators in Java are different. It can be noted that at any one feeding time, the cultured species received several different types of food and that quatity of food given vary from regions to regions. In each level of tambak management, it is often difficult to determine what kinds of food to give, how much to feed and the appropriate time to introduce new feeds (feeding time).

Introducing food at relatively low feeding rate results in cannibalism, while excessive food concentration lead to water quality deterioration and created high mortality. This is quite often the case in semi-intensive and intensive culture systems, as most tambak operators rely upon observation (visual judgement) and experience to determine food and feeding strategies resulting in variation of tambak production. Precise control and regulation of food and feeding strategies in the tambak systems (e.g. semi-intensive and intensive cultures), therefore are particularly important to be done, since they are the most critical husbandry variables in determining the economic efficiency of tambak management and tambak enterprise performance.

In order to optimalize tambak production and economic efficiency, it can be proposed that zonation of tambak areas in Java according to its level of ecological condition and supporting infrastructure in the sites is necessarily to be done. It is especially important to tambak operators e.g. potential investors to determine the selected sites and will significantly affected the tambak enterprise performance.

In conclusion, the optimal rearing conditions and husbandry management practices for tambak operation are still low not completely defined and current rearing practices are very much "rule of thumb". Sufficient scientific data and existing experiences in the field sholud be blended and applied both in apractical and economic way to tambak operation, it would undoubtedly benefit the tambak industry.

# Dynamic Cash Flow Models in Aquaculture: Amplifying the Scope of Managers

**Christopher S. Wright**

Institute of Fisheries Analysis, Simon Fraser University, Burnaby, B.C., USA

ABSTRACT

*Cash flow modeling is a crucial element of successful investment analysis and management. The cash flow models currently available for salmon farms tend to portray fish farm managers as being powerless to manage except in the choice of when to harvest their crop. The limitations of these myopic tools were not important when salmon prices were high and salmon farms could sell all that they could produce. However, as salmon farm profit margins narrow, the need for more powerful and flexible salmon farm management tools grows. Aquaculture, unlike many industries, is not limited to fixed input proportions. The complication of variable input proportions is either a curse or a benefit, depending on a manager's ability. The method of cash flow modeling developed in this paper is more representative of the broad choice of control elements that aquaculture managers have at their disposal. This is accomplished via concepts such as a standard growth function, factor shift functions (for feed ration, water temperature, density, etc.) and the use of bio-age (to free the analysis from the tyranny of the calendar). A well designed cash flow model can be used to simulate a single grow-out cycle of a fish farm. This paper examines various ways that cash flow simulation models can be manipulated and analyzed to provide insights into fish farm management. Selecting and simultaneously solving a few key decision variables over the entire cycle was found to provide a good solution. The information requirements of the cash flow model used in this paper precluded the use of Dynamic Programming.*

## 1. INTRODUCTION

Cash flow modeling is a vital element of successful investment analysis and management. The cash flow models currently available to salmon farms (e.g. Bjørndal, 1990, pp.64-79; Fisheries and Oceans, 1989 and 1990) tend to portray fish farm managers as being powerless to manage, except in choosing when to harvest their crop. However, aquaculture, unlike many industries, is not limited to fixed input proportions.

The variable input proportions that are potentially available in aquaculture can either be ignored (via simplifying assumptions) or managers can accept the more difficult challenge of optimizing over the host of margins that are made possible by varying input proportions.

However, managers can only use the opportunities presented by variable input proportions if they have a means to grasp what happens if specific input proportions are varied by specific amounts. Cash budgets can be adapted to provide that means.

## 2. WHAT IS A CASH FLOW BUDGET

The cash flow budget is a statement of the cash flows due to operations, capital acquisitions and other commitments (paying down of loans, A/P, etc.). Managing cash flows is a vital part of managing an enterprise - a firm that does not meet its cash obligations as they come due goes TECHNICAL BANKRUPT and dies.

A cash budget is (ideally) based on forecast information from all aspects of the enterprise. As a result, if the budgeting process is carefully designed, the cash budget can be a powerful information and evaluation tool for managers.

### *The focus (cost object) of cash budgeting*

A common problem with cash flow budgets in aquaculture is that they define their cost object too broadly[1]. Specifically, cash flow analysis often:

- Encompasses an entire farm or site or (multi-site) company. This melds information from several cohorts and obscures the causal link between outcomes and management choices[2].
- Mixes the effects of investment decisions with the effects of operating decisions. This mix may be of value to potential investors, but it tends to obfuscate the planning and control information needed to operate a farm.
- Hides causal relations in assumptions or formulas and shows only the end cash results of a host of management actions, decisions and/or environmental events.

If managers want to identify and manage the crucial margins in an aquaculture farm, each cash budget should:

i) focus on the progress of a cohort or even a single pen

ii) report only the effects of current operating decisions,

iii) show physical and financial flows, in separate statements (i.e. this provides better management information and provides a means to cross check results), and

iv) distinguish between exogenous factors, decision variables and endogenous variables.

This cash flow approach increases the costs of gathering and rendering operating information. However, it provides a potent source of planning and control information. It should also be noted that, while information gathered at a lower scale (e.g. data on a cohort in a pen) can be combined to provide meaningful information at a higher scale (e.g. the operating results of a farm as a whole or the return on the capital invested in a farm) the reverse process is difficult, if not impossible.

## 3. DEVELOPING A CASH BUDGET TO ANSWER WHAT IF?

The first step in creating a cash flow budget that can answer "what if questions" is to identify the key decision (control) variables. These variables must be optimized simultaneously, rather than iteratively. One way to solve this problem is to;

1. In accouting a *cost object* is a thing or a process for which we want to gather cost information.
2. In biology, a cohort is a group of individuals (within a distinct population), all born during the same time interval.

i) select a single value to be optimized (a proxy),

ii) grid the N-space represented by the feasible set of values for the decision variables,

iii) find the value of the proxy for each grid node, and

iv) identify the maximum or the minimum proxy value in the grid (depending on the nature of the proxy) and use the grid coordinates of that value as the optimum solution.

The number of grid nodes varies exponentially with the number of decision variables and with the tightness of the grid mesh. In this study, there are four key decision variables[3].

If the mesh = 4 ..... nodes = 256 = $4^4$
= 5 ..... nodes = 625 = $5^4$
= 10 ..... nodes = 10,000 = $10^4$
= 100 ..... nodes = 1E8 = $100^4$

As the grid mesh is tightened, the calculation time increases exponentially, but it becomes more likely that the estimated optimum coincides with the global maximum/minimum. However, an optimum is not always the global maximum/minimum. Specifically, in an uncertain world, managers need solutions that are relatively insensitive to minor deviations between the planned and actual values of the decision variables. This desire for well behaved solutions makes an iterative search approach a reasonable way to search for the optimum.

One way of making an iterative-heuristic search for an approximation of the optimum is to;

i) select limits (minimum and maximum values) for each of the decision variables,

ii) use a grid mesh of four, identify the proxy value at each node, select the best proxy value and note the associated coordinates (e.g. the values of the decision variables).

iii) if the improvement in the proxy value is less than two percent of the previous iteration's best proxy value, stop the program and list the coordinates of the current best-proxy-value node, otherwise

iv) reset the upper/lower limit, for each decision variable, one mesh unit above/below that variable's value at the best-proxy-value node and go back to step (b).

This process can be made more elegant if a computer program uses nested loops to:

i) flow from node to node,

ii) compare each node's proxy value with the best previous proxy value examined, and

iii) if the current node's proxy value is better, update the best proxy value and the associated node coordinates.

## 4. WHAT VALUE SHOULD BE OPTIMIZED?

A true optimum involves a multitude of attributes. Managers often express this multitude in the form of a single proxy value. Examples of commonly used proxy values are: NPV (net present value), IRR (internal rate of return), market share, total revenues and average production costs[4].

It is important for decision makers to recognize that, while some proxies are better than others, no proxy is ever perfect. Thus, blindly optimizing a proxy is almost always an inferior substitute for good managerial judgment.

3. Piece Weight at First Thinning, Thinning Rate, Ration (e.g. the conversion rate) and Number of Smolts,
4. Only out-of-pocket costs during the current growth cycle are considered in this analysis - other costs are not relevant because they normally cannot be changed during one growth cycle.

This analysis looks at two proxy values: NPV and PV (present value) average cost. The second proxy provides a minimum risk stance, but fails to maximize wealth. NPV includes the output prices and thus maximizes the expected wealth. However, this strength is also a weakness - a dramatic shift in output prices can make an earlier NPV based strategy a path to calamity.

## 5. THE CASH FLOW MODEL

Details on the mechanics of the cash flow model are available, from the author. The model is designed to meet the criteria in listed in subsection 2.0, and has the following features:

i) Growth is a nonlinear function of the feed ration, water temperature, mean piece starting weight and density. The model is stabilized by first expressing the growth rate as a function of standardized conditions and then using nonlinear indexes to adjust the growth to the nonstandard conditions actually experienced.

ii) The fish are feed a ration based on the ration rate times the expected net growth in kilograms. The expected growth is estimated by converting the period starting weight to bio-age (the age the fish would have achieved that weight under standard conditions and a feed ration of 1).

iii) At low densities, the mortality rate looks constant, but as density increases the mortality rate increases exponentially. Mortality in the first month after smolting is assumed to be five percent.

iv) The piece weight is distributed around the mean weight, the market price ($/kg) varies with piece weight and thinning takes the larger fish, first[5].

v) Only out-of-pocket operating costs during the cycle are considered. Some costs (e.g. wages) have a component that is incurred during a period, even if there are no fish.

vi) The turn-around time for the pens is assumed to be one month and any costs during that month are non-incremental and are excluded from the analysis. Thus, the effective operating cycle is 11, 23 or 35 months. The example model uses a 23 months in a two year production cycle.

vii) Variables are held constant for discrete periods of one month. This simplifies the analysis in this illustrative example. However, in an actual operating situation it may be more appropriate to use discrete periods of one week.

The cash flow model and the driving program (described in subsection 3.0) were programed using Framework IV (1991) - one of the few spreadsheet packages with a programming capability.

A baseline for evaluating results was established by setting the decision variable values at those used by Bjørndal (1990, p.96). Using those values the result is:

Proxy Values: NPV = $603,000 and PV Cost/Kg = $3.331
Decision Variables: Piece Weight at First Thinning = 3.06,
Thinning Rate = 100%,
Ration (conversion rate) = 1.7,
Number of Smolts = 180,000.

## 6. THE RESULTS OF CONSTANT RATE DECISION VARIABLES

One approach to the decision variables is to fix their values over the entire growth cycle. When the decision variables are set so as to maximize the NPV, the result is:

5. The model assumes that more agressive fish grow faster bacause they get mode feed, get bigger, get more feed, etc. The removal of large fish enables smaller fish to get more feed and grow faster - increasing the cycle NPV.
An alternative view is that some fish grow faster because of genetics. If this view is correct, thinning the larger fish may reduce the cycle NPV. Research is needed to determine which effect is dominant.

Proxy Values: NPV = $1,257,000 and PV Cost/Kg = $3.009
Decision Variables: Piece Weight at First Thinning = .71,
Thinning Rate = 6.28%,
Ration (conversion rate) = 1.46,
Number of Smolts = 547,000.

When the decision variables are set so as to minimize the PV of the average cost, the result is:

Proxy Values: NPV = $658,000 and PV Cost/Kg = $2.551
Decision Variables:
Piece Weight at First Thinning = .76,
Thinning Rate = 1.00%,
Ration (conversion rate) = 1.03,
Number of Smolts = 237,000.

*Constant rate decision variables - constrained optimization*

There is a trade-off between the proxies; maximizing for NPV causes costs to rise 18.0 percent over the minimum PV average cost; minimizing the PV average cost reduces the NPV TO 52.3 percent of the maximum NPV. As output price rises, these trade -offs are likely to become greater.

One way of resolving this trade-off problem is to optimize one proxy subject to an inequality constraint on the associated changes in the other proxy.

In Table 1, the first five columns of values represent the efficient frontier of the possible trade-offs between NPV and PV average cost (i.e. return vs risk). Figure 1 illustrates this trade off as an efficient frontier.

This analysis can also be adapted to review a large range of possible strategies. Specifically, a program can be written to record the coordinates of all nodes where the NPV and PC average cost are within prespecified limits. This approach would be particularly useful for *contrarians* (i.e. those who pursue a strategy of not doing what most others are doing)

## 7. PERIOD BY PERIOD OPTIMIZATION

Ideally, decision variable values should be optimized for each period in the growth cycle. However, there are 23 months in a two year growth cycle. Based on the cash flow model associated with best NPV results reported in Subsection 6.1, 15 of the 23 production months have thinning. The thinning rates in those 15 months are all decision variables, as are the ration rate and the number of smolts. A mesh of four lines applied to the 17 decision variables creates 1.7E10 (417) nodes - an unmanageably high number of calculations[6].

Separating the optimization process into period by period segments is difficult - *the opportunity cost* of *harvesting* or *not harvesting* a fish is only fully defined in the last period.

*Period by period optimization - dynamic programming*

A variant of dynamic programming is one way of resolving such problems[7]. However, per feature (d) in subsection 5.0, for any period, the starting mean piece weight depends on the starting population structure. This means that the harvest decision in the prior period must be known in the period under consideration - which precludes the use of dynamic programing.

6. The example model (on an i486, 33MHZ PC using Framework IV, 1991) examines 8.2 nodes per minute and would take just under 4,000 years to do one pass through the nodes.
7. Dynamic programing is a maximization theory that enables one to maximize over a whole series of states (time or other) where the results in each state are dependent to some degree on decisions that have been made in earlier states.
Rather than starting which a known present and planning to an unknown future, *Dynamic Programing* works from a known future point (a budgeted output) toward a malleable present and defines what is needed to acieve the future goal.

Dynamic programming can be used as a planning tool if:

i) The size distribution is assumed away. However, that simplification may eliminate useful information.

ii) The farm does not thin the stock in the months before harvest. However, that simplification may greatly reduce the cycle NPV.

iii) The thinning takes a representative sample of the size distribution of the population. However, that simplification may remove a potentially lucrative effect (feature c, Subsection 5).

Thus, dynamic programming appears to be an inappropriate planning process for the type of cash flow statement used in this study. However, the use of dynamic programming may be appropriate for other types of cash flow statements or conditions.

## 8. PERIOD-SPECIFIC THINNING

Thinning acts as a stabilizing influence (Section 5, feature c). Therefore, it is reasonable to start with the Section 6 optimal result and to optimize the thinning rate for each of the months where thinning takes place. When that optimization process is applied twice, the result is:

Proxy Values: Cycle NPV = $1,276,000 and PV Cost/Kg = $2.951
Decision Variables: Thinning Percent by Month:

| | |
|---|---|
| MONTH 5 Apr. | Cycle Start |
| MONTH 12 Dec. | 3.3% |
| MONTH 13 Jan. | 5.9% |
| MONTH 14 Feb. | 4.1% |
| MONTH 15 Mar. | 4.0% |
| MONTH 16 Apr. | 5.3% |
| MONTH 17 May | 5.9% |
| MONTH 18 Jun. | 7.3% |
| MONTH 19 Jul. | 8.7% |
| MONTH 20 Aug. | 9.6% |
| MONTH 21 Sep. | 9.4% |
| MONTH 22 Oct. | 6.1% |
| MONTH 23 Nov. | 5.8% |
| MONTH 24 Dec. | 5.7% |
| MONTH 25 Jan. | 10.0% |
| MONTH 26 Feb. | 6.1% |
| MONTH 27 Mar. | 100.0% |
| Ration ..... | 1.420 |
| Number of Smolts ..... | 532,000 |

In the example model, this iterative process involved a lot of effort/time and generated a meager 1.5% gain (1276/1257 - 1).

## 9. CONCLUSIONS

Aquaculture managers should seek ways to tap the potential of the cash budget as an information and evaluation tool.

Cash budgets have an immense potential to simulate the complex multiphase situations often found in aquaculture, can use several criteria when seeking budget solutions and can be adapted to show their solutions in a cash flow and/or physical flow form. The use of a cash flow simulation decision tool is also cost effective in that it generates the cash flow budget that would be needed not matter what decision tool is used.

The development and use of a cash flow simulation decision tool helps managers to visualize, in advance:

i) What decision variables are important.

ii) What cash flow and physical flow effects will arise from various decisions.

iii) The timing of when decision need to be made and/or prediction verified.

Actual period by period results can be fed into the cash flow simulation decision tool to rapidly update forecasts and to enable managers to make the best of a bad situation or to make a good situation better.

In the example analysis, the cash flow simulation generated an array of high NPV and low PV average cost solutions (Table 1) where the NPVs were all much higher than the baseline NPV and the PV average costs were all significantly below the baseline PV average cost. It should be noted that the thinning effects that give rise to these solutions would not be apparent in a poorly designed cash flow simulation tool.

Cash flow simulation, ideally, should be used as an aid to explore new ways to manage - it is a tracing board rather than a blue print. This approach of tracing out possible future will be of particular use to Contrarians (i.e. those who pursue a strategy of not doing what most others are doing).

# Elaboration d'un modèle bio-économique dynamique relatif à l'élevage de la palourde de l'Atlantique *(Spisula solidissima)*

**Michel Martin, James R. Wilson, Louise Dufresne, Lucien Adambounou and Roxanne Bouchard ***

Université du Québec à Rimouski 300, allée des Ursulines Rimouski, (Québec), Canada, G5L 3A1

RÉSUMÉ

*Dans la plupart des pêcheries, la sélectivité, à partir de la taille des espèces pêchées, est difficilement applicable. Par contre, en aquiculture, la détermination de la taille pour un marché déterminé constitue un avantage majeur. Toutefois, cet avantage comparatif peut comporter des coûts considérables en terme d'intrants, comme par exemple, l'énergie.*

*La contrainte énergétique est particulièrement évidente dans les pays froids. Afin de minimiser les impacts négatifs de cette contrainte, il serait tout à fait opportun de développer des marchés pour les jeunes individus. En effet, la croissance est beaucoup plus rapide dans les premiers stades de la vie des individus et l'apport énergétique s'en trouve, de ce fait, réduite (toute proportion gardée). De plus, il est envisagé de produire ces individus durant la saison "chaude". (de mars à octobre). Tel que déjà démontré dans la littérature bio-économique des pêches, un propriétaire seul peut choisir de surexploiter une population donnée, et ainsi satisfaire les conditions d'optimalité relatives au taux de croissance du stock et au taux d'intérêt. Le même comportement est observé dans le secteur de l'aquiculture, et pour les mêmes raisons. En aquiculture, les taux d'intérêt élevés aussi bien que les coûts de l'énergie nous incitent à modifier la fonction de croissance d'une espèce et à développer des marchés pour des produits se situant dans la structure d'âge juvénile.*

*Cette analyse explore, notamment, les relations fondamentales entre les coûts de l'énergie, les taux d'intérêt et les stratégies de marketing relatives à la taille, en utilisant les données de croissance en milieu contrôlé de la palourde de l'Atlantique (Spisula solidissima). Pour ce faire, nous utilisons les méthodes dynamiques de programmation linéaire.*

*De façon plus spécifique, l'analyse porte sur les cycles de production optimaux dans un horizon de temps à l'infini, lorsque les marchés existent pour les juvéniles et lorsque les taux d'intérêt et les coûts de l'énergie changent.*

* Nous tenons à souligner la précieuse collaboration de messieurs Louis Bernier et Réal Fournier de l'Institut National de la Recherche Scientifique (Océanologie), Rimouski, ainsi que la participation des étudiants de micro-économie des ressources maritimes, automne 1991.

*D'un point de vue plus pratique et en supposant que les hypothèses soient vérifiées, les stratégies de marketing adoptées par les pays affectés par des coûts d'énergie et des taux d'intérêt élevés, tendront vers la production de juvéniles ; les pays ayant des taux d'intérêt et/ou des coûts d'énergie moins élevés ne seront pas dans l'obligation d'adopter ces stratégies.*

## 1. INTRODUCTION

Actuellement, les stocks de palourdes de l'Atlantique (dans les eaux québécoises) sont à un niveau tel qu'il serait non-rentable et dangereux pour la survie de l'espèce de les exploiter. Quelques auteurs (dont Bernier et Poirier, 1979) ont démontré que l'espèce n'est pas suffisamment dense pour justifier une exploitation commerciale intensive. L'alternative la plus logique serait d'en faire l'élevage soit en milieu naturel, soit en milieu contrôlé, ou les deux. Il a d'ailleurs été démontré (Malouf et Bricelj, 1989) que *Spisula solidissima* est celui qui a le plus fort taux de croissance parmi les bivalves. Bien entendu, la rentabilité d'une telle activité n'est pas démontrée et passe nécessairement par plusieurs variables : prix du produit brut ou transformé, coût de l'énergie, fonction de croissance de la palourde, etc. Ce document consiste donc à dégager ces variables et à analyser la rentabilité d'un élevage de palourde au Québec, en évaluant le comportement dynamique du modèle que nous aurons construit au préalable.

Pour ce faire, il s'agit de mettre en place tous les outils nécessaires afin de réaliser une étude économique portant sur le taux de croissance de la palourde en milieu contrôlé, sur les coûts de production et sur les marchés existants et/ou potentiels. Nous avons, au préalable, développé une technologie d'élevage de la palourde que nous croyons réaliste, et sur laquelle sera basée notre étude. Par la suite, nous utiliserons la programmation linéaire pour déterminer les cycles de production optimaux qui maximiseront la valeur actuelle des profits. Il est aussi prévu d'effectuer une analyse de sensibilité sur certaines variables telles que les taux d'intérêt, les prix du produit brut et les coûts de l'énergie hydro-électrique.

## 2. MÉTHODOLOGIE

Afin de mieux cerner tous les éléments qui composent notre modèle bio-économique, il est opportun de faire une revue théorique des hypothèses qui sont à la base de notre étude. D'abord, nous avons simulé les dynamiques de production d'une entreprise qui fait l'élevage de palourdes dans un horizon de temps à l'infini, c'est-à-dire que cette entreprise existe depuis toujours et qu'elle existera toujours. Nous prenons en quelque sorte une photographie (qui couvre 19 mois, commençant en janvier) de cette entreprise et nous analysons son comportement dans un contexte dynamique (c'est-à-dire que nous débutons une nouvelle cohorte à chacun des 19 mois). Nous pouvons donc, de cette façon, éliminer les biais causés par les investissements de départ et les frais de fermeture au début et à la fin de la vie de cette entreprise.

Ces dynamiques de production se réflètent dans le choix des variables et leur coefficient qui composent la fonction objective et les contraintes de notre programme linéaire. De façon plus pratique, il s'agit de construire sur le logiciel Quattro-pro, un programme linéaire dont les coefficients des différentes variables peuvent être rapidement modifiés. La nécessité d'utiliser l'informatique s'explique par le fait que notre modèle est composé de 646 variables de décision (dans la fonction objective) et de 396 contraintes. Par exemple, il fallait recalculer rapidement tous les coefficients des variables concernées en modifiant le taux d'intérêt de 8 % à 30 % et par la suite, "exporter" le nouveau programme linéaire de Quattro-pro vers Lindo. Ce dernier logiciel permet de traiter les programmes linéaires en maximisant la fonction de profit (dans notre cas) et en déterminant les cycles de production optimaux. De façon générale, l'utilisation de la programmation linéaire dans un contexte dynamique est conceptuellement simple mais implique un grand nombre de calculs mathématiques qui nécessitent le support de certains logiciels.

### *2.1 Le modèle*

Le problème est décrit comme étant :

$$Max \sum_{i=0}^{18} \sum_{j=1}^{17} \sum_{k=3}^{18} - \delta_i(B_i) - C_i(M_i H_j) + R_{i,k}(M_i S_k) \quad \forall i, j, k . \tag{1}$$

Sous contraintes de :

$$\sum_{j=1}^{17} M_i H_j - \sum_{k=3}^{18} M_i S_k \leq 200 \qquad \forall i, j, k \qquad i = 0, 1, \ldots, 18 \tag{2}$$

$$-B_i + M_{i+1} H_j = 0 \qquad i = 0, 1, \ldots, 17 \; ; \quad j = 1 \tag{3}$$

$$-M_i H_1 + M_{i-1} H_2 = 0 \qquad \forall i \; ; \qquad i = 0, 1, \ldots, 17 \tag{4}$$

$$-M_i H_j + \alpha M_{i-1} H_{j+1} + \alpha M_{i+1} S_k = 0$$
$$i = 0, \ldots, 17 \quad j = 2, \ldots, 16 \quad k = 3, \ldots, 17 \quad \alpha = 0.5, 1 \quad k = j + 1 \tag{5}$$

$$-M_i H_{17} + M_{i+1} S_{18} = 0 \qquad i = 0, 1, \ldots, 17 \tag{6}$$

$$M_0 H_j - M_{18} H_j = 0 \qquad j = 1, 2, \ldots, 17 \tag{7}$$

$$M_0 S_k - M_{18} S_k = 0 \qquad k = 3, 4, \ldots, 18 \tag{8}$$

$$\sum_{j=1}^{17} M_i H_j + \sum_{k=3}^{18} M_i S_k \leq 200 \qquad i = 0, 1, \ldots, 18 \tag{9}$$

### 2.1.1 La fonction objective (Équation # 1)

i représente chacun des mois de la période concernée

j représente l'âge (en mois) des individus gardés

k représente l'âge (en mois) des individus vendus

$\delta_i$ représente le prix d'achat actualisé des larves

$B_i$ est la variable qui représente le choix d'acheter ou de produire des larves de palourdes ($2 \times 10^6$) au début de chacune des périodes.

$C_i$ représente les coûts de production mensuels par raceway, pour chacune des périodes, et cela afin garder un inventaire de palourdes ($M_i H_j$). Un raceway est un contenant qui sert à faire l'élevage de mollusques. Ses dimensions sont de 2440 mm de longeur, 920 mm de largeur et 200 mm de hauteur. Les coûts sont fonction de la période (i).

$M_i H_j$ est la variable qui représente le choix de garder un inventaire plutôt que de le vendre. Par exemple, $M_1 H_{16}$ signifie qu'au mois de février, l'on peut garder les individus âgés de 16 mois.

$R_{i,k}$ correspond aux revenus actualisés tirés de la vente de palourdes pour chacun des âges par raceway. Il faudra tenir compte ici de la taille des individus (cf. fonction de croissance).

$M_i S_k$ est la variable qui représente le choix de vendre un inventaire

Dans tous les cas, les choix d'acheter, de garder ou de vendre se font au début de chacune des périodes. La valeur de la fonction objective représente les profits nets actualisés maximaux que peut tirer un entrepreneur faisant l'élevage de la palourde. Ces profits sont tirés des opérations courantes de l'entreprise et ne tiennent pas compte des impôts et de l'amortissement d'un immeuble principal. Ils peuvent être représentés par l'équation suivante :

$$Max\ \Pi_a = R_a - C_a - B_a \tag{10}$$

Afin de bien saisir les dynamiques de production ainsi que le sens de chacune des variables, nous avons diminué la taille du problème de 19 à 4 mois (cette nouvelle situation est purement hypothétique et n'a pour but qu'une meilleure compréhension). La période considérée couvre donc les mois de janvier, février, mars et avril. Tel qu'illustré au tableau 1, cela nous permet d'effectuer les analyses dans une période d'activité normale (où toutes les cellules sont remplies) et ceci afin d'éviter les biais du début et de la fin de la vie de l'entreprise.

On établit la règle suivante : on garde nécessairement les post-larves, les premier et deuxième mois de vie des individus (parce que trop petit pour la vente). Le troisième mois, on peut soit vendre, soit garder les individus qui sont âgés de 3

mois. Le quatrième mois, on vend nécessairement les individus. On remarque que les variables qui sont situées dans les cellules grisées proviennent de cohortes qui ont été débutées avant la période d'analyse. Cela est le résultat de la planification dans un horizon de temps à l'infini ; c'est plus précisément la partie-$\infty$. Dans l'exemple du TABLEAU 1, la fonction objective deviendrait :

$$\text{Max} - \delta_0(B0) - C_0(M0H1) - C_0(M0H2) - C_0(M0H3) + R_{0,3}(M0S3) + R_{0,4}(M0S4) - \delta_1(B1) - C_1(M1H1) - C_1(M1H2) - C_1(M1H3) + R_{1,3}(M1S3) + R_{1,4}(M1S4) - \delta_2(B2) - C_2(M2H1) - C_2(M2H2) - C_2(M2H3) + R_{2,3}(M2S3) + R_{2,4}(M2S4) - \delta_3(B3) - C_3(M3H1) - C_3(M3H2) - C_3(M3H3) + R_{3,3}(M3S3) + R_{3,4}(M3S4)$$

ainsi $\delta_i = 500/(1+t)^i$ et $\delta_i$ = Prix d'achat des larves, actualisé.
$C_i = C_i/(1+t)^i$ $C_i$ = Coût selon le mois i, actualisé.
$R_{i,k} = R_k/(1+t)^i$ $R_{i,k}$ = Revenu à l'âge k, actualisé.

De cette façon, les coefficients des variables de la fonction objective sont facilement modifiables. En changeant, par exemple, le taux d'actualisation de 8 % à 7 %, tous les coefficients des variables de la fonction objective sont presque aussitôt modifiés, puisque les cellules sur Quattro correspondent à des formules mathématiques et sont reliées entre elles.

### 2.1.2 Les contraintes

Les contraintes sont divisées en 4 principaux groupes .

- Tout d'abord l'**équation # 2** fait référence à la disponibilité des ressources matérielles. On considère ici que l'on ne peut opérer que 200 raceways (ce qui est plausible, compte tenu de la technologie retenue. Le fait de garder le contenu d'un raceway en inventaire pour un mois additionnel, implique que le nombre de raceways disponibles est réduit d'une unité. Par contre, l'action de vendre le contenu d'un raceway libèrera ce raceway pour être utilisé ultérieurement.

- Le deuxième groupe de contraintes (**les équations #3, #4, #5 et #6**) sont les équations de transfert entre les périodes. Elles expliquent le rôle de la fonction de croissance et l'impact qu'a cette fonction sur la planification du calendrier en ce qui concerne le partage des individus d'un raceway vers d'autres raceways. Dans cette optique, on doit interpréter $\alpha$ comme la règle suivante : A partir de 1 mm, à chaque fois que la taille des individus double, nous dédoublons les raceways où $\alpha = 0.5$ (L. Bernier). Dans tous les autres cas, $\alpha = 1$. Les objectifs visés par ce groupe de contraintes sont de "suivre" les individus entre les périodes et de maximiser l'espace disponible de chacun des raceways.

- Le troisième groupe de contraintes (**l'équation #7 et #8**) concerne les conditions initiales et terminales (i.e. inventaire et vente au début et à la fin de la période de référence). Dans le contexte de la programmation linéaire, le choix des conditions initiales et terminales de notre problème pose un difficulté théorique. Il a été démontré (cf Wagner, 1977) que des spécifications arbitraires des conditions initiales et terminales impliquent également une valeur arbitraire de la fonction objective (en valeur actuelle nette des profits), ainsi que du cycle de production optimal. Ainsi, un modèle dont les conditions initiales seraient différentes des conditions terminales, n'aurait pas d'utilité pour la gestion. Les recommandations de McCarl et Spreen (1989) semblent appropriées dans ce contexte. Ils suggèrent d'égaler les conditions initiales et terminales de façon à les rendre moins contraignantes ; dans notre cas, l'inventaire et les ventes du début sont égaux à ceux de la fin et cela pour chaque cohorte.

- Le quatrième groupe de contraintes (**l'équation #9**) est aussi relatif à la disponibilité des ressources. Sans ces contraintes, nous aurions obtenu un très grand nombre de raceways dû au dédoublement de ces derniers. Cette équation limite à 200 raceways les opérations de garde, de vente et de dédoublement de raceways.

## 3. LES RÉSULTATS

### *3.1 La fonction de croissance*

Pour répondre plus adéquatement à notre question de rentabilité, il fallait développer une fonction de croissance de la palourde, à partir de données limitées. L'unité de mesure des transactions étant le $U.S. par boisseau (le boisseau est une

mesure de volume et est égal à 36,36 l.), il nous faut connaître la taille (longeur), la largeur et la hauteur des individus en fonction de leur âge. Il est donc essentiel d'estimer une fonction de croissance en milieu contrôlé et pour ce faire, nous avons utilisé les données brutes de la Station aquicole de Pointe-au-Père (les 55 premiers jours après fécondation) ainsi que celles de Goldberg (1980) pour compléter la série de données jusqu'à un an. La régression non-linéaire (à partir du logiciel NCSS) a été utilisée pour estimer le modèle de Richards (figure 1) et la forme générale est :

$$L_t = A * [\, 1 + (B - 1) * e^{-c * (t - D)} \,]^{\frac{1}{1 - B}} \qquad (11)$$

où
$A = 106.5 \quad 6.1$
$B = -0.57 \quad -1.6$
$C = 0.0019 \quad 1.8$
$D = -121.6 \quad -0.5$

$L_t$ est la taille à l'âge t, A est la longeur asymptotique et C est le taux de croissance.

*3.2 Les revenus*

Les revenus tirés de la vente des palourdes sont fonction de la taille des individus (selon le modèle de Richards) ainsi que de la mortalité et des manipulations lors des tamisages. L'estimation de la mortalité est d'au moins 75 % durant la période larvaire (de 0 à 21 jours). Les données prélevées (L. Bernier, 1992) à la Station aquicole nous indiquent que l'écart-type de la taille des palourdes est très prononcé. Cela justifierait un taux de perte élevé (25 % jusqu'à 11 mois et 5 % de 12 à 18 mois) lors des tamisages. Ces taux incluent aussi les individus morts qui ont été rejetés aux tamisages. Les cylindres de 275 mm. ont été utilisés pour l'élevage en monocouche des palourdes. 24 cylindres peuvent être placés dans chacun des raceways pour une superficie totale disponible de 1,425,500 mm.ca. Il est aussi suggéré que l'espace occupé par les palourdes ne doit pas dépasser cette dernière mesure. L'on doit toutefois s'en rapprocher le plus possible afin de maximiser l'espace disponible. Le Tableau 2 illustre les opérations nécessaires à l'évaluation de la valeur d'un raceway en fonction de la taille des palourdes. Le prix obtenu pour un boisseau de palourdes (peu importe la taille) est d'approximativement $85.00 US. On ne tient pas compte ici de la saisonnalité des prix.

*3.3 Les coûts de production*

Outre l'achat des lots de larves (à $500.00 du lot), nous pouvons classifier les coûts de production en 4 catégories. Les coûts de l'énergie hydro-électrique, les coûts de la main d'oeuvre, les coûts de production de phytoplancton et nourriture lyophilisée ainsi que les coûts du matériel et entretien général. Il est à noter que nous avons estimé tous les coûts afférents à un système de production performant. Les coûts mensuels suivants ont été estimés pour l'ensemble des 200 raceways :

i) Énergie hydro-électrique : entre $777. (juillet) et $2,590 (janvier)

ii) Main-d'oeuvre : $6,000.

iii) Phytoplancton et algues lyophilisées : $1,252.

iv) Matériel et entretien général : $1,762.

Le Tableau 3 est relatif aux coûts de production par raceway et pour chacun des mois de la période de référence.

*3.4 Sommaire des résultats*

La valeur de la fonction objective (ou profits actualisés maximaux) est de **$2,519.** pour un taux d'actualisation de 8 %. Ce dernier montant est insuffisant pour "rencontrer" les amortissements sur l'immeuble principal, payer les impôts et effectuer un réinvestissement éventuel des profits dans l'amélioration du système de production. Par ailleurs, selon le cycle de production illustré à la figure 3, il serait illogique d'initier un élevage de palourde. En effet, acheter un lot de larves au mois 12, et vendre des individus âgés de 6 mois aux mois 0 et 18 ne constitue pas un cycle de production

intéressant. Nous remarquons aussi que les palourdes ne sont vendus qu'à l'âge de 6 mois. Cela est principalement dû au fait qu'il y a un dédoublement de raceways au $7^{ième}$ mois et que, par conséquent, la valeur ($45.64) d'un raceway au $6^{ième}$ mois est plus grande que la valeur ($33.11) au $7^{ième}$ mois. L'effet du taux d'actualisation ainsi que les coûts de production plus élevés durant les mois "froids" influencent aussi la décision de vendre des juvéniles âgés de 6 mois. Dans les conditions actuelles, le projet est **non-rentable**.

## 4. ANALYSE DE SENSIBILITÉ

Dans le but d'éprouver la validité du modèle et de connaître la sensibilité de certaines variables, nous ferons varier certains paramètres. Par exemple, en diminuant les coûts de l'énergie hydro-électrique de 50 % (on peut imaginer l'utilisation de capteurs solaires), les profits passent de $2,519 à $3,074. Cela représente un coefficient d'élasticité de -0.44, et le cycle de production demeure le même que précédemment. Cette variable est très peu sensible et le projet n'est toujours pas rentable. En augmentant le prix de vente de 50 % (de $85 à $127.50), les profits augmentent à $11,271., et le cycle de production est le même. Le coefficient d'élasticité est de 6.95. Cette variable est donc beaucoup plus sensible que les coûts d'électricité et les profits commencent à être intéressants. Le cycle de production est toujours inintéressant.

Dans un autre ordre d'idée, il peut être opportun de simuler les conditions qui prévalent dans certains pays en développement. Les coûts d'énergie et de main-d'oeuvre y sont souvent plus bas et les taux d'intérêt plus élevés (ou très variables). Nous considérons ici une espèce différente de *Spisula solidissima*, mais ayant des caractéristiques semblables. En diminuant les coûts de production de 50 % (par rapport aux données du Québec) et en conservant un taux d'actualisation de 8 %, nous enregistrons des profits de $26,807. et le cycle optimal est illustré à la figure 4 (les chiffres au-dessus des histogrammes correspondent au nombre de raceways vendus). Nous sommes déjà dans la voie de la rentabilité et la production se fait de façon plus continue. En conservant des coûts de production diminués de 50 % et en augmentant le taux d'actualisation à 50 % (taux souvent rencontré en Amérique du Sud), notre profit est de $19,512. et le cycle de production est illustré à la figure 5. Il est intéressant de constater que la production a tendance à se "contracter" sur une plus courte période.

## 5. CONCLUSION

On ne peut que constater la non-rentabilité d'un élevage de palourdes dans un pays où les coûts de production sont élevés et surtout où la valeur marchande de ce produit est faible. Quelques alternatives sont à considérer. Par exemple, il serait possible de débuter les opérations en milieu contrôlé et de les terminer en milieu naturel. Les coûts de production seraient alors diminués ; par contre, la croissance des individus diminuerait (voir le modèle de Von Bertalanffy de la figure 2). Il serait aussi avantageux de développer des marchés de consommation où la valeur serait augmentée. Du seul point de vue de la programmation linéaire, il est optimal de vendre des juvéniles âgés de 3 cm (ou 6 mois) mais cela peut ne pas correspondre aux besoins du marché. Par exemple, le marché de "frais" est plutôt orienté vers les juvéniles de 5 cm (ou 11 mois). En "forçant" la vente d'individus plus âgés, nous réduirions alors la valeur de la fonction objective, ce qui est non souhaitable.

Dans les pays "chauds", l'élevage d'une espèce apparentée à *Spisula solidissima*, peut toutefois être rentable. La programmation linéaire nous suggère alors de produire des juvéniles dans un court laps de temps, lorsque les taux d'intérêt sont élevés. Dans les deux cas, il semble que le prix de vente des palourdes soit le facteur déterminant dans la recherche d'une plus grande rentabilité. Dans le secteur de l'aquiculture, il apparaît que l'utilisation d'une technologie avancée et coûteuse trouve sa justification dans la mise en marché d'un produit de haute valeur.

# A Model for the Optimal Management of Sea-Bass Aquaculture

**Gian Franco Rizzo and Massimo Spagnolo ***

IREPA Via Benedetto Croce, Italy

ABSTRACT

*A bio-economic model for the simulation and the optimal management of a plant for Sea-Bass aquaculture is presented. Growth and mortality, considered as a Markovian process, are described by a biological sub-model, taking into account the effects of water temperature, feeding level, oxygen content and water supply. Stochastic effects in growth and mortality, relating to the effects of genetic differences, can be also considered in the model. An economic sub-model evaluates costs and revenues relating to plant management.*

*The model exhibits satisfactory capabilities in predicting the effects of operating variables on fish growth and in determining the optimal strategies for plant management in different scenarios.*

## 1. GENERAL

In recent years, many applications of mathematical models to aquaculture management have been described in literature. General overviews are reported by Leung [1986] and Piedrahita [1988]. A model for simulation and optimal management of salmon aquaculture is described by Bjorndal [1990]. A prawn production management system has been modeled by Leung and Shang [1989], within a dynamic Markov decision approach. Similar methods have been adopted for the optimization of production planning in trout farm [Sparre]. Other models have been applied to social and economic aspects of aquaculture activity [IRPAI, 1990].

An important contribution to the study of sea-bass aquaculture has been given by Querellou [1984], which has proposed simple relationships among growth, mortality and water temperature, for sea-bass populations. This model, not even

* the authors wish to express their gratitude to G. Bonfiglio and F.Massa (AGEI, Rome) for their cooperation in this research.

considering all the physiological and biological aspects involved, can predict with acceptable precision growth and mortality in typical plants. Nevertheless, it does not represent a tool directly usable to define optimal management strategies, since it does not consider all biological, operating and economic aspects involved in sea-bass aquaculture.

The models described in literature, applied to different species, exhibit significant differences in structure and complexity. It emerges the unavailability of a model directly usable for the optimal management of aquaculture plants for species like sea-bass and sparus aurata and, moreover, of any comprehensive model able to represent all aquaculture systems.

A model for the simulation and optimization of sea-bass aquaculture plants has been then proposed, composed of a stochastic Markovian biological sub-model and an economic sub-model. The biological part is based on the model proposed by Querellou [1984], integrated by further relationships to consider feeding levels, oxygen consumption and additional mortality due to harvesting and fish-pond transfer. This base model has been then included in a stochastic model, in order to describe growth and mortality variability due to genetic and environmental conditions through a Markovian transition matrix. An economic sub-model expresses revenues due to harvesting and costs for stocking, food, water supply, auxiliary oxygenation, water heating and fixed costs.

## 2. A MODEL FOR SEA-BASS AQUACULTURE

The model is based on a biological sub-model, obtained starting from the relationships validated by Querellou [1984], which essentially describes the effects of water temperature on growth and the physiological mortality. This model has been integrated by further relationships in order to consider feeding levels, oxygen consumption and additional mortality relating to pond transfer. The model takes also into account stochastic effects on growth due to genetic and environmental factors according to a Markovian process [Leung and Shang, 1989, Sparre]. An economic sub-model describes revenues and the most relevant costs relating to aquaculture management, i.e. recruits, feeding, water and oxygen supply, water heating, fixed costs. The model, which can be used for both simulation and optimization analysis, is formulated according to the following assumptions :

(i) A population of sea-basses is considered, distributed in different ponds according to weight classes. The entire process is described, starting from recruitment of fries. Multiple production cycles can be also considered.

(ii) Time horizon is divided in periods in which both external variables (temperatures, prices, costs) and decision variables can be considered constant. The presented results refer to a time horizon of 2 years, divided in 24 periods of one month.

(iii) It is assumed that a whatever fraction of the biomass contained in the last $N_c$ weight classes can be harvested, and that it can be sold at a variable price independent on the supplied biomass. An additional mortality, proportional to the harvested biomass, is considered for the fish left in the ponds.

(iv) The recruits exhibit homogeneous genetic behavior and weight distribution, and their price is independent from demand.

(v) Each fish pond is defined by a minimum and a maximum weight class; biomass which exceeds maximum weight can be transferred to the next pond with continuity, in each period. An additional mortality affects the transferred biomass.

Fish farming process can be depicted as a multi-stage dynamic system (fig.1) where each stage represents a period of the process. For the K-th stage, output variables $L_k$ and state variables $x_{k+1}$, input for the next stage, are determined as a function of external variables $v_k$, decision variables $u_k$ and state variables $x_k$.

Fig 2 shows the detailed structure of an elementary stage with the relationships among external decision and state variables on the biological, technical and economic aspects.

### *2.1 The biological sub-model*

The following relationships hold for the average weight of a sea-bass population [Querellou, 1984] :

$$P = k\,(S_{01})^x \tag{1}$$

where :

$$S_{01} = \sum_{i=t0}^{tl} T'_t$$

with $t_0 = 0$, $t_1$ = fish age

$k = 0.9\ 10^{-8}$, $x = 2.81$, $T' = (T - 10)/\omega$,

with $\omega = 1$ if $T > 10$ and $\omega = 5$ if $T < 10$

The term $S_{01}$ represents the sum of the daily temperatures T' in the period $t_0$-$t_1$. The equation (1) can be rearranged in order to evaluate the weight $P_2$ at the time $t_2$, starting from the weight $P_1$ at $t_1$ and from the term $S_{12}$ referring to the daily temperatures T' between $t_1$ and $t_2$ :

$$P_2 = k(S_{02})^x = k(S_{01} + S_{12})^x$$

Where $S_{01}$ can be evaluated as

$$S_{01} = (P_1/k)^{1/x}$$

In order to take into account the effects on growth of the feeding level $F_m$ (see par.2.6.), a further term ($F_m$) has been considered, not present in the original relation proposed by Querellou :

$$P_2 = k(S_{01} + S_{12})^x\ \phi(F_m) \tag{2}$$

A simple linear relation with feeding level has been assumed :

$$\phi(F_m) = F_m \tag{3}$$

The followed approach is consistent with the assumption of Markovian process. That is, the growth, in a given period, depends only on the environmental variables (temperatures, feeding) in that period and on the initial fish weight (state variable), irrespective of how long each fish used to reach the initial weight $P_1$. The Markovian assumption is enough realistic in typical and well-kept fish farms and has been commonly adopted by other modelers [Sparre, Leung and Shang, 1989].

With regard to mortality, one should distinguish between a mortality due to particular pathologies and a physiological one. The former is not considered in the present model, since it substantially influences growth mechanism and requires ad hoc remedies. The monthly amount of physiological mortality is estimated by the following relationship :

$$TM_1 = a/N^b/100 \tag{4}$$

Where N is the fish age (months), a is the mortality rate for the first month and b is an exponent relating to fish farming conditions. The following values have been suggested for sea-bass aquaculture [Querellou, 1984] :

$a = 4$, $b = 1.17$ (optimal conditions)
$a = 7$, $b = 0.7$ (poor conditions)

Fish age can be computed from its weight $P_1$ by the relationship :

$$30\ N\ (\overline{T} - 10) = S_{01} = (P1/k)^{1/x} \tag{5}$$

Where T represents the average temperature in the period $t_0$ $t_1$. Physiological mortality coefficient $TM_2$ and $TM_3$ express mortality due to harvesting and to fish transfer between ponds ; they are proportional respectively to the fractions of harvested and transferred biomass in the previous period :

$$TM_2 = B_c / B_k \chi_2 \tag{6}$$

$$TM_3 = B_{tr} / B_k \chi_3 \tag{7}$$

The total mortality coefficient $TM_T$ can be then evaluated, for each weight class :

$$TM_T = TM_1 + TM_2 + TM_3 \tag{8}$$

The mortality probability in the given period is :

$$P_m = TM_T N_g / 30 \tag{9}$$

*2.2 The Markovian matrix*

Mortality and transition from a weight class to others are described by a two dimension Markovian matrix M, where $M_{i,j}$ indicates the probability that fish belonging to i-th weight class will grow to the j-th class during a given period and $M_i$, $N_{cl}$ represents probability of death. It is assumed that in each period, fish can either stay in the same class, grow to a larger class or die. Therefore, only the terms $M_{i,j}(i \leq j \leq N_{cl+1})$ are greater than zero and their sum is 1.

Matrix M has been evaluated considering normal distribution of weight P around its average value provided by (2). For a given standard deviation SD and for the weight classes $j \geq i$, the area $A_j$ subtended by probability curve which lies in the j-th class can be evaluated.

Probability $p_j$ is proportional to area $A_j$. In order to avoid that unrealistic growth velocities can be considered for an even small part of the biomass, the probability $p_j$ corresponding to areas less than a threshold values $c_3$ are considered zero. Therefore :

$$\begin{aligned} p_j &= 0 \quad \text{if } j < i \\ p_j &= A_j \quad \text{if } j \leq i \text{ and } A_j \geq C_3 \\ p_j &= 0 \quad \text{if } j \leq i \text{ and } A_j < C_3 \end{aligned} \tag{10}$$

Standard deviation SD is computed as :

$$SD = c_1 \Delta P_i + C_2 (P - P_i) \tag{11}$$

where $P_i$ and $\Delta P_i$ are average weight and width of the i-th class and P is the weight at the end of the i-th period. SD is then composed of two terms : the former is proportional to weight class width and reduces the effect of discretization, due to the fact that the average weight $P_i$ is associated to all the biomass in the i-th class ; the latter term is proportional to the predicted growth, and then represents the scattering due to environmental and genetic differences.

The terms of Markovian matrix for the given i-th weight class are then computed by the following relationships :

$$M_{i,j} = 0 \qquad j < i \tag{12}$$

$$M_{iJ} = (1 - p_m)\, p_j / \sum_{k=1}^{N_{cl}} pk \qquad j = i, \quad N_{cl} \tag{13}$$

$$M_{i,\, Ncl+1} = p_m \tag{14}$$

*2.3 Biomass evaluation*

The following data are considered known :

- the number of the weight classes $N_{ci}$ and their upper limit ; the average value is :

$$P_i = (P_i^* - P_{i-1}^*) / 2 \qquad (P_0 = 0) \tag{15}$$

- the number of fish ponds $N_v$, their volume $V_{v,j}$ and the minimum and maximum weight class referring to each fish pond ;

- the maximum allowable density per pond $\delta_{max}$ ;

- the weight distribution $F_{st,i}$ for the recruits among the first $i_{st}$ classes :

$$\sum_{i=1}^{i_{st}} F_{st,i} = 1 \tag{16}$$

$$F_{st,i} = 0 \qquad i = i_{st} + 1, N_{cl} \tag{17}$$

- the minimum class for harvesting $i_c$ ;

- the length of a period $D_p$ and the number of periods $N_p$ considered in the time horizon ;

- the distribution of temperature $T_k$ and fish prices $Pr_k$ in the $N_p$ periods ;

- the distribution of the decision variables in the $N_p$ periods (harvesting levels $\alpha_k$, stocking level $\beta_k$, feeding level $I_K$, pond temperature increase) ; in case of optimization analysis, these values are assumed as initial values for the iterative process leading to the optimal values ;

- biomass $B_1$ at the beginning of the process and the vector $x_{i,1}$ describing the initial fish distribution among the $N_{cl}$ weight classes ; it holds :

$$\sum_{i=1}^{N_{cl}} x_{i,1} = 1 \tag{18}$$

- the daily amount of food to furnish, as a function of fish weight and water temperature ;

- unit costs for feed $C_m$ and recruits $C_{st}$ .

The initial number of fishes $S_1$ can be evaluated as :

$$S_1 = \frac{B_1}{\sum_{i=1}^{N_{cl}} x_{i,1} P_i} \tag{19}$$

While the number of fishes $S_{i,1}$ in the i-th class at the start of first period is :

$$S_{i,1} = S_1 x_{i,1} \qquad i = 1, N_{cl} \tag{20}$$

For the k-th period, fish distribution in weight classes is represented by $x_{i,k}$, which is the ratio between the number of fishes in the i-th class at the k-th period and the total number $S_1$, at the beginning of the first period :

$$x_{i,k} = S_{i,k}/S_1 \tag{21}$$

The total number of fishes $S_k$ at the beginning of the k-th period is :

$$S_k = S_1 \sum_{i=1}^{N_{cl}} x_{i,k} \tag{22}$$

where the sum of $x_{i,k}$ can differ from unit, due to the presence of stocking, harvesting and death. Stocking can occur at the beginning of each period ; fish distribution after stocking is expressed as a function of stocking level $\beta_{i,k}$ :

$$x_{1,k,1} = x_{1,k}(1 + \beta_{i,k}) \tag{23}$$

and the stocked biomass is :

$$B_{st} = \sum_{i=1}^{I_{st}} x_{1,k}\,\beta_{i,k} \tag{24}$$

Fish distribution at the end of the period is computed according to the Markovian matrix M, which accounts for growth mechanism and mortality :

$$x_{1,k,2} = \sum_{j=1}^{I} x_{1,k,1}\,M_{j,1} \tag{25}$$

The final fish distribution is then computed considering harvesting, concentrated at the end of each period :

$$x_{1,k+1} = x_{i,k,2}\,(1 - \alpha_{i,k}) \tag{26}$$

Where the harvesting level is zero for the classes with index lower the minimum harvested class $I_c$. The number of fishes harvested in the k-th period $S_{c,k}$ is :

$$S_{c,k} = S_1 \sum_{i=1}^{N_{cl}} x_{i,k,2}\,\alpha_{1,k} \tag{27}$$

and the corresponding biomass $B_{c,k}$ is :

$$B_{c,k} = S_1 \sum_{i=1}^{N_{cl}} x_{i,k,2}\,\alpha_{1,k} P_1 \tag{28}$$

Accordingly, for the stocked fish is :

$$S_{st,k} = S_1 \sum_{i=1}^{N_{cl}} x_{i,k}\,\beta_{i,k} \tag{29}$$

and

$$B_{st,k} = S_1 \sum_{1=1}^{N_{cl}} x_{1,k}\,\beta_{1,k} P_i \tag{30}$$

All the computation relating to food, water and oxygen consumption refers to the average biomass in the period $B_k$ :

$$B_k = \sum_{i=1}^{N_{cl}} B_{i,k} = \sum_{i=1}^{N_{cl}} S_1 (x_{i,k,1} + x_{1,k,2})\,P_i / 2 \tag{31}$$

*2.4 Water and oxygen consumption*

The density of the v-th fish pond is computed as :

$$\delta_v = \frac{\sum B_{1,k}}{V_v} 10^3 \qquad [kg/m^3] \tag{32}$$

Where the sum is extended only to weight classes included in the given pond. The water flow rate theoretically needed to satisfy the oxygen requirement R can be computed as a function of the oxygen concentration in the pond $O_{2,v}$, in the input water $O_{2,i}$ and in output $O_{2,o}$ :

$$Q = \frac{R}{O_{2,i} - O_{2,0}} \quad [m^3/h] \tag{33}$$

Oxygen consumption is computed from the unit consumption per mass r :

$$R = r\ B_v\ 10^6\ [mg/h] \tag{34}$$

It has been assumed :

$$r = 0.177\ mg/g/h\ [Barnabé, 1986]$$

$$\begin{aligned} O_{2,v} &= 4.5\ mg/l \\ O_{2,i} &= 6\ mg/l \\ O_{2,0} &= O_{2,v} \end{aligned} \tag{35}$$

Mass flow rate in the pond $Q_v$ is equal to Q, if $Q \leq Q_{max}$, where this latter is the maximum mass flow rate that pumps can provide. Otherwise, is it assumed $Q_v = Q_{max}$. In this case, further oxygen will be provided by auxiliary devices ; their oxygen supply $R_a$ is :

$$R_a = R\ \frac{Q - Q_{max}}{Q} \tag{36}$$

and the corresponding energy consumption can be evaluated, given a performance index I, in KW per kg/h of oxygen :

$$E_{o2} = 24\ N_g\ R_a\ 10^{-6}\ I\ [kwh] \tag{37}$$

It has been assumed I=4.99 kg $O_2$/HP (mechanical oxygenator Nan-Rong, power=1 HP).

Water supply in terms of volume per day can be finally evaluated :

$$R_v = 24\ Q_v\ /V_v \tag{38}$$

*2.5 Pumping energy consumption*

The power $P_p$ for the pumps is computed from flow rate Q, from total head H and of pump efficiency $\eta_p$ :

$$P_p = 9.81\ \frac{Q}{3600\ \eta_p}\ H \tag{39}$$

The total head H is the sum of the geodetic term $H_u$ , equal to the difference in height from the water reservoir and the fish ponds, and of head losses $H_p$ in pipes :

$$H = H_u + H_p \tag{40}$$

for the latter term, the following formula has been used [Colombo, 1971] :

$$H_p = 2\,L((1.64\ 10^{-3} + 4.2\ 10^{-5}/D)\ Q/3600)^2 / D^5 \quad (41)$$

Where D is pipe diameter and L is its length. The energy consumption $E_k$ in the k-th period is :

$$E_k = P_p\ 24\ N_g\ [kwh] \quad (42)$$

*2.6 Feeding*

For each weight class, the theoretical amount of food to supply is computed as a function of water temperature, fish size and weight, from suitable data provided by food producers [Feeding Chart for Sea-Bass with Trouvit Branzini]. The actual amount $B_{m,k}$ is obtained considering the feeding level $F_{m,k}$ :

$$B_{m,k} = N_g \sum_{i=1}^{N_{cl}} B_{i,k}\ v_i F_{m,k} \quad (43)$$

with

$$0.5 \leq F_{m,k} \leq 1 \quad (44)$$

In default of more precise information about the influence of feeding on growth, a linear relationship (3) between $F_{m,k}$ and the growth has been assumed. The following relationship between fish length and weight has been used [Barnabé, 1986] :

$$l_i = (Pi / 9.10^{-2})^{1/3}\ [cm] \quad (45)$$

*2.7 Energy for water heating*

Given water flow rate Qv, it is possible to compute the thermal energy consumption $E_R$ needed for heating water from external temperature T to the desired value T*, in $N_g$ days :

$$E_R = 24\ N_g\ Q_v\ 10^{-3}\ (T^* - T)\ [kcal] \quad (46)$$

It is assumed that temperature in ponds is equal to T*, neglecting possible heat losses, due to the small temperature differences between pond temperature and the surrouding and to the relevant water flow rate. No heat recovery from output water is considered.

*2.8 Biological constraints*

In each period, density in each pond $\delta_{i,k}$ have to be lower than an upper limit $\delta_{max}$. A suitable constraint is so defined :

$$c_{i,k} = \delta_{max} - \delta_{i,k} \quad (47)$$

The solutions provided by the optimization method correspond to densities not greater than the maximum value $\delta_{max}$. This result is obtained by selecting suitable strategies for stocking and harvesting.

*2.9 Final period. Residual biomass*

At the end of the selected time horizon, a residual biomass could remain in the ponds. Therefore, in order to homogeneously compare different management stragegies, its value has to be considered. Given residual biomass distribution and price $Pr_{f,i}$ for each weight class, the residual value VR is so computed :

$$VR = \sum_{i=1}^{N_{cl}} VR_i = \sum_{i=1}^{N_{cl}} B_{i,\,Np+1} Pr_{f,i} \tag{48}$$

## 3. ECONOMIC SUB-MODEL. COSTS AND REVENUES

For each period, it is assumed that all the harvested biomass can be sold to a price $Pr_k$, variable in time but independent on the supplied biomass.

Therefore, revenue $R_k$ can be obtained :

$$R_k = B_{c,k}\, Pr_k \tag{49}$$

The following costs are considered :

- cost for pumping $C_{p,k}$ and for auxiliary oxygen $C_{o2,k}$ proportional to the required energy and to the unit cost for electrical power :

$$C_{p,k} = E_{p,k}\, K_p \tag{50}$$

$$C_{o2,k} = E_{o2,k}\, K_p \tag{51}$$

- cost for stocked fish $C_{st,k}$ proportional to the number of recruits supplied :

$$C_{st,k} = S_{st,k}\, K_{st} \tag{52}$$

- cost for feeding $C_{m,k}$, proportional to the amount of food provided :

$$C_{m,k} = B_{m,k}\, K_m \tag{53}$$

- cost for water heating, proportional to the required energy and to the unit cost of thermal energy :

$$C_{r,k} = E_{r,k}\, K_r \tag{54}$$

- In order to consider the incidence of all fixed costs, not depending on operative variables, a cost $C_{a,k}$ is introduced. Such cost is equally distributed over the periods.

Total cost per period $C_k$ is then given by :

$$C_k = C_{c,k} + C_{st,k} + C_{m,k} + C_{p,k} + C_{r,k} + C_{o2,k} + C_{a,k} \tag{55}$$

Profit $U_k$ is computed by :

$$U_k = R_k - C_k \tag{56}$$

In order to compare costs and revenues referring to different periods, all economic terms are multiplied by a discount coefficient $f_{at}$ :

$$f_{at} = 1/(1 + T_{at})^t \tag{57}$$

Where $T_{at}$ is the yearly discount rate, t is the time, in years,when the given term occurs.

## 4. SIMULATION ANALYSIS

In order to assess the predicting capability of the model, a simulation analysis has been performed, for the plant described in table 1. A maximum weight of 400 g has been considered, divided in 20 classes with increasing width, in order to take into account the exponential nature of the growth process. Minimum and maximum weights for each classes are shown in table 2.

Table 3 displays the parameters used by the biological model, relating to growth, mortality and stochastic effects. Values for k, x, a and b comply with indications provided by Querellou [1984]. The parameters $c_1$, $c_2$ and $c_3$ have been assigned according to growth curve spread observed in typical cases of sea-bass aquaculture by Iandoli and Saroglia [1989].

### *4.1 The base case*

The simulation analysis has been performed starting from a base-plant, described in tab.4, also analyzing the influence of the most significant parameters on the results.

For this base case, the distribution of temperatures and variables describing harvesting, stocking, feeding level and water heating are assumed constant over the periods. However, the model can also consider time varying distribution. Harvesting strategy consists in extracting in each period the 80 % of the biomass present in the last 5 classes. The 20 % remaining biomass will be affected in the subsequent period by a 1 % mortality, due to harvesting stress. A further mortality relating to fish transfer between ponds has been estimated to 2 % of the transferred biomass. The stocking of recruits, with an average weight of 1.5 g, is concentrated in the first month. The maximum water flow rate is computed to assure that the total pond volume can be changed 20 times a day. Auxiliary oxygenation occurs only when the required water flow is greater than this limit.

### *4.2. Results of the base case.*

The results of the base case are described in tabs. 5a-b and in figs. 3A-3F. For each period, table 5a reports :

- water temperature (deg) ;
- harvesting level (for the classes 5 classes) ( %) ;
- stocking level ( % of the initial biomass) ;
- feeding level ( % of the theoretical value) ;
- auxiliary water heating (deg) ;
- average fish weight AW (g) ;
- total biomass, evaluated at the middle of the period (tons) ;
- harvested biomass, evaluated at the end of the period (tons) ;
- stocked biomass, evaluated at the start of the period (tons) ;
- the amount of food supplied (tons) ;
- the number of fishes with respect to the initial value ( %) ;
- the weight limits for the central 90 % of the biomass : 5 % has a weight less than P05, while another 5 % has a weight greater than P95. weight spread is computed according to the stochastic model.

The terms of the economic sub-model are reported in the table 5b [1]. The last column displays the cumulated profit, which usually reaches its maximum value before the end of the period. The value of the residual biomass is also reported.

For the base case, sea-bass harvesting is concentrated between the 8th and the 19th period, with a maximum value in the 13th month. The maximum amount of food, pumping and oxygen costs occurs in the 11th month where the maximum biomass is present in the plant. Auxiliary oxygen is supplied only from the 9th to the 13th month, when water flow is inadequate to satisfy the whole oxygen requirement ; cost for oxygen (852) is almost equal to pumping cost for the entire period (885) : in this case, it should be more convenient to adopt higher water pumping rates, so reducing auxiliary oxygenation.

1. Economic terms are expressed in million LIT (1.000.000 LIT = 630 US $, June 12, 1992).

In the 7th month, before the start of harvesting, about 95 % of the initial fishes survive while the remaining 5 % is affected by physiological mortality. After the 16th month, only 1 % remains in ponds, with an average weight of 280 g. Maximum profit per month (about 901) occurs in the 13th month, while maximum cumulated profit is reached in the 16th month. In the subsequent period, revenues are lower than costs, which is mainly due to the incidence of fixed costs. At the end of the 24th month, however, a positive profit of about 434 million LIT can be collected.

A total production of 241 tons of sea-bass is achieved, with a conversion ratio of 3.04, maximum density of about 20 $kg/m^3$ and a maximum water flow rate corresponding to 32 volumes per day.

The incidence of the single costs on the total cost is enough well-balanced, with a light prevalence of stocking costs.

Biomass, harvest and average weight are displayed in fig.3A, while costs, revenues and profit are shown in figs.3B and 3C. It can be observed (fig.3D) that the spread of the biomass around its average weight increases with time, and that weight distribution becomes asymmetric when harvest occurs. Maximum pond density is reached in the second pond, around the 11th month (fig.3E). It can be observed that water flow remains constant in the period between the 9th and the 13th month (fig.3F), when auxiliary oxygen is provided (fig.3C).

### *4.3 Effects of the operating variables. Parametric analysis*

The model can be utilized to study the effects of the different variables. In tabs.6a, 6b and 6c, the results of a parametric analysis obtained varying each time one of the most relevant operating variables with respect to the base case are presented. The first column of the table indicates the value assumed by the corresponding independent variable. The most significant effects are briefly summarized.

#### 4.3.1 Water temperature effects

As it is known, water temperature plays a major role in growth mechanism and in locating aquaculture plant. Although the model can also consider also variable temperatures in order to stress their effects, constant temperature values between 18 and 24 degrees have been considered. It can be observed that production and revenues increase with temperature, while the opposite occurs for costs. Between 18 and 24 degrees, profit increases of about 1 600 million Lit and conversion ratio changes from 3.93 to 2.31.

#### 4.3.2 Harvesting strategy effects

The minimum weight of the harvested fish has varied from 81 g (10th weight class) to 361 (20th class). Production, maximum density, revenues, costs and process length increase with minimum harvesting weight, while maximum profit is realized for the 16th class, corresponding to the base case. However, it must be observed that the model does not consider further weight increments after the 20th weight class (400 g) and therefore, the revenues obtained by harvesting only the last weight classes may be underestimated.

#### 4.3.3 Stocking strategy effects

Stocking strategy can be varied acting on both the total amount of stocked biomass and on its time distribution. In the first series of results, stocking is concentrated on the first period. When stocked biomass changes from 0.3 to 0.9 tons, an increase in production, revenues, density and costs is observed. Profit is maximized when stocked biomass is 0.6 tons : for lower values, plant is not enough utilized, and high incidence of fixed costs results, while for values greater than 0.6 excessive costs for oxygen are required.

In the second test, a given biomass (0.5 tons) has been stocked in periods varying from 1 to 16 months. Maximum profit is reached for a period of 10 months, which allows a reduction in maximum density (from 20 to 10 kg/m3) and lower oxygen costs. In case of more diluted distributions, a residual biomass is present after the last period and lower revenues and profit result.

In order to test the sensitivity of these results with respect to other parameters, the same analysis has been repeated with a higher value of the maximum flow rate (40 volumes per day). The corresponding results are described in tab.6c.

Maximum profit is achieved when 1 ton of fish is stocked, with higher density (about 40 kg/m3). With respect to stocked biomass distribution, in this case it seems more convenient to stock all the biomass in the first month. The difference between the 2 cases is mainly due to the costs for the auxiliary oxygen, which in the first case penalize the solutions corresponding to high density.

#### 4.3.4 Water heating effects

The results show that, starting from temperatures of 22 degrees, the increase of fish production and revenues do not compensate the higher cost due to water heating for the first pond ; in this case, however, heat recovery has not been considered.

#### 4.3.5 Water supply effects

When the maximum water flow rate changes from 10 to 40 volumes per day, profit increases of about 1 300 million Lit, since the higher pumping cost is largely compensated by the lower cost for auxiliary oxygen. Pumping costs and profit depend also on the difference in height : its variation from 10 to 40 meters causes a profit decrease of about 1 300 million Lit.

This kind of analysis is particularly useful in order to clarify the influence of the single variables, but it may not provide exhaustive information on system behavior, since the effect of a variable may depend on the values assumed by other variables, due to the presence of interactions and non linearities in the model. In this case, optimization analysis represents the best tool to select the best management strategies, considering the interactions among thc variables.

## 5. OPTIMIZATION ANALYSIS

Management strategies can be optimized determining the distribution of the decision variables which maximizes profit in the given time horizon and respects the constraints on maximum density in ponds. A classical non linear constrained optimization problem [Gill et al., 1984] is then defined :

$$\min_{u} F(u) \tag{58}$$

$$C_i(u) \geq 0 \qquad i = 1, M \tag{59}$$

where the decision variables u represent stocking and harvesting strategies, and F is the sum of the profit $U_k$ in the periods and of the possible residual value, at the end of the time horizon :

$$F(u) = -VR - \sum_{k=1}^{N_p} U_k \tag{60}$$

The inequality constraints express the condition that pond density must be lower than a given maximum value :

$$ci = \delta_{max} - \delta \tag{61}$$

Using the Augmented Lagrangian approach, an equivalent unconstrained optimization problem can be defined [Gill et al., 1984] :

$$\min L_u(u,\lambda) \tag{62}$$

where :

$$L = F(u) + \sum_{i=1}^{M} \begin{cases} -\lambda_i c_i(u) = \rho/2 c_i(u)^2 & \text{if} \quad c_i(u) \leq \lambda_i/\rho \\ -\lambda_i^2/2\rho & \text{if} \quad c_i(u) > \lambda_i/\rho \end{cases}$$

The Lagrange multiplier $\lambda_i$ is a non negative number associated to the i-th constraint $c_i$ ; $\rho$ is a positive penalty factor.

The unconstrained minimization (62) is performed by an iterative Quasi-Newton technique, with the following features :

- linear search based on safeguard inverse interpolation ;
- numerical gradient evaluation ;
- iterative estimate of the Hessian matrix (second derivatives) using the Davidon-Flechter-Powell algorithm.

After each minimization, Lagrange multipliers are updated according to the following relationship :

$$\bar{\lambda}_i = \lambda_i - \min(\rho c_i, \lambda_i) \tag{64}$$

A new unconstrained minimization is then performed, until convergence is achieved.

*5.1 Results of the optimization analysis*

Some results obtained with optimization analysis are presented in the following. The decision variables are : harvesting strategy (percent of the harvested biomass, for the weight classes from 16 to 20) and stocking strategy. Tab. 7 shows the four cases considered.

For each case, the optimal results have been compared with the ones obtained with the initial distribution of harvesting and stocking levels :

80 % harvesting level for the weight classes upper to 15th, biomass of 0.5 tons stocked in the first month. Global results are presented in tab. 8, for all the cases described in tab.7 ; detailed results are shown for the case BOP2 in tab. 9a-b and in figs. 4a-f, and for the cases BOP4, BOP6 and BOP8 in tabs. 10a-b ; 11a-b and 12a-b, respectively.

In the case A, by the comparison of the initial and the optimal solutions it emerges :

- a profit increase of about 1 300 million Lit, due to a relevant increase in revenues and also to a reduction in costs, chiefly for food, pumping and stocking ;
- an increase in the stocked biomass and in production, which allows a better plant utilization and then a lower incidence of fixed costs (after the 24th month, a residual biomass is present in the plant) ;
- stocked biomass has been subdivided in different periods, spaced of about 5 months, in order to limit maximum pond density and to reduce auxiliary oxygenation ;
- harvesting level increases up to 100 % in last periods (to reduce residual biomass) and when auxiliary oxygen should be needed ; harvesting level decreases when density is lower (e.g. months 21-23), in order to allow further growth and then greater revenues in the following periods.

Economic terms, biomasses and density for the optimal case are shown in fig. 4a-f. It can be remarked that average weight, harvested biomass and density exhibit more complex trends, with respect to the traditional solution (base case, fig.3a-f). Density is usually higher, but within the imposed upper limit of 25 kg/m3, so allowing a more complete productive utilization. The second case (B) is characterized by a non uniform price distribution (tabs 10a-b). The optimal solutions are similar to case A, but with higher harvesting levels in periods where price growths. Profit increase (1480 million Lit) is higher than the previous case.

Case C (tabs 11a-b) is characterized by higher pumping height with respect to case B. It exhibits unprofitable result (440 million Lit) with standard solution, while optimal strategy gives rise to a positive result of about 300 million Lit, obtained by increasing fish production from 240 to 350 tons ; both revenues and costs increase with respect to initial solution.

In the last case (tabs 12a-b), finally, variable temperatures are considered,with lower values respect to previous cases. The initial solution gives rise to a loss of 1 370 million Lit, which is reduced to about 800 million Lit with optimized solution. This result is obtained by reducing fish production (from 0.5 to about 0.3 tons) and so eliminating costs for oxygen ; stocking is concentrated in the first period, unlike previous cases. Harvesting is maximized in the periods with higher prices, and reduced in the previous ones.

These examples, even if extended only to harvesting and stocking strategies and not representative of all possible conditions occuring in aquaculture management, show the considerable benefits obtainable with optimal management strategies, which can account for the influence of structural, environmental and economic variables and for their complex interactions.

## 6. CONCLUSIONS

A model for the simulation and the optimal management of sea-bass aquaculture plants has been presented. The model accounts for the effects on growth and mortality of water temperature, harvesting and stocking strategies, feeding level and oxygen consumption and can evaluate costs and revenues. Cost-benefit analysis can be easily obtained examining the effects of each operating variable on the management outputs.

The results of the optimization analysis prove that, for given environmental and economic conditions, optimal harvesting and stocking strategies can be determined which allow relevant benefits in profit, with respect to traditional management strategies. Further work is needed in order to include other management options, to impose the detail and the precision of the sub-models and to validate the model estimates and the optimal strategies by direct comparison on aquaculture plants.

# Simulation of Aquaculture Production for Economical and Environmental Impact

**Michael Spratt**

APPLYING EVOLVING TECHNOLOGIES, 13 rue du Nord, 34000 Montpellier, France

ABSTRACT

*Simulations of aquaculture production requires standard information often with unique technical and economical considerations, depending upon the user's current and projected requirements, budget and personnel constraints. Simple simulation tools can aid (re-)define these constraints while providing deeper insight into their relations. Using LOTUS 123, we defined and developed small functional modules which were incorporated in order to simulate production of Sea Bass (D. labrax) in cages in the open sea for five years.*

## 1. INTRODUCTION

Today, simulation of aquaculture production must include a minimum of information and features. Economical, financial, biological, geo-physical and zoo-technical data are as important as features like simple, easy to use, understand, adapt and enhance. Database management, reports and graphics are key elements, as well as the simulation execution time.

It is now possible to avoid problems associated with other models and simulation systems. Limitations include application specific, inflexible, closed, dependent upon the author(s) for enhancements and adaptations, and also reflect the author's era and methods, and become outdated quickly.

Finally, development of a simulator depends upon a need, multi-disciplinary experts, time and financing. For the project "PRIMO/MOSART", we developed a system in order to simulate the viability of different production configurations. This project was for IFREMER (Institut Français de Recherche pour l'Exploitation de la Mer) and concerned the production of Sea Bass (*D. labrax* ) in cages in the open sea (see figure 1).

## 2. PROBLEM SUB-DIVISIONS

Our main development tool was the spread sheet LOTUS 123, subdivided into several sub-tables, similar to our problem. The decomposition and grouping of the problem into manageable units was essential in order to satisfy the original

criteria. Each sub-division or area performs unique functions and operations. The figure 2 illustrates the six major sub-divisions and their relative location within the spread sheet. We will further describe the functioning of each sub-division.

### *2.1 Business control*

The simulation of production is based upon a "what-if" strategy. The cascade features of spread sheets are used to explore, develop and balance financial and production critera. The principle criteria for simulation are **Economical** and **Production** (see figure 3).

**Economics** include Financing, (starting date, tax rates, social charges and parameters used to evaluate the value of fish stock, etc.) **Credit** (type, amount, length, interest rate and number of years of repayment) and **Subventions** (ie. source, amount and number of payments) are used to vary economical constraints.

**Production** elements such as the Lots, Food Costs and Variable Charges control the biological aspects :

(i) **Lots** controls the grouping and growth of fish (starting date, number, mean weight and value per individual and projected mortality, plus a predetermined ending date, mean weight or biomass and a sale price per kilo). **Lots** also contains information needed for environmental appreciations (cage volume and length).

(ii) **Food Costs** contains the granulometery, or pellet size and purchase date with the price payed per kilo at their intersection. Based upon user estimations the computer will calculate the cost of food, using the weight of fish and the daily feeding table.

(iii) **Variable Charges** (vitamins, anaestheticss, disinfectants and medicines) are calculated using a ratio of cost per kilo of production.

### *2.2 Fixed costs*

Fixed costs contains **Investments, Salaries** and **Fixed Costs** (see figure 4).

The French accountining system, **Investments** are classified into 8 groups : (Ocean) structures, (Ocean) Equipment, Construction, Material for Functioning, Production Control, Security and Sanitary, Processing and Commercializing Equipment and General Equipment.

We established 20 lines for each of the 8 classes of investment, with each investment being defined by a name (and/or code), the quarter in which it is purchased, the number and price per unit and the duration of amortization.

This information permits the calculation of the purchase/payment date, the amount and taxes. The investment is amortized quarterly and presented annually in the Resume Of Investments and Amortization which summarizes investments by class and by year.

**Salaries** include the title, number of employees, monthly or yearly salary, plus social charges. In France, the total number of months per year is also important as a $13^{th}$ month may be added, as an employee bonus.

**Fixed Costs** can vary but usually include energy, transportation, veterinary charges, required insurances, (specific) insurances ie. for the fish stock, repair and maintenance, travel expenses, etc.

### *2.3 Geo-physical and zoo-technical areas*

The grouping of site and species parameters combines basic scientific information concerning the bio-physical charateristics. This area contains the **Geo-physical** and **Zoo-technical** sub-tables (see figure 5).

The **Geo-physical** information concerns the Thermal Profile of the Site (mean weekly water temperature by year), Daily Growth Rate - DGR (general model obtained from Leclercq & Tanguy), Daily Feeding Table - DFT (usally the

manufacture's suggested daily percentage of food in relation to the biomass), Daily O2 Consumption Rate (mean hourly rate expressed in mg per liter), Food to Nitrate Production (ammonium and organic nitrogen rate, based upon grams produced per Kg of food provided), Food to Particulate Matter Production (the conversion rate minus a constant).

The **Zoo-technical** table calculates a variety of values based upon daily activities, which are summarized by week and then by quarter. Calculations include the date, week number, mean weekly temperature, number of individuals, mean weight, mortality, biomass, daily feeding rate, daily growth rate, food costs, density, etc.

### *2.4 Details of production and environment*

Production results of the simulation are summarized in the Details of Production. For each of the ten lots, the closest simulation date to the end of the quarter is stored with the lot's status, number of individuals, mean weight, sales price (if sold) food costs with the biomass and value of the lots.

Details of Environment contains summary information concerning the mean and maximum O2 consumption in mg/h/kg and mg/h/l, the required minimum percent of hourly exchange, the minimum mean daily current speed (m/h), the quarterly and annual production of ammonia (Kg/week), organic nitrogen and organic matter (Kg).

All these values are calculated in the Zoo-Technical area and moved to their respective area via the macro command (see figure 7).

### *2.5 Results*

The financial results are calculated in the Production Resume, summarizing livestock purchases, sales, biomass produced, food costs, variable and fixed charges and annual stock variations.

The Variable Charges (ie. vitamins, anaesthesties, etc.), are calculated with the V.A.T. and stored in this table.

LIABILITIES, ASSETS and RESULTS describe the yearly economic realities of expenditures, resources and global production results (see figure 7).

### *2.6 Macro commands*

A macro command was developed in order to reduce the size and execution time of the simulator by limiting execution to specified lots and quarters and also controls the processing and storage of data.

Without the macro command, the time to load and backup the file after each modification would require minutes in addition to the recalculation time. The zoo-technical area is the best example. The simulation of ten lots, for 200 to 300 weeks (4 to 5 years) with the macro command, only requires 16 lines of calculations as opposed to 2000 to 3000 lines for the same calculations without the macro command. Ten lots is an arbitrary choice, the system is not limited by this factor.

The execution macro command relies on a control area, which contains key values, such as days per zoo-technical calculation (7 : days), division per year (4 : quarters), maximum number of lots (10) and quarters (20) etc. It also contains the location and size of the two three-dimensional tables *(Details of Production and Environment).* This makes it easier to modify the spread sheet and/or the macro command.

We also established other macro commands in order to jump from one area to another and to transfer tables spread sheets.

## 3. CONCLUSIONS

The aquaculture profession is facing increasing competition, higher costs, stricter regulations and reporting requirements for environmental and political reasons. Certain technologies like data bases, spread sheets and expert systems, hold great promises for this sector.

Simulations are just one of the many applications for spread sheets which are precious planning support and decision making tools. Every exploitation needs them as well as informed, interdisciplinary personnel, able to understand biological factors, face economical constraints and support growing technical complexity. The application of technology and its use are becoming manditory requirements for aquaculture businesses.

# Consumption and Demand
# by
# C. R. Wessels

Jusqu'à récemment, la recherche halieutique concernant le marché de la pêche a été en grande partie négligée. Cependant, on réalise maintenant dans l'industrie de la pêche et dans la recherche que les marchés jouent un rôle crucial dans l'utilisation optimale et efficace des ressources halieutiques et en particulier que les décisions de gestion ont un impact important sur les marchés des produits de la pêche lesquels, à leur tour influencent l'efficacité des programmes de gestion. Les pêcheurs, eux aussi, demandent souvent qu'une plus grande régulation soit appliquée quand les forces du marché entraînent une exploitation excessive des ressources.

Pour mieux comprendre les relations étroites entre la gestion de la pêche et le marché, nous devons d'abord mieux comprendre la complexité du marché. Cela peut se faire soit en examinant le marché en général dans le cadre d'un produit ou d'un groupe de produits, soit en se concentrant sur un aspect particulier du marché. Une meilleure compréhension du secteur est obtenue dans les deux cas.

Pendant les dernières années, et ceci afin de répondre au manque d'informations concernant la demande et les marchés des produits de la mer, un nombre croissant de chercheurs nous a apporté des éléments sur les facteurs agissant sur le marché du poisson. En général, les études se divisent en deux grandes catégories :

(i) les analyses du marché global - certaines sont présentées dans d'autres sessions.

(ii) les analyses de la demande de produits ou d'attributs de ces produits par des groupes particuliers de consommateurs. Dans les deux cas, déterminer l'élasticité de la demande est crucial dans le calcul des gains et des pertes de bien-être liés à des modifications dans la gestion des pêches ou la commercialisation des produits.

Les contributions présentées dans cette section traduisent les progrès faits dans ce domaine. Elles constituent

Fisheries market research has, until recently, been largely neglected component of fisheries related research. However, many in the fishing industry and fisheries research have begun to realize that markets play a crucial role in the optimal and efficient use of fisheries resources. In particular, management decisions often impact the markets for fisheries products which, in turn, often transmit themselves back to impact the effectiveness of management programs. Furthermore, fishermen have often requested, on their own initiative, more regulation in cases where market forces are driving excessive harvest of the resource.

To better understand the interrelationships between fisheries management and the market sector, we must first gain a better appreciation for the intricacies of the market sector. In some cases this is done by taking a global view of the market for a particular product or group of products; in other cases, researchers focus on a particular aspect of the market. In both instances, the understanding of the marketing sector is increased.

In response to a lack of information on the general area of seafood demand and markets, a growing number of researchers in the past few years have greatly increased our knowledge of what drives the market for fish. In general, the studies have fallen into two broad categories:

(i) analysis of the aggregate market - some of which are found in others sections of these proceedings;

(ii) analysis of demand for specific products or attributes of products by specific user groupes. In both cases, determination of demand elasticities are a crucial component in the calculation of welfare gains and losses associated with changes in marketing and management schemes.

The papers presented in this section reflect advances made in the latter area. The group of papers in this

un superbe exemple des efforts réalisés par la profession dans l'état-de-l'art de l'analyse de la demande de produits de la mer. Dans leur communication, Burton et Young par exemple s'intéressent à la demande domestique de poisson en Grande-Bretagne. En appliquant l'analyse économétrique de la demande aux données disponibles, les auteurs constatent plusieurs résultats en désaccord avec la théorie micro-économique de la demande du consommateur. Ils utilisent alors une analyse non paramétrique afin de déterminer si les données satisfont les axiomes de préférence révélée, au lieu d'imposer une forme standard de la fonction de demande aux mêmes données. Les résultats indiquent que la forme fonctionnelle retenue pour la demande n'est pas neutre ; le choix de la fonction peut ainsi avoir des conséquences significatives sur la détermination des élasticités de la demande.

Johnston et Larson cherchent à expliquer pourquoi une élasticité du prix positive se retrouve quelquefois dans les études de marché des produits de la mer aux U.S.A., où la consommation augmente avec la hausse des prix. Ils conçoivent leur explication sous forme d'"effet Giffen" et démontrent théoriquement comment il est possible que l'élasticité des prix soit positive. Il est clair que cela aurait alors un effet considérable sur toute analyse des effets en terme de bien-être d'un changement des régimes de gestion.

Les quatre contributions restantes dans cette section s'intéressent plus spécialement à la demande d'attributs des produits de la mer, qui reflètent pour la plupart la qualité du produit. Ces études sont identiques dans la mesure où elles utilisent les données rassemblées directement par les chercheurs à partir des groupes d'individus. Les chercheurs peuvent ainsi utiliser les données obtenues sur des aspects particuliers du marché des produits de la mer. La contribution de Brook et Anderson est une étape importante dans l'étude du marché des coquillages et des conséquences sur la demande de la perception de la qualité sanitaire du produit par le consommateur. Les auteurs s'intéressent plus particulièrement au marché de la moule dans le nord-est des E.U. Avant l'étude, le marché de la moule aux E.U. était mal compris et plus particulièrement le marché potentiel. Ces perceptions influencent aussi la demande domestique et la demande de produits importés, comme le montrent Kusakabe et Anderson dans le cas du marché Japon du saumon. Les perceptions du consommateur y sont très différenciées selon les espèces, la forme du produit et sa technique de production (pêche ou aquaculture). Kusakabe et Anderson estiment directement la demande de ces attributs, afin de déterminer quelles en sont les combinaisons préférées constituant le saumon « optimal » selon les commerçants japonais. Ces deux contri-

session is a superb exemple of the strides the profession has made in the state-of-the-art in seafood demand analysis. The paper by Burton and Young for example looks at household demand for fish in the United Kingdom by presenting an alternative method of evaluating the data. After having attempted to apply econometric demand analysis to the data, the authors found several anormalous results which conflicted with microeconomic theory of the consumer demand. Rather than continue to impose a particular functional form for demand on the data, the authors decided instead to let the data tell them directly wether or not the data were consistent with consumer theory. Specifically the authors utilized non-parametric analysis to determine if the data satisfy the axioms of revealed preference. Results indicate that functional form imposed on a demand system may have important implications. In turn, the choice of functional form may have significant consequences in the determination of demand elasticities.

Johnston et Larson seek to explain why positive own-price elasticities are sometimes found in studies of the U.S. seafood market, where consumption has grown simultaneously with a rise in price. They frame the explanation in the form of Giffen good behavior and demonstrate theoritically how it is possible that the price elasticities could be positive. Clearly, if price elasticities are positive this would have a considerable effect on any analysis of welfare effects from changing management regimes.

The remaining four papers in this section focus specifically on demand for attributes of seafood products, where in many cases those attributes reflect quality of the product. These studies are similar in that they use data gathered directly by the researchers from groups of individuals. Thus, these researchers were able to direct the focus of the data obtained to particular aspects of the seafood market. In a paper that sets a standard in the study of shellfish markets and seafood safety perceptions on consumer demand, Brook and Anderson look specifically at the mussel market in the Northeastern United States. Prior to the study, the U.S. Mussel market was poorly understood; in particular the potential market for mussels was obscure. Similarly, Kusakabe and Anderson found the complex japanese seafood market which is characterized by large differences in perceptions by japanese consumers on the various salmon species, product form and harvest method (wild or aquacultured), in turn effting domestic and import demand. Thus Kusakabe and Anderson directly estimate the demand for these attributes based on market research techniques to determine the most prefered combination of attributes to make-up the composite 'optimal' salmon from the point of view of japanese salmon traders. Both of these papers

butions sont très intéressantes aussi bien pour les chercheurs que pour les individus directement impliqués dans le marketing des produits de la mer.

La contribution d'Anderson et Wessels reflète l'intérêt accru de l'industrie à déterminer si les consommateurs sont capables de discerner la qualité des produits de la mer dans le commerce. Le contrôle de la qualité est de plus en plus réclamé par les consommateurs mais aussi de plus en plus régulé par les gouvernements. Cependant, les fournisseurs de produits de qualité doivent être sûrs que leurs sur-coûts seront compensés par le fait que les clients reconnaissent et sont prêts à payer pour cette qualité. La contribution de Wessels et Anderson envisage ce dernier point. Dans ces deux contributions, l'approche utilisée pour recueillir les données a consisté à amener les consommateurs à un marché expérimental artificiel. Cela a permis de rassembler de très nombreux renseignements quant à l'impact sur la demande attribué aux perceptions de la qualité et de la sécurité par le consommateur.

Pour résumer, les contributions de cette section reflètent une nouvelle façon de penser et un désir de s'éloigner des approches usuelles de la recherche sur les marchés de la pêche. Elles reflètent plutôt l'état-de-l'art dans l'analyse de la demande des produits de la pêche. Continuer dans une telle voie devrait permettre d'enrichir l'étude du secteur et favoriser une gestion plus proche d'un usage efficient de vastes ressources halieutiques mondiales qui maximise le bien-être du consommateur et du producteur.

are interesting to fisheries markets researchers as well as individuals directly involved in marketing seafood.

The paper by Anderson and Wessels reflects an increased interest on the part of industry to determine if consumers are able to discern quality in seafood available at retail outlets. Quality control is both increasingly regulated by governments and demanded by consumers. However, suppliers of quality must be assured that their increased costs associated with providing higher quality products will be rewarded by consumer awareness of and willingness to pay for better quality. The latter point is adressed in the paper by Wessels and Anderson. In both of these papers, the approach used in collecting data was to bring consumers to an experimental market-like setting. This allowed for a rich set of information to be gathered, focused specifically on impacts of seafood quality and safety perceptions on consumer demand.

To summarize, the papers in this section reflect innovative thinking and an unwillingness to be bound to previous approaches to fisheries market research. Instead these papers reflect the state-of-the-art of seafood demand analysis. A continued pursuit of such progress will enhance the study of fisheries and bring fisheries management closer to establishing the efficient use of the world's vast fisheries resources which maximizes producer and consumer welfare.

# Consumer Ability to Discern Seafood Quality : Results of Experimental Studies

**Joan Gray Anderson[a], Cathy Roheim Wessells[b]**

[a]Consumer Affairs Program, University of Rhode Island, Kingston, Rhode Island, 02881 USA

[b]Department of Resource Economics, University of Rhode Island, Kingston, Rhode Island, 02881 USA

ABSTRACT

*Much has been written about the absence of and need for high quality product in the seafood market. Yet, little research exists to demonstrate whether consumers will be able to distinguish high quality product at the market and consequently, compensate quality-oriented sellers for their added effort and expense.*

*The purpose of this paper is to present the results of an experimental study which was conducted at the University of Rhode Island. In a simulated supermarket setting, survey respondents were asked to evaluate the quality of seafood. Researchers sought to relate quality judgements to other consumer characteristics such as seafood consumption patterns, knowledgeability of seafood, and demographic characteristics.*

*The respondents were presented with fillets of salmon, cod and flounder. Quality differences were simulated by a controlled aging process. All portions, once purchased, were held in refrigerated conditions identical to that of seafood retailers. First, consumers were presented with fillets of differing quality and asked to choose the highest quality fillet. Results indicate that consumers' ability to discern quality differences varies by species as well as age of the fillet. Second, consumers were presented with fillets of identical quality but bearing varying prices, and were asked to choose the highest quality fillet. Results indicate that consumers do not use prices as proxies for quality, although this also varies by species. Statistical analysis indicates that frequency of consumption and education level impact one's ability to discern quality.*

*This research provides valuable information on consumers' seafood quality perceptions. The circumstances under which rewards from the provision of high quality seafood to the marketplace will be explored, as will the cases where further consumer education regarding seafood quality is required.*

## 1. INTRODUCTION

Much of the literature on consumer demand for seafood finds that the price of seafood as well as income, prices of various substitutes (such as particular species of fish, or beef, pork, and chicken), and advertising are determinants of consumer demand (e.g., Cheng and Capps, 1991 ; Hayes, Wahl, and Williams, 1990 ; Brooks and Anderson, 1991 ; Capps and Lambregts, 1991 ; Kinnucan and Venkateswaran, 1990). However, a determinant of consumer demand that is often overlooked in traditional economic demand studies is the consumer's perception of the quality of seafood products. Quality variables have been left out of demand studies despite the fact that much has been written about the absence of and need for high quality product in the seafood market. With ever increasing publicity regarding seafood quality, this factor may become the dominant factor in the seafood purchasing decision and is an issue which the seafood industry must address.

Before the effect of consumer perceptions of quality on seafood demand can be determined, a question which must first be answered is whether or not consumers are able to discern seafood quality. Little research exists to demonstrate whether consumers are able to distinguish high quality product, and consequently compensate sellers who consistently provide high quality products for the added effort and expense.

According to a leading expert in the field of seafood technology, quality is one of the most critical issues facing the seafood industry today (Kinsella, 1988). Despite the numerous nutritional benefits associated with seafood, a number of problems exist which must be resolved before consumption parallels that of other protein sources. These obstacles include : supply, cost, quality (especially flavor and odor), safety, convenience, and aesthetics. Variable and unreliable quality of seafood often discourages potential buyers. "A major problem in retail fish is the lack of consistent quality in terms of odor, taste, and texture" (Kinsella, p. 148).

Before it can improve quality, the industry must understand how the consumer perceives seafood. This is not a simple task. As noted by Anderson and Anderson (1991) :

> Seafood quality is a multidimensional attribute - nutritional value ; incidence of parasites ; presence of micro-organisms and bacteria ; shelf life ; taste ; level of additives, irradiation, pesticides or preservatives ; amount of discoloration ; size ; number of bones ; number of scars or cuts ; uniformity ; odor ; and a host of other factors may be used to define quality. In addition, as seafood ages, its quality deteriorates more rapidly than other protein sources such as chicken and red meat (pp. 148-149).

The purpose of this paper is to present the results of two experimental studies which were conducted in the Food Science Laboratory at the University of Rhode Island in which consumers were asked to evaluate the quality of seafood which had been purchased at a local market. Three species were used : flounder, cod, and salmon. Each was purchased at intervals to create an "aging" proxy for freshness/quality.

The objectives of this experiment were to determine if :

i) consumers were able to identify the highest quality (as defined by age) sample from three quality/age levels ;

ii) consumers' ability to discern quality varies by species ; and

iii) price effects on quality perceptions.

Researchers also sought to relate quality judgments to other consumer characteristics such as species consumption, seafood knowledge, and demographic characteristics.

## 2. BACKGROUND AND LITERATURE REVIEW

Seafood quality is defined differently by different groups. Siang and Tsukuda (1989) state that the methods for assessing quality can be broadly categorized into three areas : sensory (odor, color, texture, and such), microbiological, and chemical. Consumers can assess the former while laboratory analysis must be used to measure the latter two.

Several studies (Sawyer, Cardello, and Prell, 1988 ; Bisogni, Ryan, and Regenstein, 1987 ; and Hadlett and Raab, 1990) have been conducted to assess consumers' perceptions of seafood quality.

These studies indicate that :

i) consumers place a very high value on quality but use different terminology to describe it than food scientists do ;

ii) consumers would eat more seafood if they could be assured of high quality ;

iii) consumers feel quality in seafood is less certain than in other food groups, and the need exists for more assurance from retailers and the government ;

iv) consumers lack nomenclature and scientific know-how to verbalize seafood quality needs.

However, none of these studies presented actual samples of seafood to consumers for their quality assessment. It may be that consumers are able to select the best quality seafood in actual practice even though they are unable to articulate the scientific reasons behind their selection. For example, it is not necessary to understand microbial deterioration, lipid oxidation, autolysis, or hydrolytic enzyme activity to be able to determine, by odor, that fish is not fresh or notice that the color and texture make the fish look old. Thus, experimental studies were undertaken to simulate as closely as possible the conditions under which consumers actually choose seafood in a retail market.

## 3. METHODS

### *3.1 The Telephone Survey*

In the summer of 1990, a telephone survey of Rhode Island households was conducted. A sample of 256 was obtained, which is believed to be representative of the Rhode Island population. The survey was six pages long. Depending on how much seafood a respondent consumed, between fifteen minutes and two hours were needed to complete one interview. The survey included detailed questions regarding seafood consumption. Hypothetical questions were posed to elicit consumer response to changes in seafood consumption which might result from a variety of factors. Questions were also asked regarding how consumers defined and assessed quality and safety. Demographic data were also gathered.

### *3.2 Four Experimental Studies*

Respondents who answered the telephone survey were invited to participate in a set of four experimental studies which were conducted on a Saturday afternoon in the Food Science Laboratory at the University of Rhode Island. Due to scheduling conflicts and transportation difficulties, most respondents from the telephone survey were not able to participate, however, other consumers were invited at random from the telephone book. Additional self-selected respondents were included to obtain a broader distribution of income, education, and occupational groups. However, because the sample was self-selected, it was not random. Therefore, results cannot be generalized to the population at large. In all, 55 consumers participated in this phase of the study.

The four experiments conducted were :

i) a market simulation in which the consumer was asked to select the highest quality sample both with and without price data ;

ii) a three-way comparison of seafood quality assessment : in two separate groups, consumers and food scientists rated quality characteristics of three species in three age groups. Samples of the fish were also analyzed in the laboratory ;

iii) a conjoint study of the factors consumers use to select seafood ;

iv) a willingness-to-pay for alternative seafood safety assurances.

The focus of this paper is to combine the results of the first experiment with the consumer portion and laboratory results from the second. Relevant results from other sections of the study are also cited.

For the first two experiments, actual samples of seafood were used. For each experiment, fillets of flounder, cod, and salmon were purchased from a retail market with a high quality reputation at three intervals : ten days before the study was conducted ; five days before ; and the same day. Samples were stored in a manner designed to replicate those of the retailer. Care was taken to obtain the freshest fillets possible from the retailer.

In the first experiment, a market setting was simulated. Several pieces of each sample were placed on ice in three containers. The containers held three samples each of a given species--one for each age category. Initially, each sample was randomly labeled with a letter. Respondents were asked which letter corresponded to the best quality. Next, three samples of each species were again presented. However, this time, all three samples had been purchased that day and were the freshest samples. Each sample had a price : actual market price, two dollars lower than actual market price, and two dollars higher than actual market price. Respondents were asked to identify which sample they would purchase to obtain the highest quality.

In the second experiment, consumers were asked to rate (from 0 to 4) the same three species for each of the three times--zero-day, five-day, and ten-day--on each of four characteristics : appearance, color, odor, and texture. Each of the nine samples (three species each at three ages) was displayed separately on ice in a plastic container. No two samples of the same species were displayed next to each other, so comparisons between samples of the same species could not be made.

Four different laboratory tests were performed on the seafood fillets. The thiobarbituric acid (TBA) test, which measures the oxidative deterioration of lipids, was conducted only for salmon, as it is a test for fish with a high fat content and measures chemicals associated with rancidity (Tarladgis, Watts, and Younathan, 1960).

The total volatile base (TVB) test measures the level of protein deterioration. This is an excellent quality indicator as fish is comprised mainly of protein. The emergence of these bases correlates well with ammonia content, a main contributor to "fishy" odor and flavor. As quality declines, TVB scores increase.

The trimethyl amine (TMA) test assesses the deterioration of TMA-oxide to TMA, a compound which contributes to off odors (Dyer, 1945). It is considered an excellent quality indicator for spoilage of white-fleshed fish, especially cod. If levels of TMA are over 10-20 mg per 100 g fish, the fish is regarded as undesirable.

The aerobic plate count is a good overall indicator of the degree of spoilage and approximates the numbers of live bacterial cells per gram of fish. Upon storage, the microbial numbers increase exponentially. Generally, up to 10,000,000 colony forming units (CFUs) per gram are acceptable for consumption. Above this level, the flesh is considered spoiled. Details of this study are available in Reilly and Morrissey (1991).

## 4. RESULTS

### *4.1 Laboratory Tests*

Laboratory analyses (trimethyl amine, total volatile base, and aerobic plate count) indicated that the samples of cod and flounder were representative of fish kept zero, five, and ten days in storage. Results for these two species indicated that the level of spoilage increased almost linearly with days in storage.

However, results were not as expected for the salmon samples. There were no differences in the chemical or microbial tests for the zero and five-day salmon. Analysis indicated that the five-day sample was slightly fresher than the zero-day sample obtained on the day of the evaluation.

A thiobarbituric acid test was performed on the salmon samples which indicated that the zero-day sample had a slightly higher level of fat decomposition than the five-day sample. This may be the result of poor handling prior to purchase for the experiment (temperature/time abuse, physical mishandling) of the zero-day salmon at either the wholesale or retail level.

*4.2 Market Simulation*

### 4.2.1 Consumer Ability to Select Freshest Specimen

• Flounder

The majority of respondents (74.5%, n=41) selected the ten-day-old flounder as the highest quality, indicating an inability of consumers to correctly assess flounder quality. However, about one-quarter (23.6%, n=13) of those questioned thought the zero-day-old specimen to be the freshest (refer to Table 1).

• Cod

In contrast, as shown in Table 1, most respondents (87.3%, n=48) were able to correctly identify the zero-day or freshest cod fillets. Only five thought the five-day sample was the freshest, while none thought the ten-day sample was the freshest. Two respondents thought all samples were the same.

• Salmon

Results of the salmon section are somewhat more ambiguous. As discussed in the previous section, laboratory testing of specimens from each of the three age groups indicates the existence of some quality problems with the zero-day batch. As shown in Table 1, many (38.2%, n=21) of the respondents identified the five-day-old sample as the freshest. Almost one-third (30.9%, n=7) of the respondents found the zero-day salmon, which laboratory tests indicated was only slightly less fresh than the five-day sample, to be the highest quality ; 21.8% (n=12) chose the ten-day-old sample as the freshest ; while 9.1% (n=5) thought all samples were equally fresh.

To summarize, consumers were able to successfully discern real quality differences, as identified in objective laboratory tests, for cod and salmon, but were far less accurate in their judgments of flounder.

### 4.2.2 Effect of Price on Consumers' Seafood Quality Perceptions

Table 2 lists the results obtained when consumers were presented with three identical samples of each of the three species. All three samples were purchased on the day that the survey was conducted. Respondents were asked to identify which sample they believed to be the highest quality and would consequently purchase. It was assumed that consumers who were able to correctly identify no differences between the three samples, would select the lowest priced sample. It was also assumed that consumers who were unable to make quality judgments might select the highest priced sample following the "high price buys high quality" axiom.

• Flounder

Only one-quarter of the sample (29.1 %, n=16) correctly identified the lowest priced flounder as the one they would purchase, while more than one-third (36.4 %, n=20) chose the highest priced piece. The middle priced piece (actual market price) was chosen as frequently as the low priced sample.

• Cod

Respondents demonstrated better ability in their cod selection. More than two-thirds of the sample (69%, n=38) selected the least expensive sample. Less than one-third (29.1%, n=16), selected the sample with the actual market (middle) price. Only one respondent selected the most expensive sample.

• Salmon

Relative to the other two species, respondents were most successful in selecting salmon. Almost three-quarters of the sample (74.5%, n=41) selected the lowest priced salmon. However, quite a few selected the highest priced piece (18.2%, n=10).

To summarize this section, one can note that respondents selected the correct choice--the lowest priced sample--most frequently for cod and salmon. Yet for the samples of flounder, the highest priced sample was most frequently selected (36.4%, n=20). Salmon was correctly identified most often, while flounder was correctly identified least often.

### *4.3 Quality Selection and Related Factors :*

Whether a consumer's ability to correctly assess the highest quality seafood sample is related to certain attitudes, behaviors, or demographic characteristics, was analyzed using Chi-Square tests. Several factors were considered

i) how well the respondent likes seafood in general ;

ii) respondent's self-assessment of seafood knowledge ;

iii) frequency of consumption of the specific species being evaluated ;

iv) frequency of finfish consumption ;

v) frequency of finfish consumption at home ;

vi) respondent's perception of seafood safety ;

vii) education level ; and

viii) income level.

How well a respondent likes seafood was related to the ability to correctly identify the highest quality seafood in only one case, the flounder price trial. In that trial, respondents who were able to correctly identify the lowest priced flounder as the best buy were significantly more likely (more than 2 to 1) to rate seafood as their favorite food ($X^2$=5.52, d.f.=2).

No significant differences were found for any of the six trials for either knowledge self-assessment, or safety perceptions. Income was also not related to consumers' ability to assess quality in any of the trials.

The amount of seafood consumed was significantly related to ability to discern quality in only one case. Consumers who had above average consumption of flounder were significantly more likely to pick the zero-day sample than those with below average flounder consumption ($X^2$=3.06, d.f.=1). Neither quantity of fish eaten in general or at home was significantly related to the results of any of the six trials.

Finally, highest level of education attained was significantly related to obtaining the correct answer in the cod price trial. Specifically, persons with a college or professional degree were more likely to correctly identify the lowest priced cod as the best value ($X^2$=6.37, d.f.=2).

### *4.4 Sensory Evaluations*

Results of the consumers' evaluations of the nine seafood samples can be seen in Table 3.

- Flounder

Consumers correctly rated the zero-day flounder highest ($\overline{X}$=12.73). However, the ten-day sample was rated higher overall ($\overline{X}$=9.56) than the five-day sample ($\overline{X}$=8.96). Although the lab results indicated that the samples were consistent with the length of time they had been aged, the tests performed in the laboratory did not incorporate appearance into their results. The five-day sample had a different color than the other two flounder samples. There were grey flecks throughout the flesh giving it an overall "grey" appearance. This quality flaw was not detected by the laboratory tests but was clearly detected by the sample respondents in this experiment and the market simulation.

- Cod

Respondents rated the zero-day cod highest on all four characteristics. Out of a maximum of 16 points, the zero-day cod received an average of 12.76. However, they rated the five and ten-day samples almost equally, giving the ten-day sample

a slightly higher evaluation ($\overline{X}$=9.93) as compared to 9.13 for the five-day sample. In comparing these results to the market section results, it appears that for cod, consumers are more successful in quality evaluation in a market setting than in the laboratory setting.

• Salmon

Consumers rated the five-day salmon slightly higher ($\overline{X}$=12.51) than the zero-day salmon ($\overline{X}$=11.95). The ten-day sample was rated the lowest ($\overline{X}$=11.13). Their ratings very are consistent with the results of the laboratory tests. These results are also consistent with those obtained in the market experiment.

## 5. SUMMARY AND CONCLUSIONS

The results of the market simulation and the sensory evaluations in conjunction with the laboratory tests indicate that, in general, consumers are quite capable in their ability to detect quality seafood, whether it is displayed in a market-like setting or in an objective sensory test. This conclusion holds even in the cases such as the zero-day salmon, and the five-day flounder, in which quality is not consistent with expectations based on aging factors alone. Quality indicators such as color and handling were detected by respondents and incorporated into their quality evaluations. While the limited sample size makes it difficult to find factors which are significantly related to consumer ability to discern seafood quality, it is clear from the results of this study that this sample of consumers is able to discern quality. Further research is needed to determine what factors are related to this ability.

# Conjoint Analysis of the Japanese Salmon Market

**Yuko Kusakabe and James L. Anderson**

Department of Resource Economics, University of Rhode Island, Kingston, RI 02881, USA

ABSTRACT

*In 1990, cultured salmon constituted approximately 16 percent of Japan's total salmon imports. Salmon is consumed in increasingly diversified fashion in terms of product types and market outlets. Conjoint analysis was applied to elicit the structure of a salmon buyer's preferences. Relative contribution of individual attributes to the product's overall preference was estimated through two-limit tobit and rank-order logit models. The models estimated the buyer's preference function reasonably well despite the survey results from different salmon buyers at different points in time.*

## 1. INTRODUCTION

In the face of increasing aquaculture production, declining high-seas operations, and changing in consumer behavior, the salmon market in Japan is going through some major changes. Japan's salmon market has become highly differentiated and dynamic. A conventional demand approach which treats salmon as a homogeneous product does not completely explain why the Japanese salmon market is evolving the way it is. Questions such as whether cultured salmon is a perfect substitute for wild-caught salmon can only be answered by understanding what buyers perceive in these products.

Salmon is a heterogeneous product differentiated with respect to attributes such as species, country of origin, method of catch, flesh color, fat content, and price. Each attribute has several subclasses of characteristics (levels) such as the flesh color attribute has several grades of color; deep red, pink red, pale pink. Salmon can therefore be described as a composite of attributes at different levels. A buyer's overall preference for the product in question is the totality of the utility he/she derives from individual attributes of the product.

Available market data never fully identify the attributes of the product. Market data generally quantify product price and quantity as if products were homogeneous. Therefore, despite the fact that salmon is widely traded in the market, the buyer's valuation of individual attributes can not be estimated using available market data.

## 2. CONJOINT ANALYSIS

An experimental technique called conjoint analysis was applied to elicit the structure of a salmon buyer's preferences through survey measures. By obtaining buyers' evaluation for product profiles pre-specified in terms of levels of different attributes, conjoint analysis allows the researcher to estimate the relative contribution of the individual levels of attributes to the respondent's overall evaluation of the product.

The conjoint method used in this paper was originally proposed by Luce and Tukey in psychometrics literature and now widely used for market research. The first consumer-oriented application of conjoint analysis was brought out by Green and Rao in 1971. Since then, numerous theoretical and empirical contributions have been made to the advancement of this technique (Green and Rao, 1971; Green and Wind, 1975; Johnson, 1974; Green and Srinavasan 1978 and 1990). Anderson and Brooks first applied this approach for the analysis of the salmon market in New England in 1986.

One conceptual difference between conjoint measures and other non-market valuation techniques such as contingent valuation, is that the price of the good is treated as simply another component of the product and thus minimizes many of the biases that can arise in contingent-valuation studies when respondents are presented with the unrealistic task of putting prices on non-market goods.

## 3. EXPERIMENTAL DESIGN

Attributes and attribute levels for our experiment were chosen based on *a priori* knowledge of the Japanese market, a similar study done by Anderson and Brooks of the New England salmon market (1986), a survey of Japanese traders in Seattle and Vancouver, and discussions with several Japanese traders in Boston. Wholesale price information from the Tokyo Central Wholesale Market was used to select price levels. The selected attributes and the levels of each attribute are listed in Table 1. There are 12 attributes with the number of levels ranging from 2 to 8 per attribute.

If all combinations of attributes and attribute levels were considered (full factorial design), this would result in $7 * 6^2 * 4^3 * 3^5 * 2 = 7{,}838{,}208$ possible products. With the assumption of minimal interaction among attributes, a minimum design necessary for the estimation of main-effect was obtained using orthogonal main-effect plans for asymmetrical factorial experiments devised by Addelman. (Addelman, 1962)

Since occurrence of the levels of attributes is balanced regardless of whether a certain combination exists in the real world, product profiles generated by orthogonal design include unrealistic products. Pre-testing of the survey instrument with Japanese traders in Boston strongly indicated that the inclusion of these unrealistic products undermines a respondent's confidence and cooperation with the survey.

In order to circumvent this problem, a larger matrix was designed using orthogonal arrays (81 profiles), and then 27 unrealistic profiles were deleted from the original design, resulting in 54 profiles to be tested. Although the deletion of any profile from a fractional factorial design may make some attributes somewhat correlated, the presence of inter-attribute correlations per se does not violate any assumptions of conjoint analysis (Green and Srinavasan 1990).

A full-profile procedure was used for data collection where respondents were presented with product profiles which consist of a complete set of attributes. An example of the profile card can be found in Table 2. In order to avoid possible information overload on the part of the respondent, product profile cards were divided into subgroups and only 6 product profiles were presented to each respondent. With only 6 profiles evaluated by each respondent, a minimum of nine interviews with salmon buyers was necessary in order to complete all 54 cards. This segmentation of the full design across individual respondents is commonly used in conjoint experiments (Green and Srinavasan 1990).

## 4. SURVEY PROCEDURES

The survey was conducted in Japan on two different occasions; March and April, 1988 and November 1989. Respondents were chosen from the member list of the Japan Marine Products Importers Association. Out of 79 firms included in the list, 56 firms imported salmon as one of their primary products. Because of travel logistics and time constraints, those headquartered in Tokyo were targeted (51 firms out of 56).

The salmon import division of each firm was contacted. In 1988, out of 24 traders contacted, 15 traders completed the survey. Imports of salmon are handled by a relatively small number of large firms in Japan. The 15 firms surveyed in 1988 handled approximately 60% of Japan's salmon imports in 1988.[1] In 1989, out of 46 traders contacted, 29 traders completed the survey. The 29 firms surveyed in 1989 handled about 65-70% of Japanese salmon imports in 1989.

The survey was conducted using in-person interviews. The questionnaire was 4 pages long and took about 20-30 minutes to administer. It consisted of three parts :

i) description of the respondent's firm,

ii) a self-explicated utility measure, and

iii) a conjoint measure.

In the self-explicated utility part, the respondents evaluated attributes and levels of attributes directly. Respondents rated the relative importance of salmon attributes for their purchase decision on the scale of 0 to 100. The most important attribute was assigned 100 points and the remaining attributes were scored relative to that attribute. The same score could be placed on more than one attribute. The respondent then rated the levels of each attribute such as coho, king, sockeye, chum, pink, and Atlantic salmon on the scale of 0 to 10 respectively. While evaluating levels of an attribute, the rest of the attributes were assumed to be held constant.

A total of 54 salmon profile cards were divided into 9 groups of 6 profiles. In the conjoint part, the respondent evaluated these 6 hypothetical salmon product profiles and ordered them from the most to least preferred. When the ranking of 6 products was completed, a respondent placed preference scores on each product profile on the scale of 0 to 100. Prior to rating, the ideal product was composed of the combination of attributes the respondent described as most preferred in the self-explicated part. The ideal product varied among respondents. The respondent placed scores on each hypothetical salmon profile relative to the ideal product. This was done in order to establish the ceiling of the preference scoring.

## 5. MODEL ESTIMATION

Through the in-person interviews of the Japanese salmon buyers, the preference rankings and scores of the hypothetical salmon products were obtained. The rankings and scores reflect the respondent's relative preference of the products and are used as dependent variables and regressed against product attribute levels in our model.

A ranking is ordinal-scaled where it represents a simple ordering such as product A is preferred to product B. Ranking as a function of various attribute levels, therefore, was developed in a discrete choice model. Rank-order logit, a variation of a multinomial logit model which incorporates all ranking information was used for the estimation. LIMDEP's regression procedure for observed rank-order data was used, which is based on the model developed by Beggs, Cardell, and Hausman. (Beggs, et al., 1981)

Scores, on the other hand, are interval scaled, wherein the distance between any two numbers on the scale represents not only preference ordering but also the intensity of the respondent's preference for the products. Given a larger amount of information, preference scores as the dependent variable regressed against attribute levels is expected to outperform ranking in terms of specifying a respondent preference function. The preference scores obtained from our survey are limited between 0 and 100. When the value of the dependent variable is limited in a certain range, the sample data become the mixture of discrete limit observations and continuous non-limit observations and thus ordinary least squares estimator will be biased and inconsistent (Maddala, 1990).

The two-limit censored regression model, an extension of the basic Tobit model, was used for the estimation. The two-limit specification was developed by Rosett and Nelson (1975). Nakamura and Nakamura (1983) applied two-limit censored regression in the analysis of work behavior of married women.

1. The percentage was calculated from total Japanese imports of salmon in 1987 (published by the Ministry of Finance) and the aggregate of the each company's salmon import quantity.

A two-limit censored regression model is formulated as follows. Define a latent non-observable variable $y_i^*$, such that;
$y_i^* = \beta' x + l \qquad l \sim N(0, \sigma^2)$

where $\beta$ is a $k \times 1$ vector of unknown parameters, x is a $k \times i$ vector of explanatory variables and residuals. If we denote by $y_i$ the observed dependent variable,

$$\begin{aligned} y_i &= L_{1i} && \text{if } y^* \geq L_{1i}, \\ y_i &= y^* && \text{if } L_{1i} \leq y^* \leq L_{2i} \\ y_i &= L_{2i} && \text{if } y_i^* \geq L_{2i} \end{aligned}$$

where L1i and L2i are respectively lower and upper limit which are 0 and 100 in our model.

The likelihood function for this model is given by :

$$L(\beta, \sigma / y_i, x_i, L_{1i}, L_{2i}) = \prod_{y_i = L_{1i}} \Phi\left(\frac{L_{1i} - \beta' x}{\sigma}\right) \prod_{y_i = y_i^*} \frac{1}{\sigma} \varphi\left(\frac{y_i - \beta_x}{\sigma}\right) \prod_{y_i = L_{2i}} \left(1 - \Phi\left(\frac{L_{2i} - \beta' x}{\sigma}\right)\right)$$

where $\phi$ represents the cumulative distribution function and the density function of the standard normal distribution (Maddala, 1990). Maximization is obtained by equating the partial derivatives of the log-likelihood function with respect to $\beta$ and $\varsigma^2$ to zero. The two-limit tobit procedure in LIMDEP was used for estimation of our model, which utilizes OLS estimators as initial values and Newton-Raphson method as an iterative procedure.

Except for price, all the other explanatory variables included in the model are dummy variables. Price is the only continuous variable. Since there are relatively large price differentials among species of salmon, using one continuous price across all salmon species introduces inconsistency as to how the respondent perceives price. In order to circumvent this problem, base prices were calculated for each salmon species by product type from the average wholesale prices at the Tokyo Central Wholesale Market, adjusted for estimated CIF price. Price is then expressed as the difference between listed price in the product profile and the base price, converting, for example, 790 yen/kg for both sockeye and pink frozen salmon to -545 yen/kg for sockeye and +112 yen/kg for pink salmon respectively.

More detail in experimental design, survey procedure, and model estimation is available in "Conjoint Analysis of the Japanese Salmon Buyer's Preference : Market Analysis of Norweigian Farmed Salmon", published by the Center for Research in Economics and Business Administration.

## 6. RESULTS OF CONJOINT ANALYSIS

Out of the 44 traders who agreed to respond to the survey, four did not complete the self-explicated measure task, one did not complete ratings of hypothetical product, and one only partially completed the ratings. The rest of the respondents provided ratings of 6 hypothetical products. The ideal product the respondent described prior to rating hypothetical products was incorporated into the data. When the respondents voluntarily provided new product ratings by changing one of the attribute levels of the hypothetical product, they were also incorporated into the data. This has resulted in a total of 298 rating observations.

The preliminary results of the self-explicated measure and conjoint analysis are compiled in this paper where survey data of 1988 and 1989 is pooled together. Separate analysis of the data in different years is not included here.

Table 3 summarizes the weighted average of the direct evaluation of attributes and attribute levels in the self-explicated measure. It indicates that traders consider price and quality as the most important attributes in the product. The ideal product is described as; sockeye salmon from Canada, troll caught, frozen, high quality, with bright silver skin, deep red flesh color, high fat, in head-off/2-3kg size, available year-round, at the price of 580 yen/kg.

Table 4 shows the results of the estimation of the discrete rank-order logit model and the two-limit tobit models. Despite the intertemporal difference among responses by traders, the model estimated the buyer's preference function reasonably well. Higher performance was expected for the two-limit tobit model given that the score was used for the dependent

variable (rather than rankings). At least in this model specification, however, discrete rank-order logit outperformed the two-limit tobit model in terms of overall lower standard errors. The signs and relative magnitude of the coefficients, although they are not directly comparable due to different regression procedures, are in general accordance between two-limit tobit and rank-order logit models. These results are also generally comparable to the self-explicated result, which indicates the robustness of the model specification.

The sign of the coefficient for the price variable, which was the difference between listed price and estimated CIF price, conform to prior expectations for both models, though the degree of significance was low for tobit model. Quality variables also show expected signs and the difference in quality is highly significant in both tobit and rank-order logit models.

The rank-order logit model indicates that coho, king, sockeye, and Atlantic salmon are all significantly preferred to chum, which is the omitted dummy variable from species category. Pink salmon is significantly less preferred to chum salmon. The tobit model, however, indicates that coho and pink are not significantly different from chum salmon.

In the rank-order logit model, Canada is significantly preferred to Alaska as the country of origin, while all the other places of origin for salmon are not significantly different from Alaska. Two-limit tobit, on the other hand, show insignificant preference difference among all salmon origins.

The tobit model indicates that troll-caught is significantly preferred to farmed among different methods of catch. The result is consistent with the indication of the respondent's direct ratings in the self-explicated measure. The rank-order logit model, on the other hand, showed no significant differences among all methods of catch in terms of contribution to the buyer's overall preference for the product.

Fresh and salted product is not significantly different from frozen form in both models. This result does not concur with the respondent's direct ratings of product type where frozen is strongly preferred. When comparing just product type attributes holding other characteristics constant, traders may prefer frozen, since the vast majority of the product handled by traders is frozen. However, traders move different products through many market channels. In evaluating individual hypothetical products, fresh/frozen/salted attributes may not hinder buyers' overall preference for the product.

No significant differences were detected among all skin color/appearance attributes in both tobit and rank-order logit. However, deep red flesh color is significantly different from pink red color in both tobit and rank-order logit model in terms of the contribution to the buyers' overall preference for the product.

The sign of the coefficient for fat content variables conforms to the theoretical expectations for both models. High fat content, moreover, is significantly different from medium fat content for product preference contribution in both models.

The tobit model indicates that head-off/2-3 kg size is significantly preferred to head-off/1-2 kg size. All other product forms/sizes were insignificantly different from the omitted form. Rank-order logit indicates that fillet, head-on/2-3 kg, head-on/3kg+, head-off 2-3 kg, and head-off/3kg+ are all significantly preferred to the omitted base product. Seasonal availability is significantly preferred to year-round supply for both tobit and rank-order logit.

## 7. SUMMARY AND CONCLUSIONS

This is the first effort to analyze the Japanese salmon market in terms of buyer's preference of salmon as a function of product attributes. In this approach, salmon is treated as a multiattribute product. Relative contribution of individual attributes to the product's overall preference was estimated through two model specifications; two-limit tobit and rank-order logit. Although the model could be further refined, the model estimated the buyer's preference function reasonably well despite the intertemporal difference among survey results from traders. Both model specifications are in general accordance with each other. Detailed information concerning how each product attribute contributes to the buyer's preference for the product is useful to the industry as well as researchers.

# Seafood Consumption and Giffen Behavior

**Richard S. Johnston [a] and Douglas M. Larson [b] ***

[a] Department of Agricultural and Resource Economic, Oregon State University, BalE 213, Corvallis, OR 97331-3601, USA

[b] Department of Agricultural Economics, University of California, Davis, CA 95616, USA

ABSTRACT

*In recent years, at least in the U.S., consumption of several seafoods has increased at the same time as prices of these seafoods have risen. Some analysts suggest that this is a consequence of an increased demand for seafood. Explanations of this demand increase include rising prices of substitutes and changes in tastes and preferences that favor seafood because of health and nutrition issues. On the other hand, recent demand studies report that such a positive price-quantity relationship exists even in the absence of demand increases, suggesting that these seafoods may have the characteristics of Giffen goods.*

*In this paper, we provide a rationale for these findings. In particular, we expand the neoclassical model of consumer choice to embrace the notion of "local satiety," associated with upper bounds on the consumption of food due to physical limitations on ingestion. The model leads to the hypothesis that, for some configurations of the consumer's budget constraint, if several protein sources can be used to achieve local satiety, the consumer will expand purchases of the cheapest good when its price rises, as long as that price continues to be lower than those of its substitutes. The result is apparent Giffen behavior by the consumer.*

## 1. INTRODUCTION

In recent years, several apparent anomalies have been reported in empirical studies of food, including seafood, consumption. For example a number of econometric investigations report finding positive price elasticities of demand for particular food items. These include margarine in the U.K. (Stone), chicken and turkey in the U.S. (Lambert), and food

* Partial support for the research reported here was provided by the Agricultural Experiment Stations at Oregon State University (Regional Research Project S-216) and the University of California, Davis. Support was also provided by the Cooperative States Research Service, U S. Department of Agriculture (Agreement No. 92-34276-7140).

in total in the U.K. (Deaton and Muellbauer). A recent report on the increased demand for generic grocery items in the face of declining real incomes suggests negative income elasticities, if not Giffen effects (Feigenbaum, 1991). A 1988 study by Kim, et al. reported positive price elasticities of demand for some seafood in Japan. Many other examples are scattered throughout the literature, and are often dismissed as being associated with problems of data, of model specification, or of various econometric problems.

We propose an alternative explanation : namely, that particular food items may, over a range of prices, behave as if they were Giffen goods and that this phenomenon is more common than previously thought. We suspect that this may also help explain why per capita seafood consumption peaked in the U.S. in 1987 and has been declining since.

Our argument rests on a model of consumer behavior in which choice is constrained by two, not one, restrictions. This, then, is an extension of the neoclassical theory of demand, which derives from a model of individual choice in which a consumer seeks to maximize satisfaction subject to a single constraint on expenditures. The theory predicts a negative relationship between a good's relative price and the quantity of it demanded. Giffen behavior — that is, behavior that yields a positive relationship between prices and quantities demanded — can exist only if a positive income effect outweighs an always negative substitution effect. In the standard neoclassical framework, then, Giffen behavior is a phenomenon associated with highly restrictive — and, therefore, unlikely — characteristics of the consumer's utility function. Over the years there have been numerous attempts to uncover goods that are likely to give rise to such functions, with mixed results. A recent experiment shows that some animals demonstrate such behavior and suggests that economic theory must accommodate, not abandon, the phenomenon, despite "the very small likelihood of its existence" (Battalio et al., 1991, p. 969).

One difficulty with finding empirical examples of Giffen behavior in humans is that the neoclassical model provides few clues for locating either goods or individuals where the behavior is likely to be seen. Under what circumstances can one expect to observe not only positive income effects but also positive income effects that swamp substitution effects ? Hicks argued that, for a good to be Giffen, a high proportion of the consumer's income has to be spent on it (Hicks, 1956, p. 65). Ng (1972) suggested looking for this where consumers engage in stepwise optimization, with income being distributed initially among categories of goods, along lines first proposed by Strotz (1957). While the proportion of the consumer's income spent on a good may be low, the proportion of the expenditure assigned to each category could be high, increasing the likelihood of observing the Giffen phenomenon. This suggestion may help to narrow the search but, so far at least, it has provided no guidance for how to select either categories or goods to look for Giffen behavior. Thus Giffen goods continue to be viewed as theoretically possible but empirically unlikely.

In a recent article, Gilley and Karels (1991) (hereafter G-K) develop a convincing argument to explain Giffen behavior as a consequence not of preference characteristics but, rather, of a constraint on behavior : in particular, a nutrition constraint. Their results lead them to conclude that "the most likely place...to look for Giffen behavior...would be among the very poor, consuming a few staple items with limited substitution possibilities" (p. 189). Here, then, is a concrete guide for empirical discovery of the phenomenon, although they endorse the view that the behavior is probably rare.

We maintain that Giffen behavior may be a much more pervasive phenomenon than commonly believed and we suggest where it may be found [1]. We argue that, where preferences are characterized by local satiety, the associated behavior is restricted by an upper bound on consumption, allowing analysis to proceed along lines similar to those suggested by G-K. We therefore, focus the search for Giffen behavior through illustrating how a plausible characteristic of preferences, independent of specific functional form, can generate such behavior in a one constraint world.

The argument that local satiety may give rise to Giffen behavior was first advanced twenty years ago by Lipsey and Rosenbluth (1971) (hereafter L-R). While this work has been cited by almost all who have written in the area since, the principal idea of the piece — that Giffen behavior may be observed in goods whose characteristics (see Lancaster, 1965) are subject to satiation — has not been explored empirically. We suspect the reason is similar to that associated with the earlier argument about relationships between income and substitution effects : without guidance on where to find satiation in characteristics, the phenomenon remains only a theoretical possibility with little empirical relevance. The contribution of the present paper is to provide concrete suggestions for where and why one might locate local satiety and, in so doing, illustrate how the G-K framework generalizes to other areas that offer a high likelihood of finding Giffen phenomena.

1. Actually, G-K recognize that their model extends to other arenas, pointing to a study that found Giffen behavior among drug addicts who seek to achieve a minimum intoxication level with a limited budget. This example implies a belief, however, that the phenomenon is relatively rare.

It is useful to summarize the G-K model, in which the consumer seeks to maximize satisfaction from bundles of food, subject to two constraints : budget and subsistence. The former places an upper limit on the quantity of food consumed while the latter imposes a lower bound. Beginning with the case in which the consumer chooses among combinations of two goods, G-K illustrate their argument with the diagram that appears below, in expanded version, as Figure 1.

In Figure 1, quantities of the two goods, X and Y, appear on the horizontal and vertical axes, respectively (In G-K these goods are meat and potatoes.). Indifference curves $I_1$, $I_2$,... come from a utility function whose form, G-K argue, need not be specified[2]. Line MM is the consumer's budget constraint, while NN is the nutrition constraint, whose slope is the ratio of X's contribution (per unit) to nutrition to Y's unit contribution (e.g., calories per unit of X consumed / calories per unit of Y consumed). Note that the slope of line NN exceeds that of line MM. When both constraints are binding, the consumer maximizes satisfaction by consuming (Y', X'). Notice that the nutrition constraint and the budget line define the feasible set for consumption.

Suppose the price of X rises, shifting MM to MM'. The feasible set shrinks and the optimum bundle is now (Y",X"). Consumption of X rises and of Y falls : good X has the "appearance" of a Giffen good. Intuitively, this makes sense. Suppose X and Y were equal in their contributions to nutrition, so that the slope of NN were -1, and that the consumer views the two goods as close, but not perfect, substitutes. With a relatively small budget available for purchases of X and Y, the consumer will tend to select a bundle with more X, the cheaper good, than Y. If the price of X rises, *but remains lower than the price of Y*, the consumer will choose to substitute the cheaper good for the more expensive good in order to meet the nutritional constraint while staying within his or her budget.

## 2. GENERALIZING TO OTHER CONSTRAINTS

The G-K model is instructive in predicting Giffen behavior in the presence of a nutrition constraint. Our contention, however, is that the model can be modified to predict Giffen behavior in a variety of settings. G-K anticipate this generalization in their paper's abstract, wherein they speak of "a theory of Giffen behavior that results from a second rationing constraint" (p. 182). The particular second constraint they select imposes a minimum bound on the choice set. There are, however, at least two cases in which a second constraint, like the budget constraint, imposes an upper bound — a second upper bound — on the consumer's choice set. These are : time-constrained decision-making (Becker, 1965) and points rationing (Scitovsky, 1942 ; Tobin, 1952). The present paper suggests, following L-R, that Giffen behavior may also appear in the presence of another phenomenon, that of local satiation, in which the consumer's utility function is characterized by one or more upper bounds on consumption. We choose this case because it portrays some of the essential elements of the other cases and because it is easily exemplified by food, thereby preserving the G-K setting. In addition, by offering a specific rationale for and concrete example of local satiety, it helps to provide the L-R framework with a basis for hypothesis testing.

Notice that the satiation case presents a useful counterpoint to the G-K analysis, for two reasons. First, Giffen behavior is shown to arise because of a plausible characteristic of preferences (independent of specific functional forms), rather than because of the presence of an additional constraint. Second, it demonstrates that the phenomenon can occur equally well when there are two upper bounds to consumption, rather than with an upper and a lower bound as in the G-K model.

## 3. LOCAL SATIETY AND THE DEMAND FOR MEALS

In the standard exposition of the neoclassical theory of consumer choice little attention is paid to the phenomenon of satiation, largely on the grounds that "the interesting region (of the utility function) is where you have *less* than you want

2. Although, as discussed below, its properties play an important role in determining the likelihood of Giffen behavior. Note that, for the intersection of the constraints to be the consumer's choice position, the indifference curves from a quasi-concave, twice differentiable utility function must be flatter than both of the constraints throughout the feasible region. An observation by Lew Queirolo leads us to point out that, under G-K conditions, the indifference curves do not extend below NN because in the region ONN the consumer is either dead or suffering from malnutritution.

of most goods" (Varian, pp. 43-44). However, there are numerous goods for which consumption takes place at the point of local satiation. During a given time period, the average consumer is unlikely to purchase more typewriter ribbon, shoe polish, lawn fertilizer, attorney's services, or copies of today's newspaper in response to higher income levels or lower prices, even if the latter fell to zero [3]. Satiation is especially likely to be seen in the consumption of goods and services that are close substitutes for each other but which, as a group, have few close substitutes and are associated with a durable asset. This is especially true of goods for which storage is costly or impossible, including perishable goods. Perishability may be a property of either goods or their services, the former exemplified by some foods and the latter by newspapers. For the residential householder with a lawn in place, a reduction in the price of lawn fertilizer below some threshold level is unlikely to increase the quantity demanded in a given year (although this may not be the case for a particular brand of fertilizer). The same argument can be made for items such as typewriter ribbon and shoe polish, although contributing to the explanation in these cases is the relatively high cost of increasing their use (changing the typewriter ribbon frequently, polishing the shoes more often). Attorneys are hired to perform highly specific services, for which the quantity demanded is unlikely to rise if unit costs fall below some level at which it pays to hire the attorney in the first place but above the unit cost of other services that attorneys are able to perform, such as unskilled labor. One could employ the attorney to perform "non-legal" services but it is not clear why one would choose an attorney if other providers of the service are available at a lower cost.

A similar argument can be made for food, at least for some dining patterns. For physiological reasons there is an upper limit to the amount of food and beverage that a consumer can ingest during a short period of time. Economic manifestations of this include "all you can eat" offers in some restaurants and "free" refills of cups of coffee. If satiety were not a pervasive phenomenon, these restaurants would have high bankruptcy rates. The key here is the time dimension. "All you can eat" restaurants, in contrast to other restaurants, do not offer "doggie bags" to clients, permitting future consumption.

Thus satiety is a phenomenon for food consumption during short periods. But what about longer periods ? Would one not expect the annual consumption of a particular food to increase if its price were to fall ? Of course. But this is probably not the case for broad categories of food. Most food is consumed, at least in Western cultures, as part of a meal — and meals last a relatively short period of time. Furthermore, for most consumers, there are no more than three meals in any day. Thus, if satiety is an aspect of consumption for any given meal, it is an aspect of consumption during any given day and, by extension, for any time period. This argument lies behind the often-observed phenomenon of a highly price-inelastic demand for food in the aggregate. While the demand for any particular food item, such as beef, may be relatively price elastic, this is not the case for all food — or even groups of food — taken together. This relationship goes beyond the "number of substitutes" argument. Its explanation lies, as well, in the limited capacity of the human consumer to eat and drink.

This appears to be a concrete example of what L-R had in mind when they spoke of "satiation in characteristics" of goods as possible explanations of the Giffen phenomenon. Food's characteristics include flavor, color, texture and fragrance. But food also contributes to the feeling of fullness. At any meal additional units of food may provide utility to the diner through the flavor, texture, color and fragrance characteristics, but generate discomfort in the fullness dimension, generating pleas of "I'd love to have more but I'm stuffed."

Consider the average, middle-income American household. Most of its members consume three meals per day, or a total of twenty-one meals per week. Focus on the evening meal. That meal generally consists of an entree item (beef, pork, poultry, seafood), vegetables, salad, a beverage and, possibly, dessert. Of course there are exceptions, including meals prepared for vegetarians, but, in general, this is a reasonable description of the typical American dinner.

Reasons for this are partly cultural, partly habit-determined and partly economic, perhaps having to do with minimization of transaction costs. Consider the purchase problem faced by the individual having the responsibility for buying food to prepare the evening meal. Note that, even if the food for this meal were available at a zero price, no more than can be physically consumed would be purchased [4]. This is true for every meal : despite additional utility from flavor, etc., no

3. The consumer could purchase today for future consumption. Aside from the problem of storage there is the additional question of why the consumer would do this if the zero price were not expected to change.
4. This abstracts from storage possibilities. But it is not clear why, if the price of a food item falls and is expected to remain at its lower level, the consumer would choose to purchase now for future consumption, thus incurring a storage cost. Storage is more likely to occur to minimize transaction, including transportation, costs and/or because of expectations regarding future prices. At zero price, would the consumer not purchase

more would be purchased for each meal than can be physically consumed during that meal. Thus, for the average week, the typical food buyer will choose no more than seven entree items per week, having a combined maximum weight per person of, say, seven pounds [5].

For simplicity, suppose that each meal consists of only one item, the entree, but that the consumer can choose from among several foods for that entree. Examples include beef steak, hamburger, fish fillets, pork chops and other protein sources. Consider one such item, say, beef steak. Suppose, further, that for any dinner meal and a given household member, the utility of beef steak—such utility associated with flavor, color, texture, and fragrance — increases with the size of the portion. The beef steak also adds to utility through contributing to the feeling of fullness. In this dimension, however, there is a limit, beyond which the marginal utility is negative. In fact it may be so negative that it swamps the contribution of the other characteristics of a larger portion. The "net" marginal utility, then, is negative. Consumption is not observed in that range, a case of local satiety.

Next, introduce a second food that could also serve as an entree item, such as fish fillets, having similar characteristics. One could think of a given meal being designed to consist of a particular combination of beef and fish, where that combination may yield flavor, texture, color and fragrance levels that are different from those of other combinations. However, in the "feeling of fullness" dimension, any given volume of fish and beef will make the same contribution to utility as any other combination having the same volume. Thus, no matter whether the meal consists of only beef, only fish, or some combination of beef and fish, there is a physical limit to the size of the entree yielding positive net marginal utility to the consumer. Local satiety produces an upper bound on consumption. This argument extends to combinations of any of the foods included in the entree category but, for ease of graphical presentation, it is assumed that there are only two such foods. Figure 2 depicts the situation.

In Figure 2 the elliptical-shaped curves are indifference curves indicating levels of satisfaction realized by the individual for various combinations of beef (b) and fish (s, for seafood) consumed at a single meal. These curves are truncated at the line AB, along which the consumer is satiated [6].

The equation of line AB is $s + b = 1$. Thus, the consumer reaches satiety at one pound of food (combination of beef and seafood) [7].

Where $s + b < 1$, all of the marginal utilities are positive, by assumption. Note that AB itself is not an iso-utility contour, since utility is first increasing and then decreasing as one moves along its length. Line MM is the budget constraint in this two-good model.

In the Figure 2 case, it is drawn such that the price of beef exceeds the price of seafood. The feasible set, in contrast to that of G-K, is OMΘB. The utility-maximizing consumer selects s* pounds of seafood and b* pounds of beef. At a higher price of beef (no change in the consumer's budget or the price of seafood), represented by MM', the consumer chooses the combination (s', b'). This is a standard result : with an increase in the price of beef, consumption of beef falls and consumption of seafood rises.

However, this new combination is also the consumer's choice for the budget constraint given by MM'', along which the price of seafood is above its initial level, with the price of beef and the budget level unchanged. That is, an increase in the price of seafood, while reducing the feasible set to OM'ΦB, leads, in this case, to lower beef consumption and *higher* seafood consumption. The intuitive explanation is that, as long as the consumer maximizes satisfaction by consuming to satiation, more of the less expensive good will be chosen when the price of that good rises because, with a fixed budget,

---

more than can be eaten, finding some other use for the excess ? This could be the case if disposal costs were zero and/or if there were gains from this other use. Food, however, is perishable. If it is not eaten or stored, it spoils, creating discomfort that is costly. This plus disposal costs militate against excess food purchases.

5. The number is irrelevant to the argument but is provided to indicate that there is such a number, although it may vary among individuals. The point is simply that there is an upper limit, for both cultural and stomach capacity reasons, on the volume of dinner entrees that can be consumed by an individual in any given week. This capacity is not determined by economic considerations.
6. Note that AB is the crest of the "utility hill" and that it need not necessarily coincide with the line along which the marginal utility in the fullness dimension is zero. It is possible that, because of gains in utility from taste (or other characteristic) the consumer will endure some discomfort from being "full." Eventually some limit will be reached where the "net" marginal utility is zero and beyond which it is negative. The combinations of b and s for which this is true are those along AB. We expect that, in most cases, these will also be the combinations of b and s for which the marginal utility in the fullness dimension is zero. In any event, consumption will not be observed to the northeast of AB because of disposal, storage, or discomfort costs.
7. Alternatively, one could think of the selection of entrees for an entire week, or other time period. Using the numbers indicated in the text, the constraint would be $s + b \leq 7$.

the loss of effective income accompanying a price rise of either good requires that the less expensive good play a larger role in achieving satiation. It is as if the two goods were perfect substitutes in achieving satiation, so that the less expensive good would provide the least cost way of reaching satiation. The reason this good is not chosen to the exclusion of the second good is that the two goods are not perfect substitutes in the provision of taste, color, texture, and fragrance. In addition, local satiation is not associated with a single level of utility, analogous to a "bliss point." Rather, the consumer is satiated at all combinations of the two goods that sum to unity, and those combinations have different levels of utility associated with them that differ from those of adjacent combinations.

All of this is really the consequence of an income effect, since there is no substitution effect along AB, as noted by G-K [8]. By keeping prices at their original level and decreasing income appropriately, the consumer will move to (b',s'). With a lower entree budget, the consumer will substitute the lower priced seafood entree for beef.

These ideas can, perhaps, best be illustrated via an explicit utility function. It is also appropriate to introduce a third good to generalize the problem, enabling the consumer to spend part of his/her budget on that good.

For purposes of illustration, the following function is chosen :

$U = b^{0.5}s^{0.5} + z^{0.5}$, for $b + s \leq 1$, the local satiety condition on $s + b$, and for b, s and z all $\geq 0$.

This function has the property that, in consumption, b and s are independent of z but not of each other. The consumer is constrained to choose combinations of b, s, and z such that $b + s \leq 1$. The consumer also faces the budget constraint $P_s\, s + P_b\, b + P_z\, z \leq 0.5$, where P denotes price. Consumer choice is computed for different levels of $P_s$ but with $P_b = 1$ and $P_z = 9$. The results appear in Table 1.

As revealed by Table 1, when $P_s$ increases from.20 to.25, the consumer increases consumption of s from.719 to.739. At an even higher price, $P_s$ =.30, consumption of s is higher yet, at.758. Thus, in this range, the consumption of s and the price of s move in the same direction. When the price of s rises to.35, however, consumption of s declines to.659. This is because the consumer maximizes satisfaction by moving away from local satiety, consuming b and s such that $b + s < 1$. The situation is depicted in Figure 3, where, for purposes of illustration, it is assumed that the consumer's entire budget is spent on goods b and s.

In Figure 3, as $P_s$ increases from zero, consumption of s first exhibits no change (it remains at s*), then rises, and eventually declines. During the phase of rising consumption the consumer moves along the line $b + s = 1$. Total utility declines with the price increases, since b consumption declines, but local satiety is maintained. The consumer is simply trading off units of the higher priced good for units of the lower priced good, while maintaining local satiety. For a sufficiently high price of s, e.g., along MM", the consumer is induced to cut back consumption of both goods, and will leave the table hungry (i.e., not satiated). At (b", s") local satiation is not binding [9].

Here, then, is a possible explanation of the uncovering of positive price elasticities in empirical estimates of the demand for food items. Through the imposition of restrictions on meal purchases (because of either satiation considerations or custom), consumers may increase purchases of a food item when its price rises, as long as that item continues to be the least-cost way to satisfy those restrictions. In the U.S. this may help explain why per capita seafood consumption rose during the 1980s to its 1987 peak. Perhaps the period since 1987 has seen continued increases in seafood prices such that seafood no longer satisfied the least cost criterion, leading to declines in per capita consumption.

## 4. THEORETICAL CONSIDERATIONS AND EMPIRICAL COUNTERPARTS

Are there properties of the consumer's utility function and/or the constraints (s)he faces that make Giffen behavior more or less likely ? It has been argued above that, under conditions of local satiety, as in the case of some food consumption decisions, Giffen behavior is likely to be observed. When combinations of two (or more) goods lead to conditions of local satiety, the good with the lower price may bring forth Giffen behavior. This is even more likely when the consumer has a relatively low budget available for those goods. The demands for particular brands of a good exhibiting local satiation, ranging from cigarettes to newspapers, may be examples.

8. Although, in a sense, the goods are perfect substitutes in their contribution to fullness and, thus, local satiation.
9. Because there is a third good, the budget constraint would have to shift to reflect changes in expenditures on that good. Incorporating this consideration would unnecessarily complicate the graph while adding no new insights.

As illustrated in Figure 3 above, however, Giffen behavior is less likely to appear if local satiety is not an effective bound on consumption. This, in turn, is more likely the less substitutable the two goods, i.e., the more "bowed" the indifference curves where they cross the "iso-satiation" curve.

A second issue merits examination. Refer back to Figure 3. Note that, at both Giffen equilibrium positions (b'', s'') and (b''', s'''), the marginal rate of substitution of s for b (-db/ds) is less than the slope of AB. For quasi-concave, twice-differentiable utility functions, this means that both equilibrium positions must be to the southwest of point *, where * is the bundle yielding the highest satisfaction level subject only to the AB bound. If the intersection is to the left of *, as depicted in Figure 3, it is not an optimum for the consumer, who can increase satisfaction by moving to *, where the budget constraint is non-binding. In this case, when the price of s rises, as long as the new budget line does not intersect AB below *, the consumer will not change his or her consumption bundle in response to the price change [10].

With these caveats, the above analysis suggests that Giffen behavior is likely to appear more frequently than generally believed. It has been argued that, while Giffen behavior is a logical possibility for individuals, it cannot occur at the market level (Dougan, 1982). Nonetheless, as reported at the beginning of this paper, there has been increased reporting of estimated positive price elasticities. We believe the issue merits additional investigation. Perhaps the present paper, an extension of the G-K and L-R work, will stimulate a more thorough investigation of the issue.

## 5. CONCLUSION

Giffen behavior, far from being merely a theoretical oddity of little practical importance is an entirely plausible consequence of consumer choice in the presence of multiple constraints (G-K) or local satiety (L-R). There is both conceptual and empirical support for this contention, as illustrated for the case of food consumption. The search for examples of Giffen behavior may be more successful if it begins with examples of where either multiple constraints or local satiety exist. We believe the dining room may be one place to begin.

10. The argument is similar to the L-R requirement that Giffen goods have a "comparative advantage" in the satiated characteristic relative to the other characteristics in the utility function. In their model, the marginal contribution of each good to a given characteristic is constant, allowing them to determine comparative advantage in terms of relationships among the constant coefficients. Because we do not impose this condition on the contributions of goods to their characteristics, we require only that, in equilibria consistent with Giffen behavior, the slope of the "iso-satiation" curve AB exceed the slopes of the indifference curves where they meet AB.

# The Changes Affecting the Demand for Fish and Fishery Products in Poland

**Adam Gwiazda**

Dept of Fishery Economics, Morski Instytut Rybacki, Ul Kollataja, 81332 Gdynia, Poland

ABSTRACT

*This paper analyses the recent trends in the consumption of fish and fishery products on the basis of a survey carried out among 3 400 consumers and 200 fishmongers in Northern Poland.*

*It presents the changes both in the volume and structure of the consumption of those products and outlines the future possible trends in this field. The need for the adoption of an appropriate marketing strategy has been stressed as the further increase in the consumption of seafood in Poland can be expected when the incomes of the population will rise in the next few years.*

## 1. RECENT CHANGES ON CONSUMER MARKETS IN POLAND

The most visible achievements of the programme of a radical transition from centrally planned system into a market economy were : the reduction of the hyperinflation from the level of 1800 percent on an annual basis in 1989 to 584 percent in 1990 and about 4 percent on a monthly basis in 1991, the elimination of shortages, which, however, had been attained not through a substantial expansion of domestic industrial and agricultural production (the first one fell in 1990 by almost 30% and the second increased, due to the bumper harvest by 8%), but through wage freezes, price liberalization and the elimination - till August 1991 - of import restrictions. Another positive achievement was the introduction in January 1990 of the uniform exchange rate of polish zloty in relation to US dollar and other convertible currencies which have made Poland's domestic market very attractive to both domestic and foreign companies.

All those events have led to the collapse of the producer's market and the emergence of consumer's market with still rather limited consumer's sovereignty. This stems from the fact that, in the previous two years, Polish consumers were buying almost everything reagardless the price and quality because goods were better than zlotys with a triple-digit inflation. And these habits still prevail, although Poles are offered a wide choice of various consumer goods, including the imported foodstuffs in which a substantial part constitute the fishery products. It should be recalled that the fear of

inflation, unstable market conditions, recession in the national econmy and insufficient purchasing power in society [1] are all those factors which put the pressure on incomes and force families to cut their expenditures for various types of goods. Taking into account the fact that the overwhelming portion of the family budget goes towards food (52 - 60% compared to 33% in Czechoslovakia in 1990), so it is understandable that families as consumer group must refrain from buying many other articles and services. Therefore, their "free consumer choice" is rather limited. This is also visible on the most expanding foodstuff-market in Poland where the great variety of hardly available imported food-stuffs in the previous years makes this choice even more difficult.

## 2. THE IMPORTANCE OF FISH AND FISHERY PRODUCTS IN POLISH DIET

To some extent, the Polish consumer's demand for fish and fishery products is determined - as in other countries - by traditional preferences and tastes largely influenced by geography. To another extent the consumption of fish depends also on the availability and price of other basic protein foodstuffs, in particular meat and meat products, milk and eggs. Taking into account the first fact it can be said that Polish consumers were used mostly to consume fresh-water fish than the salt-water fish. In the inter-war period there was very poorly developed Baltic fishery (mostly coastal fishery) and after the second World War, the fishery industry continued to be an insignificant component of the Polish economy till the middle of the 1950's. Since that time, when Poland developed its deep-sea fishery, there has been a steady increase in the supply of fish and fishery products on the domestic market which expanded greatly in the last two years.

Generally speaking the fish and fishery products have been regarded by the polish consumers mostly as the substitutes of meat and meat products and not as healthier than meat foodstuffs.

It is interesting to note that in 1957-1960, the share of expenditures for fish and fishery products as compared to total expenditure for foodstuffs was rather very low (1,7-2,0%), so at the end of 1980s it was 5% and in the middle of 1991 almost 6,7%-9,8% (depending on the category of household) [2]. During the last few years the consumption of fish declined significanly by about 42% per cent in 1990 as compared to the 1970 level (see table 1).

On the other hand the consumer's expenditures for fish and fishery products increased at the same time which was due not to the increase in the per capita consumption but to the introduction in 1990 of more or less realistic market prices for those products.

It should be stressed on the fact that the consumption of fish and fishery products is still more occasional than regular in Poland. As the substitute of meat and meat products the fish and fishery products are very often consumed - mostly for religious reasons - once a week, i.e. on friday which is regarded by polish Catholics as a day of fasting. For the poor families (i.e. very low, low and middle-income households) fish and fishery products are also the substitute of other than meat products, such as eggs, dairy products and edible fats. This group of people consume more fresh (both salt-and-fresh water) fish than fishery products, which had become during 1990-1991 more expensive compared to the previous years.

On the other hand, the consumption of fresh fish is not so popular among better-off Polish consumers who prefer the fishery products and consume such products on a more regular basis i.e. not as the main dishes as it is the case in the poor families but as snacks, refreshments and side-dishes. According to the survey which comprised 3400 Polish consumers about 50,6% buy regulary fresh and frozen salt-water fish and 49,4% buy them only from time to time (the same indicators for the fresh-water fish are : 38,1% and 61,9% respectivly). On average Polish consumers purchased in the middle of 1991 about 0,4 kg of fish and fishery products per month. The most popular species and products bought by Polish consumers in the first half of 1991 were herring : 15% of all purchases ; frozen fillets (of hake and pollock) : 10% ; carp : 8% ; hake : 7% ; pollock : 6% ; mackerel : 6%.

According to the survey, about 70% of the respondents buy fish and fishery products because they consider them "healthier" than other foodstuffs and roughly 41% of Polish families buy fish because it corresponds to their consumption

1. According to the AMEX Bank Review, september 1991, n7, the per capita GDP in Poland was in 1990 about 3910 US dollars at purchasing power parity from 1988. This can be compared to other estimates the GDP per capita in Poland of 1850 dollars in the fist half of 1991.
2. According to the classification adopted by the Statistical Yearbooks and Statistical Bulletins the Central Statistical Office in Poland, the average per capita consumption of the selected foodstuffs is presented in four types of households : farmer's households, retired persons and pensioner's households, employee's and employees-farmers households.

habits and tastes. It is interesting to note that about 62% of the surveyed consumers considered the present prices of fish and fishery products "too high" compared to meat and meat products, whereas only 35% find these prices acceptable. No respondent characterized the prices of fish as too low. Further, the majority of Polish consumers were not satisfied with the structure of the fish market and the organisation of its distribution : 64% of all answers.

In that context the surveyed consumers are classified among these three opinions :

- 47% think that fish and fishery products should be sold exclusively in fishmongers,
- 35% think that fish and fishery products should be sold in most of the grocery shops (supermarket),
- 17% think that fish and fishery products should be sold in selected grocery shops.

Such recommendations are in sharp contrast with the typical pattern of Western European countries where fish and fishery products are increasingly being sold by supermarkets rather than by specialty shops. For example, in France, the share of supermarket chains in the seafood market is 34% while that of traditional fishmongers equals 32%.

The idea of distributing fish and fishery products predominantly through specialty shops in Poland is hardly consistent with another view expressed by the respondents. The majority of the respondents - 58,8% - were, namely willing to buy more fish and fishery products depending on their greater availability, while only 17,6% epoused no desire to buy more, 23,5% had no opinion. Another issue worth emphasizing is that 70,6% of the surveyed consumers deemed marketing of fish and fishery products highly unsatisfactory - this opinion pertains in particular to poor advertising and only 14,7% considered the expanded marketing effort appropriate with the remaining 14,7% who have no opinion on the subject.

## 3. CHANGING MARKET CONDITIONS FOR FISH AND FISHERY PRODUCTS

During 1990 and 1991, the major factor affecting the evolution of the fish and fish products market in Poland was the supply of these products and not necessarily the behavior of the consumers and their effective demand. The shifts in price and foreign exchange rate policies of 1989-1990 made Poland's domestic market more profitable to foreign and domestic fishing companies. However, it soon became evident that despite lower incomes and limited purchasing power of the society as a whole, the prices of fish and fishery products in Poland remained relatively high compared to those in the OECD countries.

Since the end of the 1980s until mid-1991, Poland increased its finfish exports to western countries in order to earn hard currency. For example, in 1987-1989 almost the entire Polish catch of Baltic cod was exported mainly to the Danish island of Bornholm. At the same time, however, there has been a significant increase in the imports of finish (table 2). Deliveries of fish and fishery products to the market by domestic suppliers decreased to 67 600 tonnes in 1990 from 88 200 tonnes in 1989. At the same time, exports of fish and fishery products remained more or less stable at 142 000 tonnes. It should be noted that the majority of the seafish supplies came from imports, while domestic supplies declined in 1990 from the previous year level. This was due to the decline of Polish catches on almost all distant water fishing grounds [3]. The gap has not been fully closed by increasing imports.

It should also be pointed out that the progressive disintegration of the state-owned handling and distribution network and a recession in the state fish processing industry had a big impact on the market situation. Until recently, fish processing has been an almost exclusive domain of the huge, "half-monopolistic" state companies, such as Centrala Rybna and Zakkady Rybne as of the end of 1991 these state entreprises were in disarray and numerous private processing and wholesale companies have been established. Needless to say, these companies are free to choose their supply sources, i.e. select either domestic or foreign fishing companies.

A similar process can be observed among fish retailers. According to a recent survey, more than 69% of formerly state-owned fish shops have been privatized. These outlets are mostly medium sized operations according to Polish

3. The highest catches by Polish vessels recorded in 1975, i.e. 816 thousand tonnes, compared to 429,7 thousand in 1990 and 395 thousand in 1991, in which 100 thousand accounted for Baltic Sea catches and 295 thousand tonnes for deep-sea catches. Compare with the Statistical Bulletins of the Sea Fisheries Institute in Gsynia. See also Gwiazda, 1992 : Polish fisheries : development trends ans prospects, *"World fishing"* 1992, (4) pp. 28-29.

standards, employ on the average two people excluding the owner and are equipped with the chilling, freezing and cold storage facilities much superior to those of the state-owned shops. The survey which was conducted among 200 selected fish retailers revealed that fresh and frozen fish accounted for 50,1 percent of total sales in mid-1991, with smoked fish representing another 19%, canned and marinades 19,1% and other fish products 11,7%.

According to this survey of fish retailers the most popular fish products among Polish consumers were the salt-water frozen fish. Smoked fish was ranked second, followed by the fresh-water fish which during the second half of 1990 and the first half of 1991 was less expensive than seafish. Fresh saltwater fish came next, especially cod which was in short supply in 1991, as well as herring and canned products. The preferences of Polish households differ significantly from German consumers who are probably among the most demanding in Europe. In (the Western part of) Germany, herring is still the most popular variety followed by salmon, cod, tuna and redfish. Further, the canned products represent in Germany 29% of the market, frozen fish account for 22%, the share of fresh fish is only 11% and smoked fish 5% [4].

Due to the previously mentioned decline in domestic production and insufficient imports, present supplies of fish and fish products lag behind the existing demand. Deliveries of fresh and frozen fish were estimated by the owners and managers of fish shops to be falling 50% below consumer demand, while for fish products the estimated shortfall was 20%. The limited domestic supplies of fish and fish products influenced Poland's pattern of consumption. However, the multiple increase in price also played a role. During 1990-1991 prices of fish and fishery products not only equalled the corresponding level of meat and meat products but with respect to certain varieties salmon, eel and other "luxury" species-greatly surpassed the average price of other competing food products. According to estimates by the Sea Fisheries Institute in Gydnia, between 5,7 and 9,8% of the monthly food expenditures by Polish households was during this period spent on seafood. Fish and fishery products are mostly consumed at home because of the highly underdeveloped infrastructure in Poland (lack of fish restaurants, small bars, fast-food outlets).

Moreover, recent changes in import tariffs encourage neither any rationalization of food consumption pattern in Poland nor any substantial growth of consumption growth of seafood-the import duties for fish and fish products brought into Poland were increased as of August 1, 1991 to 20% for whitefish and processed fish products and to 5-10% for other fish products - some tariffs are subject to seasonal adjustments like those imposed for imports of herring and sprats - 15% for the period June-February and 5% at other times. Other tariff rates have been temporarily "frozen" at a level of 10% until the end of 1991. Consequently, if the present relationship between the prices of basic foodstuffs is maintained, consumption of seafood in Poland might go down.

## 4. PROSPECTS FOR MARKETING SEAFOOD IN POLAND

As observed earlier, the per capita consumption of fish and fishery products in Poland declined in 1990 to 4,5 kg due to a fall in the household's disposable incomes and the consumer's perception that seafood prices are relatively high. This decrease was also due to the drop in deliveries of fish and fishery products to the market-certain species and products were hardly visible.

The fact is, however, that the total production of fish coming from capture fisheries (especially from deep-sea fisheries) will decrease in the near future. Moreover, the level of production provided by the Baltic Sea Fishery remains more or less fixed. Even if the Polish cutter fleet fully utilizes the catch quota allocated to Poland by the International Baltic Sea Fishery Commission the total catch from this fishing area cannot surpass the volume of 160 to 180 thousand tonnes a year. Thus, in order to meet the growing demand for seafood, more fish and fishery products will have to be imported. This, however, depends on Poland's ability to maintain at least the present (as of 1991) level and the accompanying growth of exports which would generate the balance of trade surplus.

Opportunities for expanding the consumption of seafood in Poland can improve greatly if and when the income of the population will start growing faster than in the first two years of the transition period. Much will depend also on the proper generic marketing/advertisement strategies of the polish seafood industry which should be more in promoting the

4 Compare with West German fish consumption up again in 1991, *"Eurofish Report" 1990,* (360), pp. SP1-SP2. and with German Pleasure, *"Fish International"* 1991, (3), July, pp. 45-48.

consumption of fish and fishery products and stress first of all on the health benefits of the regular consumption of those products. Also, the development of network of fish-restaurants and small bars can bring about a substantial increase in the consumption of seafood following the pattern of many Western countries.

Another opportunity lies in the development of the market for the ready-to-eat seafood products which are especially convenient for Polish consumers used to eating fish and fishery products market. Therefore, it would be highly desirable to continue the so called comparative market research of the seafood market in selected European countries whose level of per capita consumption of fish and fishery products varies from very low to a much higher level than in Poland. Needless to say, this would help to estimate the expected rise in consumption of seafood in Poland as well as possible structural changes.

# Testing the Consistency of Fish Consumption Data with Neo-Classical Demand Theory

**M. Burton and T. Young**

Department of Agricultural Economics, University of Manchester, Manchester, England. M13 9PL.

ABSTRACT

*In earlier work (Young and Burton, 1988), several different demand systems were applied to quarterly data on fish consumption in the UK. A common feature of this work was the difficulty in obtaining statistically significant results that did not violate the fundamental restrictions suggested by demand theory. In this paper we return to this data set but apply an alternative, non-parametric, technique, that of revealed preference. The advantage of using the theory of revealed preference is that it allows one to test the data for consistency with demand theory, without making any assumption about the underlying functional form (Varian 1982). Tests which rely on a specific demand system are necessarily conditional on the validity of the restrictions imposed by the parametric structure of that system. In addition, the approach offers a convenient means of investigating the appropriate aggregation of fish products (e.g by species or form of presentation).*

## 1. THE THEORY OF REVEALED PREFERENCE

Revealed preference theory dates from the work of Samuelson (1938). It is based solely on observed and measurable phenomena, namely the commodity bundles actually purchased by consumers and prevailing prices and consumer income or total expenditure. Early empirical work on the subject includes that of Koo (1963) and Mossin (1972). Recently, there seems to have been a revival of interest, following significant contributions in the field (regarding the specification of non-parametric tests), from Varian (1982,1985). An empirical analysis, relevant in the present context, was undertaken by Chalfant and Alston (1988), who apply non-parametric methods in their study of meat consumption in the United States and Australia. The work reported here follows similar lines of enquiry.

The theory may be briefly outlined as follows. If the consumer chooses a bundle of goods (**a**) when an alternative bundle of goods (**b**) is obtainable with the same budget outlay, the consumer is revealing a preference of bundle **a** over bundle **b**. In conventional jargon, **a** is "revealed preferred" to **b** (usually denoted **aRb**). The theory of revealed preference requires two consistency conditions on consumer choice.

The **Weak Axiom** states that if **a** is revealed preferred to **b**, then **b** cannot be revealed preferred to **a**. In other words, bundle **b** will only be chosen when it is cheaper than **a** (bundle **a** is not obtainable with the same outlay). Figure 1 illustrates situations in which the axiom is satisfied and in which it is violated. Assuming only two goods, X1 and X2, the line through **a** represents the budget line when the consumer chooses bundle **a**, and the line through **b** is the budget line, for a different set of prices and total expenditure, when bundle **b** is chosen. The weak axiom would be satisfied if commodity bundle **a** is chosen when **b** is available ( **b** is in the budget set bounded by the budget line through **a**), and **b** is chosen when **a** is unattainable with the given budget ( **a** is outside the budget set). On the other hand, the weak axiom would be violated if bundle **a'**, rather than **a**, is chosen when **b** lies within the budget set but **b** is chosen when **a'** is available.

The axiom can be expressed in terms of expenditures. For **a** to be revealed preferred to **b**, then both **a** and **b** must be available for a given outlay :

$$P^a.\mathbf{a} \geq P^a.\mathbf{b}$$

where $P^a$ denotes the set of prices when **a** is chosen. Thus the expenditure on **a** is at least as great as expenditure on **b**. If the weak axiom is satisfied (**a** R **b** and **b** R **a**), then

$$P^a.\mathbf{a} \geq P^a.\mathbf{b} \text{ and } P^b.\mathbf{b} < P^b.\mathbf{a}.$$

In other words, for **b** to be chosen, **a** must involve a greater outlay at the ruling prices.

The second consistency condition, the **Strong Axiom**, concerns transitivity of consumer choices. It states that if **a** is revealed preferred to **b** and **b** is revealed preferred to a third bundle **c**, then bundle **c** cannot be revealed preferred to bundle **a**. This condition can be extended to any number of bundles. The two axioms are related in so far as a violation of the weak axiom implies a violation of the strong axiom, but not vice versa[1]. It is therefore not sufficient to test only for violations of the weak axiom.

If consumer choices satisfy the Strong Axiom, then they are consistent with the hypothesis that the consumer acts "as if" maximising a stable utility function, with conventional, neoclassical properties. Hence, if no violations to this axiom are uncovered in the data, it is possible to find a stable demand system, for which the general restrictions of neo-classical demand theory hold.

## 2. DATA

The data set, supplied by the Sea Fish Industry Authority, comprises quarterly observations on expenditure and prices of various fish products in the U.K. for the period 1980.2 to 1986.2. In Young and Burton (1988a) these data were aggregated by form of presentation into 'wet', 'frozen', 'shell' and 'processed'. As a multi-stage budgeting procedure was assumed (see Annex), the frozen fish data were subsequently sub-divided into 'white', 'fat' and 'other'; wet fish data were apportioned conformably. The analysis reported in Young and Burton (1988b) was conducted on the same data for wet and frozen fish but aggregated by species (cod, haddock, plaice, whiting and 'other'); shellfish and processed fish were excluded.

In this exercise, the non-parametric tests were applied to both forms of data -

a) aggregated by form of presentation, *viz.* :

i) 'wet', 'frozen', 'shell' and 'processed',

ii) wet 'white', 'fat' and 'other',

iii) frozen 'white', 'fat' and 'other',

b) aggregated by species, *viz.* cod, haddock, plaice, whiting and 'other'. In addition, the analysis was conducted using the disaggregated wet and frozen fish data in which 22 categories of fish are identified.

1. When the number of commodity bundles being compared is reduced to two, the strong and weak axioms are equivalent.

## 3. THE NON-PARAMETRIC TESTS

The test of the Weak Axiom proceeds as follows. Firstly, given a data set of n commodities and T time periods (in the present context, n ranges from 3 to 22; T = 25), define the vectors of prices (dimension [1,n]) and quantities (dimension [n,1]) at time t as $P_t$ and $Q_t$. These are then used to construct a matrix M with elements $M[i,j] = Q_i.P_j$. Each element in column j represents the expenditure if the period i quantities were valued at period j prices. The leading diagonal M[i,i] represents the actual expenditure in each period i.

Now, define a matrix Z such that elements $Z[i,j]=M[i,j]/M[j,j]$. If any element $Z[i,j]\leq 1$, then $Q_j$ has been revealed preferred to $Q_i$ (i.e. commodity bundle i was affordable at period j prices, but bundle j was selected). If $Z[i,j]\leq 1$ and $Z[j,i]\leq 1$, then the weak axiom is violated. Hence the elements of matrix Z provides the basis for the test of the Weak Axiom.

The test of the Strong Axiom, an axiom of transitivity, is more complex. Firstly, a matrix X is defined such that $X[i,j]=1$ if $Z[i,j]\leq 1$, otherwise $X[i,j]=0$. Then the algorithm suggested by Varian (1982) can be applied :

For i,j,k =1,..,T : if $X[i,k]=1$ *and* $X[j,k]=1$, then $X[i,j]=1$.

Having manipulated the matrix in this way, its elements are then scanned for violations of the strong axiom[2]. These occur where : $X[i,j] = X[j,i] = 1$. A full explanation is given in Varian (1982).

## 4. RESULTS AND CONCLUDING REMARKS

In each of the three sets of non-parametric tests - on the data aggregated by form of presentation, on the data aggregated by species, and on the disaggregated data - no violations of either of the axioms of revealed preference were found. The data are therefore consistent with the neoclassical theory of consumer behaviour.

This conclusion does, of course, rest on the power of the non-parametric tests. If real expenditure rises over time then the budget lines depicted in Fig. 1 may never cross, thus making it impossible to identify violations of the theory even in those cases where actual purchases are not made in a rational and consistent manner. Some indication of whether meaningful results are obtainable is given by inspection of the elements of the Z matrix. If real expenditure on fish had risen consistently over the sample period, then all the upper triangle elements would have a value less than 1 and all the lower triangle elements would be greater than 1. In this case, no violations of the axioms could be detected. If real expenditure on fish had fallen consistently over the data period, the distribution of elements greater than and less 1 would have been reversed and again the tests would have no power.

For the data set on which this exercise has been based, there are 600 off-diagonal elements in the (25x25) Z matrix. An examination of the disaggregated data set reveals 303 off-diagonal elements greater than 1, with 86 of these (28%) lying above the diagonal. This suggests that there has been some increase in real fish expenditure over the data period but that there is perhaps adequate scope for detecting violations of the axioms. Inspection of the more aggregated data sets yielded similar results.

Since the data appear to be consistent with demand theory, the anomalous results evident in our earlier work could have been eradicated if alternative empirical specifications of the demand system had been employed. However, the approach offers no guidance as to the form of the empirical specification and it could be very highly parameterized.

2. A violation of the Weak Axiom implies a violation of the Strong Axiom, but not *vice versa*.

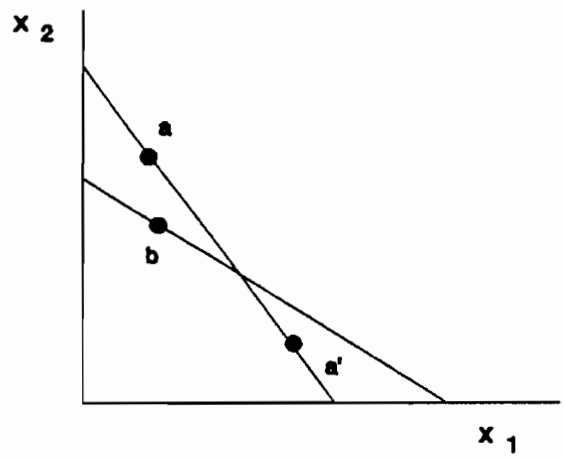
# ANNEX

In a previous study (Young and Burton,1988a), an attempt was made to determine the major economic factors influencing the composition of the demand for fish products over time. A basic premise of the approach was that consumers adopted a budgeting procedure in making their purchase decisions. With regard to food products, it was posited that the consumer first decided how much of a total food budget should be spent on broadly-defined food products, given their prices : dairy products, meat, fish etc. Having determined the allocation of funds to fish expenditure, a secondary, independent decision was how much to spend on each of four fish categories : processed, frozen, wet and shell. In the third stage of the process, expenditures on wet fish and on frozen fish were further subdivided among 'white', 'fat' and 'other' fish.

The empirical model chosen to satisfy the econometric requirements was the *Generalised Addilog Demand Systems* (GADS). The explanatory variables were the prices of the subset of commodities and the expenditure allocation at each stage. The models of fish demand were estimated over the period 1980-1986 using quarterly data. Although on the whole the analysis established a plausible set of economic relationships determining the composition of the demand for fish, at some levels of the budgeting procedure and for some individual fish products, the restrictions suggested by economic theory were rejected by the data and so in these cases the response of the consumer to economic stimuli appeared to be perverse.

Specifically, in the sub-model in which fish expenditure was allocated to frozen, processed, wet and shell fish, the own substitution effects were found to be positive, but not significantly different from zero. The more disquieting case arose in the sub-model in which wet fish expenditure was allocated amongst 'white', 'fat' and 'other' fish. Here the substitution effect for the 'other' fish was positive, significantly different from zero and the implied own-price elasticity was positive (around 0.02). There could be no reasonable explanation for this perverse response and yet experimentation with alternative specifications failed to alter the result. Given that the chosen methodology was such that a complete, consistent system of demand was being estimated, this anomaly cast some doubt on the validity of the other findings in the study.



A follow-up study (Young and Burton,1988b) focused on the inadequacies of the chosen empirical model and of data as possible causes of the perverse results noted in the previous study. More specifically two alternative empirical models of demand have been utilised : the *Rotterdam Model*, which was developed in the mid 1960s and the *Almost Ideal Demand System* (AIDS) of much more recent origin.[3] In addition, although the quality of the raw data was taken as given, in some of the analyses these data were grouped in a different manner (by species - cod, plaice etc. - rather than by the form in which fish was presented to the consumer - fresh, frozen etc.) and were handled differently in the investigation of their seasonality.

Of the three models, the Rotterdam approach proved to be the most successful both in meeting the requirements of the theory and in generating a plausible set of consumer responses with respect to price and expenditure changes. The GADS and AIDS failed to produce negative substitution effects for all products at both levels of the budgeting procedure.

Although none of the absurd results encountered in the previous study were replicated by the Rotterdam model applied to the re-classified data and although the model was able to mimic the historical pattern of market shares reasonably well, nonetheless the analysis had a major shortcoming in that few of the price coefficients were statistically significant. In other words, the explanatory power of the system rested with the seasonal dummies and the expenditure variables.

3 Details of the GADS, AIDS and Rotterdam model can be found in Bewley (1986).

# The Northeast United States Market for Blue Mussels : Consumer Perceptions of Seafood Safety and the Demand for Mussels

**Priscilla M. Brooks and James L. Anderson ***

Department of Resource Economics, University of Rhode Island Kingston, Rhode Island 02881 USA

ABSTRACT

*A survey of consumers was conducted in the northeastern United States to examine consumer perceptions of seafood safety and the impact of those perceptions and other factors on demand for mussels. This paper analyzes the first stage of the consumer's decision process : the initial choice by the consumer to participate in the market for mussels. Results indicate that consumers perceive some risk in eating mussels and that this perceived risk has a negative and significant impact on the probability that a consumer will participate in the market for mussels.*

## 1. INTRODUCTION

Unlike many European countries where there exists a rich tradition of mussel aquaculture and consumption which spans centuries, the United States has a mussel industry which is relatively young, with significant production occurring only in the last two decades. Despite the recent expansion of the U.S. market, production of mussels fell significantly in 1989 and 1990 and real wholesale and ex-vessel prices have declined steadily since 1987. This decline in the market has occurred despite innovative marketing campaigns by the nation's largest mussel producers. All of this lends doubt to the continued expansion of this relatively underdeveloped U.S. market and the viability of this industry.

* Funding for this research was generously provided by the URI/NOAA Cooperative Marine Education and Research Program. The authors are thankful to Cathy R. Wessells and Joan G. Anderson for their ongoing assistance in this research. The enormous cooperation of Great Eastern Mussels Farms of Maine is gratefully acknowledged.

Continued development of the U.S. market for mussels faces two major obstacles :

i) a lack of market information on consumer preferences for and attitudes towards mussels which limits the effectiveness of marketing efforts; and

ii) a perceived health risk from eating mussels, exacerbated by recent incidents of shellfish poisoning and adverse media publicity about seafood safety.

To address this lack of market information and evaluate the impact of consumer perceptions of seafood safety on demand for mussels, a survey of consumers was conducted in supermarkets in the northeast United States. The focus of this paper will be to analyze the first stage of the consumer decision process: the initial choice by the consumer to participate or not participate in the market for mussels. The key question to be answered is whether consumers perceive some risk in consuming mussels and to what extent these perceptions impact their decision to buy mussels.

The paper is organized as follows. First, trends in world and U.S. production of mussels will be discussed. Current issues regarding seafood safety and inspection in the U.S. will then be outlined. Next the model of consumer choice will be developed followed by a description of the supermarket survey and general results regarding seafood safety perceptions. Finally, the estimated model, results and conclusions will be presented.

## 2. WORLD AND U.S. PRODUCTION OF MUSSELS

World landings of mussels increased about 100 percent during the 1980s, from 620 thousand tonnes in 1980 to 1.24 million tonnes in 1989 (FAO 1991). The world catch of mussels consists of 12 species; blue mussels (*Mytilus edulis*) are the primary species produced with at least 40 percent of the total catch[1], followed by the Mediterranean mussel (*Mytilus galloprovincialis*) with 9.4 percent (FAO). Spain is the largest European producer of mussels with 194 thousand tonnes produced in 1989, followed by the Netherlands with 107 thousand tonnes, Italy with 101 thousand tonnes, Denmark with 76 thousand tonnes and France with 59 thousand tonnes.

The United States also saw tremendous growth in mussel production in the 1980s, although production levels are small compared to that of the major European producers. U.S. landings of mussels increased over 270 percent from about 6.8 thousand tonnes in 1980 to a record 25.4 thousand tonnes in 1988, at a value of U.S. $4.6 million (Alaska Dept. of Fish and Game; Collins; Lukas; U.S. Dept. of Commerce 1991a and 1991b; Washington State Dept. of Fisheries). Since then, production has fallen a total of 14.3 percent to 21.7 thousand tonnes landed in 1990. While U.S. mussel landings have a long history of sporadic increases and decreases in annual production, the past two percentage decreases in annual landings for 1989 and 1990 proceed 14 years of near continuous growth in landings. Although 1991 landings figures are still preliminary, they suggest a continued decline in production.

Accompanying this fall in landings is an equally disturbing fall in the value of landings, and perhaps more importantly, the value per pound landed. In 1988, despite record quantities of mussel landed, total value of landings fell about two percent to US $4.6 million from a record US $4.7 million set in 1987. Total value of landings continued to fall a total of 16.9 percent in 1989 and 1990. Furthermore, the total real value of U.S. mussel landings fell 30.2 percent from 1987 through 1990.

The decline in total value of landings is exacerbated by a concurrent fall in the per pound value of landings. The average nominal value per pound landed was US $0.080 in 1990, a 16.7 percent change from US $0.096 in 1987. However, in real dollars, the average value per pound landed declined 29.4 percent. Furthermore, real wholesale prices for mussels sold at the New York City Fulton Fish Market declined approximately 22.8 percent in the period 1987 to 1990 (Urner Barry Publications, Inc.).

No single factor can explain the fall in landings and value. From conversations with fishery managers and members of the mussel industry, the natural supply of mussels is abundant and hence a decline in stocks is not likely to be a serious

1. The reported percentage of blue mussels in the total world catch is likely to be underestimated, as China, the world's largest producer of mussels, reported production of 490.5 thousand tonnes of unspecified sea mussels in 1989, most of which are known to be blue mussels (De Franssu, 1990).

factor. Some members in the industry claim decreased landings in response to a decline in demand caused by a fear of seafood safety on the part of the consumer and the general economic malaise brought on by the current recession in the U.S. economy.

## 3. ISSUES IN SEAFOOD SAFETY

Despite the rapid growth and development of the U.S. mussel industry, declines in production, landings value and wholesale prices are not indicators of a healthy and thriving industry. Recent incidents of shellfish poisoning and the media focus on seafood safety may be contributing to the weakness in the mussel market and may hamper its continued expansion.

One of the most serious incidents regarding seafood borne illness specifically related to mussels occurred in November of 1987 when 103 people became sick and three died after eating cultivated mussels from Prince Edward Island, Canada (Committee on the Evaluation of Safety of Fishery Products 1991). This outbreak was attributed to an unusually high level of domoic acid, an algal toxin, and resulted in a temporary shutdown of the regional industry and substantial though temporary declines in demand in both Canada and the U.S (Seafood Business). The public was reminded of the Prince Edward Island mussel incident almost three years later when the nationally broadcast television news program "20/20" aired a story in June 1990 about the domoic acid outbreak. Mussel producers also experienced temporary declines in demand due to the much publicized incidents of medical waste washing onto Mid-Atlantic and New England shores in the summer of 1988 (Blue Gold Sea Farms). Currently, the U.S. is experiencing a wave of media publicity sparked by a seafood safety study published nationwide in the magazine *Consumer Reports*. The study claimed that much of its limited sample of seafood was "spoiled" or "contaminated" (Consumer Reports). This study continues to receive widespread media attention.

These consumer reactions result from a perceived risk from eating mussels, influenced by actual incidents of health problems as well as media attention and consumer ignorance. Shellfish, particularly bivalve mollusks such as clams, oysters and mussels, have long been associated with such health problems as paralytic shellfish poisoning caused by red tide and hepatitis due to pollution of shellfish beds. The Centers for Disease Control found shellfish to be the cause of 66 percent of all seafood related illness cases from 1978 to 1987 (Committee on the Evaluation of Safety of Fishery Products 1991). However, during that same period, shellfish and finfish accounted for only about 3.6 percent of all cases of foodborne illness.

Currently there is no mandatory seafood inspection program in the United States similar to that in place for the inspection of red meats and poultry. The lack of mandatory inspection and the media focus on seafood safety has led to increasing public pressure for a mandatory seafood inspection system. The debate on seafood inspection has focused on the need to ensure a safe and wholesome seafood supply and to protect the public health. Another benefit to mandatory seafood inspection, often overlooked by policy makers, is renewed consumer confidence in seafood and a potential increase in the demand for seafood. This lack of confidence in the safety and quality of seafood, particularly shellfish, poses a threat to the seafood industry in terms of reduced or stagnant demand. The seafood industry needs to understand consumer perceptions of seafood safety so that it can educate consumers and help them make more informed purchase decisions.

Incorporation of consumer perceptions in retail demand analysis is rarely found in the fishery economics literature, yet perceptions play a critical role in consumption behavior. Two notable exceptions are studies done by Kinnucan and Venkateswaran, and Lin. It is important to note that an individual's response to external stimuli depends not only on the specific stimuli but also on his or her often unique perceptions of those stimuli (McNeal). It is perceptions that are incorporated into the consumer's purchase decision. In the case of risk perceptions, it is not the objective risk that consumers react to (consumers often lack information on the true risk), rather it is the subjective or perceived risk that is incorporated into the purchase decision. Furthermore, each consumer develops his or her own set of individual perceptions about seafood safety, based on what they know about the objective risk, and many other factors including prior illness with the particular seafood, health status, and the perceived controllability of the seafood-borne illness (Lin).

## 4. THEORETICAL FRAMEWORK

Mussels are a relatively unusual food product in the U.S. Unlike such staples as bread and milk, mussels are not a product which is consumed by virtually every consumer. If mussels are consumed, they are typically consumed infrequently and often not at home. Results from a supermarket survey of consumers in the Northeast indicate that about 74 percent of the sample had consumed mussels before, but only 50 percent of these respondents currently ate mussels at home. Moreover, the majority of at-home mussels consumers ate mussels six or less times per year. Interestingly, it is only in the last decade that mussels have become widely available in supermarkets, due mainly to the recent proliferation of full service wet seafood counters in supermarkets and the marketing efforts of the large mussel companies.

In gauging potential demand for mussels, the first question which must be asked of consumers is not how many pounds of mussels would the consumer buy at a given price, but rather would the consumer ever consider buying mussels at all ? The demonstration program allowed for the unusual opportunity of surveying consumers in a supermarket setting as they were offered free samples of freshly steamed mussels and were faced with a real purchase decision. After being offered a sample of mussels, consumers were asked whether they would buy Great Eastern mussels if they were available in their local supermarket. Both consumers who sampled the mussels and those who did not were interviewed.

There is a wealth of theoretical (Cragg; Amemiya; Blundell and Meghir) and empirical (Haines *et . al.*; Gould) literature which models the food consumption decision as a multi-step process in which consumers first decide whether to participate in the market, and then decide on the frequency or amount of purchase. Most of these models are based on secondary consumption data where the researcher observes (a) whether a purchase was made and (b) how often and how much was purchased over a specified time period.

What the researcher cannot observe in this secondary data, however, is whether the non-buyer of a specific product would ever purchase that product. All the researcher can observe is that the consumer did not purchase the product during a specified time period. Usually the researcher must speculate on the meaning of the zero consumption values. Are these zero observations true corner solutions or are they the result of infrequent purchasing behavior and a short survey period ? Moreover, are the zero values the result of a discrete choice to participate or not participate in the market ?

In the case of mussels, many consumers have made the decision to never buy the product for home consumption, and in the case of some consumers, never at all. The primary data gathered in this supermarket survey allowed the researchers to separate would-be buyers of mussels from non-buyers. It is this initial decision to consider or not consider buying mussels, and the factors affecting this decision, that is the focus of this paper. The general model of consumer choice to buy mussels or not buy mussels is based on the probit model. Following Greene (1990), consider the unobservable variable, $Y_i^*$, as the measure of an individual's buying potential or desire to buy mussels. If an individual's desire to buy mussels is greater than some threshold level, say 0, then the individual will buy mussels. $Y_i^*$ is a linear function of the explanatory variables $X_i$ and the unknown parameter vector $\beta$ and the random error term $e_i$, which is assumed to be independently and normally distributed with mean zero, and variance equal to one :

$$Y_i^* = \beta' X_i + e_i$$

One cannot observe an individual's degree of buying potential, one can only observe, in this case, the consumer's verbal reply to the question, "Would you ever buy these mussels if they were available in your store." The observable binary variable is $Y_i$, equal to 1 if the individual responds that he or she would buy the mussels, and zero if he or she responds negatively. The observable binary variable $Y_i$ is related to the unobservable $Y_i^*$ as follows :

$$Y_i = 1 \text{ if } Y_i^* > 0$$

$$Y_i = 0 \text{ if } Y_i^* \leq 0$$

The probability that an individual responds yes to an interest in purchasing mussels is equal to :

$$\Pr [Y_i = 1] = \Pr [Y_i^* > 0] = \Pr [\beta' X_i + e_i > 0] = \Pr [e_i > -\beta' X_i]$$

If the distribution is symmetric, as is the normal distribution :

$$\Pr [Y_i = 1] = \Pr [\ e_i < \beta' X_i\ ] = \Phi(\beta' X_i)$$

where $\Phi(.)$ is the cumulative distribution function of the standard normal distribution. The joint probability for all individuals or the likelihood function is :

$$L = \Pi_i [\Phi (\beta' X_i)]^{Y_i} [1 - \Phi (\beta' X_i)]^{1 - Y_i}$$

Taking the natural log results in the log-likelihood :

$$ln\ L = \Sigma_i [Y_i\ ln\ \Phi (\beta' X_i) + (1 - Y_i)\ ln\ (1 - \Phi (\beta' X_i))]$$

This model can be estimated with maximum likelihood techniques.

The marginal effects of changes in the explanatory variables on the predicted probability of saying yes are calculated as :

$$\frac{\partial \Phi (\beta' X_i)}{\partial X_i} = \phi (\beta' X_i)\beta$$

where $\phi(.)$ is the standard normal density function..

## 5. DATA COLLECTION : THE SUPERMARKET SURVEY OF CONSUMERS AND CONSUMER PERCEPTIONS OF SEAFOOD SAFETY

In order to investigate consumer attitudes toward and demand for mussels, an extensive in-person survey of 401 consumers was conducted in conjunction with Great Eastern Mussel Farms of Maine who were then engaged in a supermarket demonstration program of their fresh mussels. Great Eastern has long been conducting supermarket demonstrations of their mussels as a way to

(i) educate consumers and retail sellers about the handling and preparation of mussels and

(ii) to stimulate demand.

Surveys were conducted in the fall and winter of 1989 and 1990 during 36 demonstrations in stores associated with five supermarket chains located from a Virginia suburb of Washington D.C. to Maine.

In designing the survey to gather information on mussel demand, individual demand for mussels was hypothesized to be a function of retail price, the retail prices of substitutes, the perceived risk from consuming mussels, prior and current experience with mussels, an individual's overall seafood consumption, and demographic variables. During the survey, consumers were offered an opportunity to sample freshly steamed mussels and were then interviewed whether they sampled the mussels or not.

After being offered a sample of mussels, consumers were asked whether they would buy mussels. Consumers were then interviewed about their attitudes toward and experience with mussels. Of particular interest were consumer perceptions regarding the safety of mussels. In an effort to avoid an emphasis on seafood safety problems in the sensitive setting of a supermarket, questions regarding seafood safety perceptions were limited to gathering information on media exposure to seafood related issues, fears of eating mussels and risk perceptions of eating various foods.

Analysis of the data indicates that consumers perceive some risk from eating mussels and that this risk is significantly higher than the perceived risk from eating some other foods. Furthermore, perceived risk from eating mussels is higher among consumers who have never eaten mussels and consumers who say that they would never buy mussels. (See Brooks (1993) for a more detailed discussion of the findings on consumer perceptions of seafood safety.)

When asked about what they had seen or heard in the media regarding seafood, most responses concerned some negative aspect of seafood. The most prevalent issue was pollution and the contamination of seafood, mentioned by 37.6 percent of the respondents, followed by red tide mentioned by 22.5 percent of respondents. The red tide response is not surprising

in the Northeast where shellfish beds are routinely closed in the summer due to red tide. There was frequent mention of contaminated seafood, particularly shellfish. Only 8.7 percent of the respondents mentioned any positive health aspects of seafood.

When asked why they do not eat mussels or eat them more often, the responses to this open-ended question varied, but 8.6 percent of the respondents claimed that they were afraid to eat mussels. These consumers were then asked what they were afraid of; 31 percent said that they were afraid that the mussels were contaminated by pollution, while another 27.6 percent said that they were afraid of the mussels being tainted with red tide. Fourteen percent of the respondents were wary of where mussels come from, many having seen mussels exposed on the beach at low tide or clinging to docks and pilings. Another 14 percent of the respondents could not pinpoint a specific reason.

Consumers were then asked what they perceived to be their chances of getting sick from eating the following foods: cod, clams, mussels, bluefish, lobster, salmon, chicken and beef. They were asked to rate their chances on a scale of 0 to 100, where 0 was no chance at all and 100 was a certain chance. This question was left purposefully open-ended regarding the definition of "sick" so as to elicit the consumer's overall perceived risk. Note that the relative perceived risk of eating mussels compared to other seafood is the key issue here, rather than the absolute level of risk perception, since the 0 to 100 scale is not appropriate for eliciting realistic risk estimations.

Clams and mussels scored higher risk ratings than the other foods, with average risk ratings of 26.9 and 23.7, respectively. Furthermore, mussels were rated as having a significantly greater health risk (at the 95 percent or better significance level, based on a two-tailed t-test) than all other foods except for clams.

The relatively high risk rating of mussels compared to other foods is made even more clear when one examines the standardized risk rating of mussels, STDMUSS. In order to compensate for the differences in the individual respondent's subjective scale as well as the differences in their subjective origin (zero point), each individual's risk rating of mussels, $RISKMUSS_i$, was standardized over the set of each individual's risk ratings of all foods using the mean ($AVGRISK_i$) and standard deviation ($STDRISK_i$) of the individual's set of risk ratings :

$$STDMUSS_i = \frac{RISKMUSS_i - AVGRISK_i}{STDRISK_i}$$

A standardized risk rating ($STDMUSS_i$) greater than zero indicates that the consumer perceives mussels to have a higher risk of getting sick than all of the rated foods averaged together. The mean standardized risk rating of mussels for the total sample was 0.36, indicating that consumers, on average, perceive mussels to be a relatively risky food.

The sample was then divided between those consumers who said that they would buy mussels (75 percent of the total sample) and those who said that they would never buy mussels (25 percent of the total sample). Not surprisingly, the mean standardized risk rating of 0.57 by non-buyers of mussels is significantly greater (at the 99 percent significance level) than the mean risk rating of 0.30 by buyers of mussels. In addition, the mean standardized risk rating of 0.45 by consumers who had never eaten mussels (26 percent of the sample) was greater than the mean rating of 0.33 by those who had eaten mussels (74 percent of the sample), although this difference was only significant at the 80 percent significance level.

## 6. THE ESTIMATED MODEL AND RESULTS

The consumer decision to consider buying mussels or to not consider buying mussels is modeled as a function of age, education, income, geographic area of residence, number of children in the household, standardized perceived risk rating of mussels, previous mussel consumption experience, overall seafood consumption, exposure to negative media reports concerning the safety of shellfish, whether or not the individual consumes bivalve mollusks, and current home consumption of mussels. The list of explanatory variables and their construction are found in Table 1.

Perceived risk, STDMUSS, is expected to be negative implying that the greater the perceived risk from eating mussels, the less likely one would be to purchase mussels. The same is true of the dummy variable, NEGMEDIA, exposure to negative media reports regarding the safety of shellfish. The dummy variable EATEVER, signifying whether or not an individual has consumed mussels before, is expected to be positive; individuals who have had previous consumption

experience with mussels are expected, on average, to be more likely to buy mussels. Individual overall consumption of seafood, CONSUMHR, is hypothesized to have a positive impact on the probability that an individual will buy mussels; consumers who eat seafood more frequently may be more likely to buy this relatively unusual seafood. At-home mussel consumption, HOMEFREQ, is expected to be positive. There are no *a priori* expectations regarding the significance or sign of the demographic variables on age, education or geographical area. Income is expected to be positive, as one would expect that higher income individuals would be more likely to allocate part of their budget to this unusual and non-essential food. The variable representing the number of children at home, KIDS, is expected to be negative, as many consumers expressed reluctance to buy mussels saying that their children would not eat mussels. An individual's predisposition towards eating bivalves, BIVALVE, is expected to be positive, as one would expect that consumers of bivalves such as oysters and clams, might also consider eating mussels.

Results are presented in Table 2. As expected, perceived risk from eating mussels has a negative and significant influence on the decision to buy mussels. Figure 1, presents the effect of prior mussel consumption experience and perceived risk on the probability that consumers will buy mussels. AGE, EDUC, INCOME, KIDS, CONSUMHR, and HOMEFREQ are held equal to the sample means, while NEGMEDIA, BIVALVE, NYNJ, and WASHDC are held equal to zero. As is illustrated in the figure, perceived risk has a greater impact on those who have never eaten mussels than those who have, all else held equal.

Age was found to have a significant and positive influence on purchase probability, while education, income, geographical area, and number of children did not. EATEVER was positive and very significant, as expected, as was home consumption of mussels, HOMEFREQ. BIVALVE was of the correct sign, but only bordered on significance. NEGMEDIA and CONSUMHR were insignificant.

## 7. CONCLUSIONS

Results from a supermarket survey of consumers in the northeastern U.S. indicate that consumers perceive some risk in consuming mussels and that this risk is greater for mussels than for some other foods. Also, perceived risk from eating mussels has a negative and significant impact on the probability that a consumer will participate in the market for mussels. This impact is accentuated in the case of consumers who have never eaten mussels.

Mandatory seafood inspection could help reduce consumers' perceived risk by instilling confidence in the seafood supply, while consumer education by both government and industry could help eliminate misconceptions about seafood safety. The net result would be more informed purchase decisions, greater benefits to the consumer and increased demand for seafood. The mussel industry can help achieve these results through strict enforcement of rigorous quality and safety standards for their products.

# Seafood Safety Assurances : Implications for Seafood Marketing and International Trade

**Cathy Roheim Wessells[a] and Joan Gray Anderson[b] ***

[a] Department of Resource Economics, University of Rhode Island, Kingston, RI 02881, USA

[b] Consumer Affairs Program, University of Rhode Island, Kingston, RI 02881, USA

ABSTRACT

*Worldwide, seafood safety has received increased attention. The recent cholera epidemic in South America has generated concerns among exporting and importing countries that unsafe product will slip through the safety net of inspection and regulations. In the U.S., deaths from raw shellfish consumption and negative publicity, such as advertisements displaying fish with hypodermic needles protruding from their bodies, have increased safety concerns. In U.K. supermarkets, farmed salmon with chemical residues above permissible levels were discovered. Each of these incidents has decreased seafood sales. As seafood consumers have been exposed to seafood safety concerns, they have reacted by demanding industry and government protection from unsafe or poor quality seafood, both domestic and imported. This is particularly true in the U.S. where there is no mandatory inspection program for seafood.*

*The objective of this paper is to investigate the factors which influence consumers' preferences for alternative types of safety assurance information and their consequent willingness to pay for that information. Consumer preferences for safety assurance information were revealed using a contingent valuation survey given to U.S. consumers which determined the consumer's willingness to pay for each of ten alternatives. Alternatives included information such as : inspection by a government agency, inspection by the retailer ; or, catch date, catch site, and handling procedures since caught. Consumers were asked to specify the additional amount, over the price of non-labeled seafood, they would be willing to pay per pound for seafood labeled with each of ten alternatives. Results indicated that consumers were willing to pay more for information regarding catch date, site and handling. Willingness to pay for government inspection was lower. Consumers were willing to pay little, if anything, for assurances of safety from retailers/processors/wholesalers. Factors such as seafood consumption patterns and demographic characteristics which influence willingness to pay for one type of information versus another were analyzed using limited dependent variable techniques. These results and their implications for seafood marketing, regulation of quality and safety, and international trade will be delineated.*

* The authors gratefully acknowledge the research assistance of Jeffrey Kline.

## 1. INTRODUCTION

Worldwide, seafood safety has received increased attention. The recent cholera epidemic in South America made some importing nations fearful that contaminated seafood products would slip through the safety net of inspection and regulations. In the United Kingdom, farmed salmon containing chemical residues above permissible levels were pulled off supermarket shelves. These chemicals included antibiotics and a feed additive designed to enhance the flesh pigmentation of the salmon. While the long-run effects of these and other chemicals are still not fully understood by the scientific community, episodes such as those described create concern about seafood safety among consumers. This may negatively affect sales of imported and domestic seafood products.

In the U.S. extensive media publicity focusing on the safety and quality of fish and shellfish have increased safety concerns. In the summer of 1988, as medical waste and pollution were found on Atlantic Coast beaches, numerous stories began to appear in the popular press and on television. Water pollution and its effect on the fish growing in contaminated waters were emphasized. The role of PCB's, heavy metals, and bacterial and viral contamination in the seafood supply were discussed. Such stories, in combination with closed beaches and fishing grounds, caused seafood consumption to drop by about 6 percent on a national per capita basis (Burros, 1988)[1]. In addition to the dangers occurring from polluted waters, articles detailed unclean processing facilities and the near absence of inspections of processing plants. Most recently, media attention has focused on improper handling of seafood at retail outlets throughout the U.S. Reports have concluded that supermarkets, even those believed to be quality seafood vendors, often sell poor quality fish.

Confused and frustrated by what they have seen and read in the media, some consumers have looked to the government to assure them that the seafood they consume is safe. Some states have enacted their own laws. For example, the state of California, in response to worry over the dangers of consuming raw oysters from the Gulf of Mexico, requires that prominent warning signs be placed in restaurants which serve this product. These signs, with bright red backgrounds and bold black writing, warn of the dangers of eating raw oysters from the Gulf of Mexico.

The implementation of a mandatory seafood inspection program at the Federal level might alleviate public fears. Such a program does not currently exist. However, before a program can be instituted, several issues must be resolved. Implementation of a seafood inspection program will not automatically communicate to the consumer that seafood is safe. Both government agencies[2] and the seafood industry must find methods to communicate seafood safety to the consumer. The means of communicating must include signals that the consumer both understands and believes. It may be that consumers require more specific information than simply, for example, a stamp of inspection similar to that found on beef. For example, some consumers might demand information such as catch site and catch date, which the consumers would evaluate as indicators of seafood safety and quality.

The objective of this paper is to investigate the factors which influence consumers' preferences for alternative types of safety assurance information and their willingness to pay for that information. The first section of this paper provides background information on seafood safety issues in the U.S. Next, the survey procedures are discussed, and in the following section, qualitative results are explored. Then, the consumers' willingness to pay for the added information is econometrically analyzed using a limited dependent variable technique with seafood consumption patterns and demographic characteristics of the consumers as explanatory variables. The final section concludes with a discussion of the implications for seafood marketing, regulation of quality and safety, and international trade.

## 2. THE FACTS ABOUT SEAFOOD SAFETY IN THE U.S.

Various agencies of the U.S. government have studied the actual health risks posed by the consumption of fish and shellfish. Reports have been released by the Government Accounting Office (GAO), the Food and Drug Administration (FDA), the Center for Disease Control (CDC), and, most recently, by the National Academy of Sciences (NAS).

1. The 6 percent drop in consumption per capita nationwide understates the drop in some areas of the nation. For example, several merchants on the East Coast claimed sales were off 25 to 50 percent (Burros 1988).
2. Which agency will ultimately be in charge of seafood inspection is a subject of heated debate in Congress and within the industry. The primary seafood inspection vehicle of the past has been the National Marine Fisheries Service of the U.S. Department of Commerce, National Oceanic and Atmospheric Administration, which runs a voluntary, fee-based inspection system. Recently, the Food and Drug Administration has teamed up with NMFS to introduce an expanded, voluntary, fee-based seafood inspection program. Several bills have been introduced in Congress (although none have passed to date) proposing mandatory seafood inspection. Some of the bills have advocated the U.S. Department of Agriculture as the lead inspection agency, others advocate either NMFS or the FDA.

The 1988 GAO study concluded, based on data from the CDC and the FDA, that there was no evidence of a widespread problem with the nation's seafood supply. CDC data indicated that seafood accounted for only five percent of all foodborne illness and only five deaths between 1978-84. The majority of problems that did exist were related to three specific cases : raw molluskan shellfish (microbial pathogens), ciguatoxin and scombrotoxin.

The following year, the FDA convened its own Seafood Task Force. This group concurred with the conclusions of the GAO study. Their major conclusions were :

i) Harvesting and production of aquatic species as a source of human food has reached record levels and will continue to increase in the future.

ii) Some microbial contaminants, natural toxins and decomposition products associated with seafood do represent a serious threat to human health. These problems are, however, isolated to identifiable portions of the industry, leaving the majority of seafood to represent no greater hazard than the food supply in general.

iii) Inspection activities could, however, be significantly expanded to provide increased consumer protection for this important commodity.

iv) Aquaculture presents concerns relating to the safe use of feed additives and drugs.

v) Public health problems connected with seafood would not be solved by a federal seafood inspection program similar to USDA's meat and poultry inspection program. (pp. iv-v).

Like its predecessors, the report on seafood safety compiled by the National Academy of Sciences (NAS, 1991) concluded that, overall, the U.S. seafood supply is safe, however, there are some risks involved in seafood consumption. In addition to risks mentioned in previous studies, "some risks, in particular those associated with environmental contamination, may be increasing" (p. 3). Environmental contamination is a problem in both commercially and recreationally caught fish. Therefore, the report emphasized the need for a comprehensive monitoring system of the water supply.

## 3. METHODOLOGY

The focus of this paper is a subset of a larger on-going study at the University of Rhode Island. The larger study was partitioned into two phases. In Phase I, data was collected from randomly sampled Rhode Island consumers using a telephone survey. The telephone survey of 256 Rhode Island consumers contained detailed questions pertaining to :

i) seafood consumption;

ii) factors which might increase or decrease consumption;

iii) attitudes regarding seafood safety; and,

iv) demographic characteristics.

Phase II brought a sample of 55 consumers to a survey site at the University of Rhode Island Food Science laboratory. The purpose was to present respondents with an experimental market-like setting in which they could view actual pieces of seafood in a manner similar to what they face when making selection and purchasing decisions at the store. Five experiments were conducted.

One component of the experimental section focused on respondents' willingness-to-pay for alternative pieces of consumer information, including mandatory inspection and labeling information. The following questions were asked :

i) what specific information will most assure consumers that seafood poses little health risk; and,

ii) how much are consumers willing to pay for this information? Data gathered from a random telephone survey of Rhode Island residents was used to determine specific information alternatives which would communicate seafood safety. These alternatives included information stating that seafood had been inspected (with a choice of five different inspection entities), information regarding catch date, site and handling, and money-back guarantees. The actual task for respondents in the experimental, market survey was to evaluate the alternatives.

The technique used to elicit the information regarding willingness-to-pay (WTP) was based on contingent valuation techniques. Contingent valuation (CV) methods use surveys rather than market data to determine willingness-to-pay for a composite good. It is often used to analyze non-market goods or goods which are not currently on the market, for example, in environmental economics to value the potential benefits from a particular change of policy. Contingent valuation is based on the assumption that "individual responses to hypothetical markets are comparable to actual markets" (Mitchell and Carson 1989). Contingent valuation is often used to value non-market goods, such as air quality, but has also been used to establish values from reducing health risk (Tolley and Babcock 1986) and for estimating consumer's willingness-to-pay for reductions in foodborne risk (Hammitt 1986). Other studies of seafood consumption using survey data have also followed these techniques (Lin 1991).

Within the contingent valuation framework, the respondent is given a detailed description of the good being evaluated and the hypothetical circumstances under which it is made available. Questions are asked to elicit the respondent's WTP for specific well-defined changes. A "valuation" function can be estimated where valuation characteristics and certain other preference and use characteristics are the independent variables.

To implement this CV experiment, the respondent was asked to consider a pound of flounder selling at the current market price ($4.50)[3]. Respondents were told the flounder fillet carried with it no consumer information other than price, and the store clerk would not be able to provide any additional information. However, they could purchase an additional piece of information regarding the quality of the seafood from a list of 10 possibilities (listed in Table 1) [4].To do this, they were asked first to rank the ten pieces of information from most to least desired. Having all ten pieces of information in order, respondents were then asked how much, if anything, they were willing to pay per pound above $4.50 for their most desired piece of information. Next, they were asked what, if anything, they would pay for their least desired piece of information. They were then asked to assign a WTP value to each of the remaining pieces of information. Respondents were told that they could use the same amount, including zero, as often as they wished. The only restriction was that the magnitude of the values must decrease with the rank of the information. They were free to re-arrange their initial ranking until they were satisfied that the rankings and WTP values were representative of their preferences.

## 4. QUALITATIVE RESULTS

Results from the respondent ranking of the alternatives are displayed in Table 1. Forty percent of the sample ranked catch data as the most important information. Information that the flounder had been inspected by the National Marine Fisheries Service (NMFS) was ranked first by 12.7 percent of the sample. Eleven percent of the sample ranked information regarding where the flounder was caught as most important. Inspection by the U.S. Department of Agriculture (USDA), FDA and a money-back guarantee of quality were each ranked first by 9.1 percent of the sample. Storage temperature was ranked first by 5.5 percent. Only one respondent ranked inspection by retailer and processor as their first choice. None of the respondents ranked money back guarantee of safety first.

Table 1 also lists the average additional amount respondents were willing to pay per pound for the various information alternatives with a reference point of flounder selling at $4.50 per pound. The most highly valued piece of information was when the fish was caught. Consumers would be willing to pay an average of 47 cents above $4.50 for this indicator of quality/safety. The next highest valued pieces of information were the temperature at which it had been stored and where it had been caught. Both of these pieces of information reflect quality as well as safety factors. The sample was willing to pay an average of 34 cents additional for each of these. The next three ranked pieces of information were related to inspection.

Respondents indicated a willingness to pay an additional 31 cents per pound if the product were inspected by NMFS, 23 cents per pound if it were inspected by the FDA and 22 cents per pound for inspection by the USDA. The next highest

3. Flounder was chosen because virtually 100% of the sample eat flounder either at restaurants or at home, thus consumers are familiar with the item. It was felt that it is important to provide the respondent with a product they are familiar with in order to derive a reasonably accurate measure of their willingness to pay for the information. It is possible that the results would be different if an alternative species had been chosen, for example, shellfish.

4. Only one piece of information was allowed to keep the experiment simple, however, it is likely that consumers would have liked some combination of the choices. This is being incorporated into the next endeavor.

valued piece of information were money-back guarantees. Apparently, the respondents did not place much value in the seller's ability to inspect his own product. It is interesting to note that consumers appear to put far more credence in the government's inspection process than in the industry's.

## 5. REGRESSION RESULTS

To evaluate the factors which affect respondents' willingness to pay for the individual pieces of information, a limited dependent variable technique was used. Since the values for the survey respondents' willingness to pay is either zero, or some value greater than zero, a limited dependent variable technique is the most appropriate for statistical analysis of the data. In particular, the Tobit, or censored, regression model is required. For a censored sample such as this, suppose $y_i$ has a normal distribution, with mean $\mu$ and variance $\sigma^2$. We consider a sample of size N, and record only those values of $y_i$ greater than a constant 0, otherwise record the value 0. The Tobit model then is specified as :

$$\begin{aligned} y_i &= x_i\beta + \epsilon_i \quad \text{if} \quad x_i\beta + \epsilon_i > 0 \\ &= 0 \qquad\qquad\quad \text{otherwise} \end{aligned}$$

where $\beta$ is a K x 1 vector of unknown parameters, $x_i$ is a K x 1 vector of known constants and $\epsilon_i$ are residuals that are independently and normally distributed with mean zero and common variance $\sigma^2$. An important characteristic of this model is that we actually know the values of the explanatory variables, $x_i$, for the individuals who are not willing to pay for a particular piece of information. The Tobit models are solved in a maximum likelihood framework, and the software package SHAZAM was used[5].

Due to the small sample size, the results should not be generalized beyond the sample of Rhode Island residents. There are two primary reasons for the small sample size. First, this survey was done in an experimental setting which attempted to simulate a true market setting. Since this was the first time an experiment of this type had been attempted by the project researchers, the study itself was viewed as experimental, to serve as a trial for future work. Second, it was extremely difficult to convince consumers to travel to the URI Food Science laboratory to spend two hours on a Saturday afternoon being surveyed about seafood. This was a major commitment on the part of the participants. To somewhat offset their personal costs, each respondent was given a $10 gift certificate from a local seafood retail outlet.

The demographic makeup of the sample was compared to the demographic profile of the population of Rhode Island, and the sample was found to be quite representative. The largest differences were that the sample was more educated than the average Rhode Islander, and tended to reside in the southern portion of the state, whereas most of Rhode Island's population resides in the northern portion of the state.

Therefore, while the results should be interpreted with caution, they provide an indication of the expected success of a larger scale experiment of the sort undertaken here. In addition, the results present an indication of which factors (explanatory variables) most strongly affect Rhode Island consumers' willingness to pay for seafood quality information. These factors may or may not be the same for other U.S. consumers.

Models of willingness to pay were run for five of the ten pieces of information individually. In addition, willingness to pay information was grouped into average willingness to pay for private information, which contained catch site, catch date, and temperature held since caught, and for government inspection, including NMFS, FDA and USDA. The written survey from Phase I of the project was also given to each respondent. This provided data on the explanatory variables for the respondents' willingness to pay.

Five models were run to estimate respondents' willingness to pay. These models represent those pieces of information respondents chose as the most important, based on their average willingness to pay presented in Table 1. These include models for catch date (DATE) and catch site (SITE) where the average WTP was $.47 and $.34, respectively. A model for temperature held information was not run because, while this information is interesting, it is not currently feasible

5. It can be argued that, due to the conditional nature of the willingness to pay data (i.e. the willingness to pay for the second ranked choice is dependent on the willingness to pay for the first ranked choice), a system of regressions should be estimated simultaneously. While this is true, with the limited sample, it is doubtful that much efficiency would be gained.

to provide it to the consumer. The length of time which it takes for a fish to reach a consumer from the time it was caught, together with the processing it may go through, makes it difficult to document the temperature levels. However, a model for all private information (PRINFO) which includes average willingness to pay for information on catch date, catch site and temperature was run. In addition, since it seems likely that government inspection will be mandatory, a model was run for average willingness to pay for government inspection by the three agencies (GOVINSP). Of those agencies, the willingness to pay for inspection was highest for fish inspected by NMFS, so a model was included for this information as well. The results of these models are presented in Table 2.

The independent variables used in the analysis include : MANDINSP = 1 if consumers responded that their seafood consumption would increase given a mandatory inspection program, 0 if consumption would not increase; FREQSHELL = number of times per month the consumer's household consumed shellfish; FREQFIN = number of times per month the consumer's household consumed finfish; KNOW = the respondent's relative knowledge of seafood, 5 if extremely knowledgeable, 0 if know nothing (each respondent subjectively answered this question); HOME = 1 if consumers eat flounder at home, 0 otherwise; SAFE = 1 if consumers answered they thought seafood was very safe, 0 if they felt it was somewhat unsafe or unsafe; INC = income level of the respondent's household; PERINSP = percent of seafood supply respondent believes is inspected. There are many other possible explanatory variables which could be used from the written survey, however, the variables listed above were believed to be the most important.

Across the board, the consumer's rating of their seafood knowledge had a negative effect on their willingness to pay extra for information beyond that which they can see or smell when looking at the fillet. In other words, the more knowledgeable they felt they were about seafood, the less they were willing to pay for additional information. The magnitude if the coefficients are relatively large, and with the exception of the GOVINSP equation, were marginally significant. Conversely, if the respondent indicated that they eat flounder at home (i.e. prepare it within the home), the effect on willingness to pay is positive, but only significant in the SITE equation. In addition, if the respondent felt seafood is safe, there is a negative effect on WTP for information on catch site or date. If the respondent indicated he/she would increase consumption with the implementation of a mandatory seafood inspection program, this would translate into a higher willingness to pay for information that inspection by a government agency had indeed occurred, as indicated by the positive coefficient on MANDINSP. Finally, the percent of seafood respondents believe is inspected is positively related to their WTP and generally significant. This seems somewhat counterintuitive. However, it is possible that, if the respondents believe a large percentage of the seafood supply is inspected, yet they are continually hit by negative reports on seafood safety, then they may be willing to pay for information that they can use to personally evaluate the safety of the seafood they are purchasing.

Note that the willingness to pay for government inspection in general is not significant, however, willingness to pay for information that NMFS was the inspection agency is significant. There was little correlation between the demographic characteristics and seafood consumption habits of the respondents and their willingness to pay for information that either the USDA or FDA had inspected the fish. For this particular sample of individuals, that should be of interest to those who are debating the appropriate agency to head a mandatory inspection system.

## 6. CONCLUSION AND IMPLICATIONS

The United States does not currently have a mandatory seafood inspection program in place. However, it seems inevitable that one will be in place within the near future. In fact, the "Consumer Seafood Safety Act of 1992" bill is now before the Senate. This legislation calls for the administration of a national seafood safety program which will set tolerances for contaminants in seafood, monitor growing areas and fishing grounds for water pollution, and devise processing and handling requirements and an inspection system. The safety program would be a cooperative effort between NMFS, the FDA and to a lesser extent, USDA, at the national level, and the states. Imported seafood will be required to meet the same specifications as domestic products[6] and seafood importers must register with the U.S. government. The FDA will

6. Currently, domestic standards differ from those of other nations, in particular, Canada. The free trade agreement between the U.S. and Canada, which became effective in 1989, requires that the two nations adopt the same product quality guidelines. To date, no agreement on product standards has been reached. Similarly, product standards differ substantially between the U.S. and Europe. Differences such as these often lead to disputes since product standard differences are sometimes interpreted as non-tariff trade barriers.

evaluate foreign seafood inspection programs, and develop inspection agreements with other nations. The Food Safety and Inspection Service, a branch of the Department of Agriculture, will conduct inspections overseas and at the port of entry. The product will be required to be labeled with the country of origin.

While policy makers have justifiably been concerned with public health as the primary issue, and have reacted by proposing bills of the sort discussed above, in doing so, they have given less attention to the area of consumer perceptions of seafood quality. It is interesting to note that nowhere in the bill is there any reference to the communication of the safety of the product to the consumer. While the government may not be cognizant of the importance of consumer perceptions of seafood quality and safety, the seafood industry has recently come to understand that safety perceptions may be as important, if not more important, than the actual hazards arising from unsafe seafood. Even when a mandated seafood inspection system is in place, unless it is designed based on research regarding consumer information needs, it may not be sufficient to change negative perceptions, increase seafood demand or increase profits.

Therefore, the results of this trial study provide some important initial insights to both domestic producers and those who export to the U.S. in terms of marketing strategies. The industry must alleviate consumer perceptions of the health risks from consuming seafood. To do so, they must provide information to the consumer in which the consumer will place some credence, such as the purity of the waters from which the fish or shellfish was harvested, or the rigorousness of the inspection system. Some marketing campaigns have been successful with these strategies. For example, Norwegian salmon is perceived to have high product standards and product quality which emphasizes clean Arctic waters in its marketing campaigns. However, much of this information generally only goes to the wholesalers or restauranteurs, and does not reach the average consumer. Educating the consumer through package presentation and through advertisements may be a smart marketing strategy.

# Development of the International Trade in Seafood Products in the Context of European Economic Integration

**Jean Pierre Boude and Patrice Guillotreau**

ENSAR, environmental and natural resources Dept, 65 rue de S[t] Brieuc, Rennes, France

ABSTRACT

*Theoretically, spatial integration of economic activity has a twofold effect : re-allocation of productive resources due to the free movement of goods, and factors and potential linked to the economies of scale inherent in the extension of the market and strengthening of international competition.*

*When applied to the seafood processing industries, the combination of these effects should lead to changing specialization within Europe and an acceleration of intra-European trade.*

*Observation of the structural development of international trade in several production sectors (fresh, chilled and frozen products ; dried, salted and smoked fish ; prepared and tinned products etc.) validates or undermines certain theoretical suggestions and allows some explanation of the framework of international trade flows.*

## 1. INTRODUCTION

According to the FAO, the proportion of seafood products traded throughout the world represents about 30 % of nominal global catches. In Europe, this share has been increasing for slightly more than a decade : from 35.8 % in 1976, the share of exports by volume reached 41.6 % of Community production in 1990, in spite of a stable situation concerning territorial stocks of primary resources.

The purpose of this paper is to interpret the development of international seafood product trade, in order to highlight the factors determining international mobility of goods.

The scope of the study is the EEC countries from 1976-1990. During this period, institutional factors, such as the creation of Exclusive Economic Zones (EEZ), European economic integration and the assertion of the Common Fishing Policy (CFP) were combined with the specific features of the goods traded in an explanation of trade (derivatives of a renewable natural resource, which must satisfy high internal demand with sustained growth etc.)

However, in this paper, specialization is aproached in a simplified manner, since only the commercial aspect of internationalization is considered. As revealed by international trade flows, specialization is above all the result of the internationalized action of companies and notably movements of capital and technology [1].

Part One therefore suggests an economic interpretation of the dynamics of seafood product trade, complemented in Part Two by a discussion of the impact of institutional decisions on the observed development.

## 2. ECONOMIC INTERPRETATION OF THE DYNAMICS OF SEAFOOD PRODUCT TRADE IN THE EEC

The empirical data concerning international trade in seafood products was processed using factor analysis methods. It is therefore important to present the principles of these methods in order to assess their scope and limits (2.1). The results are then presented for all EEC countries, followed by the disparities observed between different countries (2.2).

### *2.1 Method*

The choice of method, which partly depends on the type of data used, is discussed in terms of the scope and limits of factor analysis.

#### 2.1.1 Type of data

The data available for the whole period (1976-1990) have two sources : the FAO and EUROSTAT. The data from the first source concerns the territorial stock of seafood products represented by quantities landed (DOTA), the level of domestic production (PROD), as well as apparent consumption of countries expressed as the sum of non-exported domestic production and imports (CAPA) [2]. The second source provides all overall and broken-down data for the main international trade product categories [3].The variables obtained are :

Exports (X) and Imports (M)
X and M301 : Fresh, chilled, frozen fish
X and M302 : Dried, salted, smoked fish
X and M303 : Fresh, chilled, frozen crustaceans and molluscs
X and M604 : Prepared and preserved fish
X and M605 : Prepared and preserved crustaceans and molluscs

It should be noted that the aggregated FAO data (production and apparent consumption) includes, in addition to these product categories, oils and meals from aquatic animals. This difference represents another possiblity for analysis if the importance of these products in Denmark, for example, is considered.

The EUROSTAT aggregrated trade data was used to derive several other variables such as :

- average import price (PIMP)
- average export price (PEXP)
- intra-EEC share of imports (PICI)
- intra-EEC share of exports (PIEX)
- the proportion of intermediate goods imported (PABI) ; this calculation assumes that this proportion applies to categories 0301 and 0303.

1. Concerning international investment flows, P. Guillotreau "A Meso-Systemic Analysis of the International Specialization Process Applied to the EC Seafood Processing Industry", paper for the 4th EAFE conference, Salerno, Italy, 22nd-24th April 1992.
2. FAO statistical directories 1976-1990.
3. Due to a change in the European seafood products schedule in 1987 (division of certain categories), the series were reformed in 1998.

- external balance X-M (SOLD).

Except for average trade prices expressed in ECU per kg, all values and percentages are based on quantities of thousands of tonnes, in order to minimize any price effect.

The individual elements in the data table are countries and years identified by three characters [4]

### 2.1.2 Choice of analysis tool

Due to the configuration of the data table (individual elements in rows and continuous variables in columns), the *Principle Component Analysis* (PCA) was the *ad hoc* tool for factor analysis.

• Presentation and scope of PCA in the study

Factor analysis is a data analysis method. Its main advantage is a *multi-dimensional* approach to a phenomenon and geometrical representations which can easily be interpreted.

Among the numerous factor analysis tools, Principle Component Analysis allows assessment of the similarities between individual elements and assessment of the links between variables. These assessments can also lead to typologies base on multiple criteria. These typologies contribute to an interpretation of a complex reality so as to distinguish strategies or economic policies according to the type of the groups of elements thus defined[5].

Put simply, the PCA uses a matrix calculation to project the elements (variables and individual elements) of an n-dimensional space onto a two-dimensional factor plane. Therefore, each axis of the factor plane represents a factor which synthesizes in a more or less pronounced manner a set of variables.

In an PCA, the variable coordinates on the axes represent the correlation of these variables with the factor considered and therefore express the explanatory power of the variable relative to the weight of the factor itself in the overall explanation of the phenomenon. The weight of the factor is linked to its *inertia* observed by the relative size of calculated *eigenvalues*.

The analysis uses 32 describable values as follows : 10 product trade active variables (two types of flow - import and export - and five product categories) and 22 illustrative variables. Only the active variables are used to construct factors, whereas the illustrative variables are projected onto the factor plan thus defined. The latter variables therefore appear as explanatory variables and the former as explained variables.

The illustrative variables concern total trade flows (XVOL and MVOL), primary resource stocks (DOTA), the internal market (CAPA), the variables described above (PIMP, PEXP, PICI, PIEX, PABI, SOLD) as well as some basic ratios concerning International Economics (coverage ratio by product category (TC0i), export effort ratio (TEFF), import penetration ratio (TPEN) and ratio of domestic needs coverage by national production (TPNA). Two qualitative variables (PAYS and ANNEE) have also been integrated into the analysis in order to highlight two important effects : the marked territorial disparities and the dynamic prospects for trade growth.

The questions approached are part of the issue set forth in the introduction : what are the dynamics of Community seafood product trade and what are its determining factors ? It is linked more to the territorial resources available or to the size of the internal market ? What is the direction of trade flows and how does it develop ?

• Limits of analysis

The major limit of the data analysis, apart from the statistical reliability of the figures themselves, certainly stems from the arbitrary choice of variables. This choice is not neutral with respect to the answers to the previous questions.

The results must therefore be referred to the territorial industrial structures and markets considered, because trade is only the tangible manifestation of these.

4. Examples : F76 (France 1976), D85 (Denmark 1985). The initials of the countries are as follows : France (F), Belgium/Luxembourg (B), Netherlands (N), Germany (A), Italy (I), United Kingdom (U), Ireland (R), Denmark (D), Greece (G), Portugal (P) and Spain (S).
5. B. ESCOFIER, J. PAGES 1990 "Analyses factorielles simples et multiples" Dunod Paris, 2nd ed.

In addition, the analysis shows very large differences in national situations, and each country, by its size and its involvement in exploitation of seafood resources, represents a particular case. A more detailed analysis should therefore be carried out by considering specific products.

Finally, an approach based on clear division of Europe into nations for all product categories is a little simplistic to the extent that production activity is highly regionalized within countries and is transnational for many companies which trade. Certain flows registered in imports or exports therefore occur within a single company.

### *2.2 Results of factor analysis*

The interpretation of factors initially reveals the variables which determine trade dynamics and the nature of the different apparent specializations, before providing the elements required for country typology.

#### 2.2.1 Decisive factors for all countries

Firstly, the eignenvalues indicate that the first three factors contain 81 % of total inertia, *i.e* . 4/5 of the explanatory power of the analysis. This inertia is made up of : 41 % for the first factor, 25 % for the second, and 15 % for the third ; the weight of the fourth factor is not negligible (9 %). In other words, strong correlation between the variables and the first factor will have a great significance for revelation of key variables.

Put simply, the first factor corresponds to exports, while the second refers to imports of all products[6].

The strongest correlations concerning the first axis of the factor plane (figure 1) correspond to fresh, chilled and frozen products, both fish and crustaceans/molluscs.

The important intra-industry trade (crossed flow of similar products), represented by this axis, is significant. By pivoting the axis to the left by a few degrees, the projection of variable coordinates onto the new axis obtained (F1) accentuates the contribution of imports to the first factor, in particular for fresh, chilled and frozen fish, and tinned crustaceans/molluscs.

In other words, *countries with high exports also have high goods imports*, notably of intermediate goods. These countries import to supply an extensive internal market (judging by the proximity of M301 and CAPA) but also to produce and re-export (positions of PROD and XVOL).

Nearly all the trade aggregates are positioned on the same side of the axis, which represents the size effect on the analysis (disparities between "large" producing countries, such as Denmark, Spain, the Netherlands, France etc. and the "small" countries like Belgium, Greece, Portugal and Ireland). In this respect, it is observed that the small countries favour trade with their European partners over trade with the other countries, especially for imports (contrast on axis of DOTA, PROD and PICI, PIEX variables). Their trade therefore appears "tied" to their close neighbours (Portugal and Spain, Ireland and the United Kingdom, Belgium and the Netherlands).

Concerning the second axis, dominated by imports, it is also possible to interpret the position of the variables more precisely, by interpreting F2 perpendicular to F1. For this factor, variable X302 appears to be an exception, like M301 for the first factor.

This particularity in fact expresses the regional character of the production and consumption of dried, salted and smoked products. The phenomenon thus reflects the historical nature of specialization in these products in the Northern European countries (fishing and processing of herring in the North Sea) and in Portugal (dried cod). A similar, but less pronounced, situation is observed for preserved products in the Iberian Peninsula and Italy. The apparent specialization in these countries is therefore linked to the traditions of production and consumption.

On the other hand, for fresh, chilled and frozen fish, *the trade flows which result in specialization are more determined by the process of internationalization*, itself driven by generalized use of refrigeration techniques.

6. See the variable coordinates on axes 1 to 5, in the appendix.

Concerning the illustrative variables which are strongly correlated to the second factor, the marked contrast between the external balance (SOLD) and the average import price (PIMP) is significant. It reflects the link between the size of the deficit expressed in physical quantities and the price of imported products. In fact, an increase in the value of the deficit is caused both by an increased volume of seafod product imports and by higher import prices. This result must be qualified, since the data table considers series of current average prices.

Finally, the fourth factor is also notable for the product categories which are contrasted (imports and exports being correlated in the same direction) - fresh, chilled and frozen crustaceans and molluscs, and tinned fish - but especially for the test values of the PAYS variables (see table in appendix). The test values measure the distance between the individual elements-countries and centre of gravity of the individual element cloud. Two national situations are contrasted in this fourth factor : those of Spain and Germany. This contrast is explained by the fact that these two countries have record deficits in each category (respectively crustaceans/molluscs and tinned fish), but which are nevertheless compensated for by a high level of exports.

### 2.2.2 Type of specializations apparent in different countries : a typology test

Based on the first two factors (representing 2/3 of total inertia by themselves), an initial typology of individual element (figure 2), largely determined by a size effect, can be built up.

| COUNTRY | SIMILARITY CRITERIA |
|---|---|
| 1) Netherlands, Denmark | Characterized respectively by export dynamism and high stocks. |
| 2) Spain, United Kingdom | Strong intra-industry trade at a high level of exchange, high stocks and extensive internal market. |
| 3) France, Germany, Italy | Very high deficit, average stocks but different characteristics*. |
| 4) Ireland, Greece, Portugal, Belgium | Small countries with low stocks. Low exports, except for Ireland. |

* France : higher primary resource stocks and apparent consumption than the other two countries.Germany : low stocks balanced by a high level of production and trade.

Italy : very low exports.

Italy is not positioned lower on the second axis because a large part of its deficit is due to imports of dried, salted and smoked fish, a variable which is weakly correlated with factor 2. On the other hand, on axis 3 where this correlation is -0.90, the test value for Italy is very high, like Portugal (imported dried cod) and unlike the United Kingdom. However, in this latter traditional exporting country, the trade balance in dried, salted and smoked fish is tending to settle at a very low level (the surplus fell from 22000 t in 1976 to 3000 t in 1990.)

To summarize, these countries all have very specific features. It would be interesting to develop the analysis by creating data indices to highlight the characteristics of "small" countries which are masked by the size effect.

### Intermediate conclusion

Although the "country effect" appears more important than the "year effect", representing relative structural stability with time, diagram 3 describes a marked development during the period.

This trend is clearly situated in the south-west quadrant of the chart. It indicates both a growth in the volume of imports and exports, but also a more sustained growth in imports, since the balance has deteriorated. Likewise, the development of the external EEC trade in seafood products appears to be more due to apparent consumption growth than to that of production or the level of quantities landed, notably since the entry of Spain in the Community.

It should also be noted that the apparent specialization of countries in fresh, chilled and frozen products is increasingly produced by the process of internationalization and the level of domestic demand (which contributes to the marginalization of traditional goods production in Europe) and less by stocks of primary resources.

However, relatively clear changes of rate are observed on the factor plane. After a period of relative trade stability up until 1984, their growth increased, both for imports and exports.

Institutional aspects may be advanced to explain this.

## 3. DEVELOPMENT OF EUROPEAN SEAFOOD PRODUCT TRADE IN THE CONTEXT OF SOME INSTITUTIONAL EVENTS

Certain institutional events explain the development of European seafood trade (3.1) and the development of apparent territorial specializations (3.2).

### *3.1 Development shaped by three major events*

The analysis clearly reveals that the development of international seafood trade has been shaped by three major events : creation of the Exclusive Economic Zones (EEZ) on 1st January 1977 (agreements in the Hague in 1976), agreement of 25th January 1983 which created, after years of adjustment, Blue Europe, the extension of the EEC to include Spain and Portugal on 1st January 1986.

Figure 3 illustrates the impact of these events during the period. In this respect, the most spectacular changes concern the creation of the EEZ (1977) and the entry of Spain and Portugal into the common market. The development of international seafood products trade increasingly depended on the growth of internal markets such as those of the countries in categories 2 and 3 of the above typology.

For all EEC countries, demand for seafood products increased thoroughout the period. Trade deregulation since the end of the 1960s has favoured the rise of international trade despite the fact that world supply has grown less quickly over the last decade. This growth has generated large price increases and increasingly frequent product substitutions, including food products other than seafood.

#### 3.1.1 Creation of the EEZ in 1977

The almost general introduction of EEZ in 1976 and 1977 resulted in important structral changes in primary product supply. Concerning catches within the European EEZ, certain fleets, and in particular those of the Eastern European countries, were quickly withdrawn. These Eastern European fleets concentrated their efforts mainly on well identified stocks to allow large catches by volume at low cost. This withdrawal produced a reallocation of catches which benefitted member countries, but this reallocation concerned stocks which were often fully exploited, and even over-exploited, and the effects for the whole Community were quickly stabilized. ICES data indicates these developments well. At the same time, access to distant fishing areas outside European seas and in the EEZ of third party countries, was heavily restricted.

European countries with fleets traditionally devoted to this type of fishing experienced a very rapid falling off of quantities landed from distant areas. The countries most concerned were France, the United Kingdom, West Germany and Italy. Although trends vary significantly according to species, the creation of the EEZs resulted overall in a sharp reduction in EEC supply, compared to the previuos decade.

It is difficult to distinguish the supply structure changes due to the EEZ from those due to continuous deterioration of certain stocks. However, the 1977 situation represented a clear break compared to 1976, and the relative stabilization of positions seems to favour the EEZ effect as an explanatory factor. Increased imports, where possible, were therefore a solution to the problem of reduced supply. This solution still, however, depended on both available world supply and the evolution of international prices. When substitution by imported products was not possible, the consequences for national markets were marked : price rises, changes of consumption habits from fresh products to processed products, market division etc. The development of the national markets in mackerel, sardines and herring is very representative.

### 3.1.2 Implementation of the Common Fisheries Policy in 1983

The break in 1983 was less clear, but was sufficently significant to be taken into consideration. It corresponded to the creation of Blue Europe, which covered both aspects of resource control and the assertion of a joint organization of markets and producers. 1983 represents more the creation of Blue Europe as an administrative reality than as a profound change in practices, since the agreements implemented on 1st January were the result of twelve years of negotiations and gradual adjustments.

For everything concerning external resources, the European entity replaced the member states. Therefore, negotiating power was strengthened and improved access to distant resources in certain cases. In particular, the adoption of common rules for market organization seems decisive. They had two objectives : to stabilize the markets by guaranteeing supplies and a fair standard of living for the fishermen ; and secondly to ensure reasonable consumption prices, whilst increasing sector productivity. These two objectives could therefore sometimes produce a conflict of interest between European producers and consumers.

The system created - Community price scheme and marketing standards - no doubt allowed markets to be extended and a certain number of products to be standardized. But numerous regulations dated from before 1983, in particular concerning the price scheme. In addition, each country could use health and hygiene requirements to erect non-tariff barriers, often very effectively. The United Kingdom thus prohibited import of salmonids and fresh molluscs (diseases of fish acts (1937) and sea fisheries shellfish acts (1983)), Germany introduced specific rules on the use of additives and their labelling (December 1991), and the Netherlands introduced regulations concerning fish (visbesheit) which were relatively vague on the specification of harmful substances and colourings etc. Concerning marketing, Community directives were not systematically applied. For example, in Germany, the production and import of seafood products are subject to special packing and labelling conditions.

The system of subsidies was intended to adjust and reorganize fishing activities by fleet restructuring. Subsidies allowed : temporary or permanent stoppage of ship activity, construction of new ships, creation of companies in conjunction with third party countries, financing of experimental fishing seasons etc. In a situation where catches were stabilizing, they also improved the financial results of fishing companies more than creating non-tariff barriers to the development of international trade.

### 3.1.3 Extension of the EEC in 1986

The break in 1986, linked to the entry of Spain and Portugal into the common market, is far more significant. By themselves, these two countries had a fishing fleet of 875 000 gross tons at this time, equivalent to that of the ten other countries combined. The situation was similar concerning engine power, the number of sailors (140 000 men) and catches. In 1986, the Spanish and Portuguese markets represented 30 % of the total EEC market expressed in tonnes. Between 1961 and 1989, their markets grew by +60 %, while the overall European markets only grew by +47 %.

The inclusion of Spain and Portugal in the EEC, combined with the growth in their internal demand, favoured the development of both intra and extra-European imports. In 1986, Spain had a external trade coverage ratio of 55 % for an import value of 720 million dollars and Portugal a 57 % coverage ratio for an import value 260 million dollars. This ratio has consistently worsened since and the total imports of Spain and Portugal represented in 1990 20 % of total EEC imports by value compared to only 13 % in 1985 (source : EUROSTAT).

## *3.2 Effects on development of territorial apparent specializations*

Examination of the apparent specializations of different countries reveals four groups of countries (see part I). Based on a detailed analysis of these groups, national "routes" were mapped out which trace the development of behaviour according to the variables in the analysis.

### 3.2.1 Netherlands, Denmark group

The first group concerns the Netherlands and Denmark. Their route shows a strong contribution to axis 2 (imports) at the start of the period, moving towards a strong contribution to axis 1 (exports) at the end of the period. In both cases, but more clearly for Denmark, the change occurred in 1982 and 1983.

This development towards the edge of the north-west quadrant of the factor plane is more significant for Denmark, whose position with respect to axis 2 changes from 1.32 to 2.31, while the Netherlands fluctuate between 2.19 and 2.11. On the other hand, on axis 1 the respective figures are 0.08 to -5.04 and -0.82 to -5.16. The route of these countries - with high primary resource stocks - towards high levels of exports between 1976 and 1990 is very clear. The Danish situation is due to its meal production and exports.

In both these cases, the export effort ratio is notable, as well as the ratio of domestic needs coverage by national production. Relative specialization towards export of salted, dried and smoked fish and crsutaceans/molluscs seems to be increasing.

### 3.2.2 Italy, France, Germany group

The second group of countries is Italy, France and Germany. Their routes represent an increasing contribution to axis 2 for France, Italy and Germany. For the latter two countries, axis 4 (crustacean/mollusc and tinned fish trade) increasingly affects the explanation from 1984. The period 1980-84 was a time of relative stability of observed developments.

The change of direction from the centre-east to the south-west quadrant of the factor plan is especially significant for France. The other two countries experience more of a descent down axis 2, reflecting the stronger correlation with this factor (increasing imports).

The route of these countries with average stocks, or with Mediterranean or extra-EEC fishing areas (Italy) towards an increasingly high external trade deficit by value is explained by the characteristics of their internal markets with high purchasing power (France, Germany and Northern Italy). Developments were accentuated after 1984, although they occurred at different rates. In France, for example, limited resources and increased requirements for products with high import value, as well as the supply of intermediate goods for its processing industry, were the main factors explaining this trend.

### 3.2.3 Spain, United Kingdom group

The third group is Spain and the United Kingdom. The contribution to axis 2 is decisive here and there is no break in the trend as previously. This indicates that penentration of their respective markets was continuous over the period studied[7].

The gradual opening of Community waters to Spain from 1986 did not satisfy this country's internal market. On the contrary, the integration of Spain into the European Community appears to have helped increase penetration of this market by goods from other partner countries. For the United Kingdom, the level of intra-industry trade increased during the period, driven by a larger volume of imports[8]. In both cases, the internal market remained very extensive.

### 3.2.4 Portugal, Ireland, Greece, Belgium group

The fourth group is a set of "small" countries : Portugal, Ireland, Greece and Belgium. Their contributions to the axes vary very little. It will simply be noted that axis 3 is important for Portugal (imports of salted, dried and smoked fish), but that its contribution fell between 1984 and 1989 (7.10 to 8.50) ; the importance of axis 1 for Greece which fluctuated between 1.30 and 1.10 ; that of axis 5 for Belgium which increased from 1.00 to 1.80 (exports of crustaceans and molluscs) as well as that of export axis 1, which changed from 1.10 to 0.50.

Ireland nevertheless stands out from these countries with an increase in the quantities landed and with its remarkable export dynamism, mainly to EEC partners (in 1989, France, the United Kingdom, Germany and Spain absorbed nearly 2/3 of Irish exports by value[9]).This observation tends to undermine the theory that an extensive domestic market affects export performance.

7. Only after 1984 for Spain.
8. The Grubel-Lloyd index (1 - IX - MI/(X+M)) measuring the intensity of two-ways trade in similar products, calculated for the United Kingdom from FAO external trade data, nearly doubled from 1970 to 1988 (0.32 ot 0.62).
9. Source : Bord Iascaigh Mhara 1990 "Irish Fish Exports/Imports in 1989 and Previous Years".

The position of Greece hardly changed during the period considered. That of the three other countries moved to the west with a slight growth in exports. Only Portugal shifted south-west.

**Intermediate conclusion**

The study of each individual country reveals three types of route :

(i) A trend towards an increasingly large external deficit, both by volume and by value (see the level of average import price on axis 2 for these countries) : France, Italy, Germany, United Kingdom and Portugal ("march" to the south-west).

(ii) A trend towards increased export effort : Denmark, Netherlands and Ireland ("march" to the north-west).

(iii) Maintenance of positions, mainly due to a size effect : Belgium and Greece.

## 4. MAIN CONCLUSION

The analysis of the international EEC seafood product trade highlights the very different situations in member countries. Although a typology could be described according to the type of external balance, primary resource stocks or the size of the domestic market, each country has it own structural characteristics and a certain type of trade dynamics. This great disparity makes implementation of Community fishing and seafood product processing policy more difficult.

It appears that the apparent specialization of member countries can no longer be interpreted only according to territorial seafood stocks.

Firstly, its interpretation requires other types of economic factors. Therefore, it is the multi-dimensional internationalization process itself (flow of goods, capital and technology etc.) which seems to condition the development of trade. This is because countries import to produce and then re-export ; processing companies are not longer satisified by resources which are landed locally. The generalized application of refrigeration techniques has made a large contribution to the division of the production process of seafood goods, and to the modification of European food behaviour. The increase in production and consumption of chilled and frozen products tends to marginalize traditional production (such as tins and herring curing) which face strong competition from new producing countries. These phenomena are relatively clearly reflected in the type of goods traded. Concerning these traditional products, the regional aspect of specialization is very marked (dried-salted fish in Portugal, smoked fish in Northern Europe) and the goods are distinguished from each other (according to species and processing mode).

Secondly, institutional factors seem to have significantly influenced the direction, structure and intensity of seafood product trade flows. These elements can be referred to three key dates which mark changes in the internationalization trend : creation of the EEZ in 1977, extension of the EEC to include Spain and Portugal in 1986, and to a lesser extent, the implementation of the common Fisheries Policy in 1983.

The deregulation of the seafood product trade and its rapid increase in volume, in particular that of the extra-Community share of the goods flow, shows that Community regulations alone cannot regulate the markets (notably concerning the sales policy applied to these products) and modify the trend towards internationalization of activity.

However, such an analysis, based on the commercial aspect of internationalization, still deserves to be complemented with a study into the production/marketing structures existing in the different countries and a study into transnational capital flows.

ABSTRACT

*The establishment of coastal nations' exclusive economic zones in the late 1970s resulted in major shifts in the structure of production and trade in fish products as distant water fleets lost access to traditional fishing grounds. Canada is the world's largest exporter of fish products. The U.S. is Canada's major market.*

*In this paper, we model the supply of and demand for Canadian frozen fish products in the U.S. market. Earlier work has estimated demand equations for the U.S. market, but few have looked at the supply side. We estimate a simultaneous equation system using Three-Stage Least-Squares for a number of species-product types. We obtain estimates of own-price and cross-price elasticities for both supply and demand, allowing us to say something about substitutes in production and in consumption. For example, cod fillets are found to be a substitute for cod blocks in consumption, but not vice versa. Our results are consistent with institutional studies that argue the block market is a more homogeneous commodity market, while the frozen fillet market allows for more product differentiation. Our model extends current work and provides a more complete analysis of the groundfish market.*

## 1. INTRODUCTION

The establishment of coastal nations' exclusive economic zones in the late 1970s resulted in major shifts in the structure of production and trade of fish products in the world as distant water fleets lost access to traditional fishing grounds. While total fish catches rose by 36.6 percent from 1977 to 1987, international trade in fish products increased by 73.5 percent in volume and 198.3 percent in value. For frozen fish products over the same period, production increased by 39.8 percent, while trade increased by 64.7 percent (FAO, 1987).

* This research was supported in part by Social Sciences and Humanities Research Council of Canada research grant n° 410-89-1193.

This shift in the volume and pattern of trade in fish products has increased interest in understanding how the markets for fish products work. This has been particularly true in countries such as Canada and Norway, where fishing, while not large on a national scale, is important on a regional basis, and Iceland, where fishing is the major industry. Canada, while only the sixteenth in the world in terms of landings, is the world's largest exporter of fish products. For this reason, understanding world fish products markets is important for Canada.

Previous studies of fish products markets have almost all considered only the demand side of the market [1]. The few simultaneous models which have been developed (e.g., Paez, 1981 ; Crutchfield and Gates, 1983) have incorporated supply considerations, but at a highly aggregated level, without distinguishing among species or product forms (an exception is Schrank et al., 1984). In this paper, we develop a simultaneous equations model of both the supply of and demand for Canadian frozen groundfish products in the U.S. market, and estimate it for four groundfish species : cod, haddock, redfish, and flatfish [2] Our approach is unique in that we explicitly incorporate the supply side into the model and that we explicitly model different product types rather than an aggregate "fish product". Although we include the supply side of the market, the model is still a partial equilibrium one in the sense that we treat the demand for and supply of other countries' products and the demand for and supply of Canadian products to other countries as exogenous to the model [3]. In addition, the markets for non-frozen fish products (e.g., fresh) are also treated as exogenous. In essence, this model can be thought of as a submodel of a more general equilibrium model of world groundfish supply and demand, and as a prototype module of a global model of world groundfish trade.

## 2. THE ATLANTIC CANADA GROUNDFISH PROCESSING INDUSTRY

Over 97 percent of Canadian groundfish landings occur on the Atlantic coast. For this reason, we concentrate on the Atlantic Coast industry. In terms of landed value, cod made up nearly 65 percent of groundfish landings in 1988, while haddock accounted for 6.7 percent, redfish, 7.6 percent, and flatfish, 9.9 percent. In terms of production, for cod, frozen blocks make up nearly 35 percent of production, followed by frozen fillets at 30 percent, then salted cod at 21 percent, fresh fillets (9 percent), and fresh and frozen whole fish. For flatfish, frozen fillets accounted for nearly 81 percent of production, followed by frozen blocks (9 percent), and fresh fillets and fresh and frozen whole fish. In redfish production, fresh and frozen fillets comprised the bulk of production (nearly 95 percent). For haddock, fresh and frozen fillets accounted for 79 percent of the value of production (DFO, 1989a).

The United States absorbs 65 percent of Canadian groundfish exports by value (DFO, 1989a). Frozen and fresh products move through different marketing channels into the United States (Mazany et al., 1987). Salt fish products are sold primarily in the Caribbean and Portugal. As there is no U.S. demand to speak of (outside of immigrant groups, primarily in New York, and demand in Puerto Rico), we do not estimate equations for salt cod. The fresh market involves primarily local (Canadian) demand, as well as fish trucked from mainly Nova Scotia to New England markets. Because of the relatively low volumes of fresh products, we limit our analysis to the frozen market for the four species.

## 3. MODEL

An important characteristic of the Atlantic Canada groundfish processing industry is that it produces a variety of end-product forms, sold in distinct markets. Thus, the processors must decide whether to process and market the raw fish as, for example, fresh fillets, frozen fillets, frozen blocks, or other product. Clearly, then, it is appropriate to view the processing of groundfish as a multi-product technology.

The processors can be viewed as processing a multi-output profit function $\Pi(p,w)$, where p is a vector of product prices and w is a vector of factor prices. To be consistent with profit maximization, this function must be convex, positively

1. There are a number of studies of groundfish markets. Summaries of earlier studies are found in Nash and Bell (1969) and Roy et al. (1991).
2. Flatfish is actually a category containing a number of different species.
3. U.S. production of frozen products is small and therefore is not modelled.

linearly homogeneous, non-decreasing in p, and non-increasing in w (McFadden, 1978). If the profit function is differentiable, then by Hotelling's Lemma, the supply function for the ith product, $y_i$, can be derived by differentiating the profit function with respect to the price of the ith product, $p_i$.

$$y_i = \partial\Pi / \partial p_i = y_i(p,w) \tag{1}$$

The supply of the ith product is thus a function of own price, the price of alternative products produced by the processor, and input prices.

There is one respect in which this specification of the model does not adequately reflect the institutional structure of the Atlantic Canada groundfish processing industry. Processors' decisions are conditioned not only by price levels, but also by a supply of raw fish that is irregular, unpredictable, and perishable. This would be of no consequence if local port markets established market-clearing prices promptly. Then the effect of fluctuations in landings on supply decisions would be reflected perfectly through the resultant change in the ex-vessel prices. The level of landings per se would have no independent influence on supply. But port markets in Atlantic Canada do not have this required degree of sensitivity to market forces (DFO, 1989b). In Newfoundland, ex-vessel prices in the inshore sector are determined through collective bargaining at the beginning of the season. While technically these are minimum prices, in practice, deviations from negotiated levels are infrequent. In Nova Scotia, substantial amounts of inshore groundfish are sold through non-market transactions. For both provinces, the ex-vessel price in the offshore sector is an internal transfer price set within vertically integrated companies.

Thus, the ex-vessel price of landings is an imperfect indicator of the supply of raw groundfish to processors. At the same time, we cannot preclude its having a significant influence on supply decisions, if only because if affects the relative profitability of various products. Consequently, we modify the supply function of equation (1) to include the level of landings, L, as a variable. Our modified supply function is therefore of the form

$$y_i^s = s(L, p, w) \tag{2}$$

The Canadian processors sell their production to wholesalers, retail outlets, and institutions in the U.S. (Mazany et al., 1987). The demand for frozen products at the processor level is thus a derived demand, as the buyers, in turn, sell to other companies or directly to the local consumer. We specify a standard demand function as a function of own-price, the price of alternative products, and income.

$$y_j^d = d(q, I) \tag{3}$$

where q is a vector of appropriate prices on the demand side and I is income.

We assume that market prices adjust so that supply is equated to demand. While this is not an unrealistic assumption in the fresh fish market, where the products must be sold quickly or they will not be saleable, it is not always appropriate for the frozen market, where inventories can be held. Nevertheless, we impose the assumption as a first approximation.

In order to estimate the model, we need to specify function forms for the supply and demand equations. We chose a log-linear form, with homogeneity of degree zero in all prices imposed on the supply equation and homogeneity of degree zero in prices and income imposed on the demand equation.

The regression equations for each particular product are

$$\ln y_{it}^s = \alpha_i + \beta_i \ln L_t + \sum_j \gamma_{ij} \ln p_{jt} + \sum_k \delta_{ik} \ln w_{kt} + \sum_k D_{kt} + u_{it} \sum_j \gamma_{ij} + \sum_k \delta_{lk} = 0 \tag{4}$$

and

$$\ln y_{it}^d = a_i + b_i \ln y_{i,t-1}^d + \sum_j c_{ij} \ln q_{jt} + d_i \ln P_t + e_i \ln I_{t-1} + \sum_k D_{kt} + v_{it} \sum_k c_{ij} + d_i + e_i = 0 \tag{5}$$

where

$y_{it}$ is the production of the ith product in time t ; i = 1, 2 for frozen fillets and frozen blocks, respectively ;

$L_t$ is landings of the species in time t ;

$p_{jt}$ is the price of the jth product produced by the processor in time t ;

$w_{kt}$ is the price of the kth factor of production in time t ; k = 1, 2 for labor and raw fish, respectively ;

$u_{it}$ is the random disturbance term in the ith equation in time t ;

$\beta_i$ is the elasticity of supply of the ith product with respect to landings ;

$\gamma_{ij}$ is the elasticity of supply of the ith product with respect to the jth product price ;

$\delta_{ik}$ is the elasticity of supply of the ith product with respect to the price of the kth factor of production ;

$y_{i,t-1}$ is the quantity of the ith product lagged one period ;

$q_{it}$ is the price of the jth product demanded in time t

$P_t$ is the U.S. Consumer Price Index for all items ;

$I_{t-1}$ is U.S. disposable income lagged one period ;

$D_{kt}$ are monthly dummy variables, k = 1,...,11 ;

$v_{it}$ is the random disturbance term in the ith equation in time t ;

$c_{ij}$ is the elasticity of demand for the ith product with respect to the jth product price ;

$e_i$ is the elasticity of demand for the ith product with respect to income ;

$b_i$ is the partial adjustment coefficient for the ith product.

A few words of explanation are needed for the demand equation. We estimate the model using monthly data. We thus include the variable, $y^d_{it-1}$, the quantity demanded in the previous month, in order to reflect habit persistence. That is, the quantity demanded in the current month is partially determined by what was demanded in the previous month. Further, when the time period is a month, it is reasonable to assume that immediate past income rather than current income determines demand (cf. Tsoa et al., 1982). The dummy variables are included to capture seasonal fluctuations in supply and demand. There is evidence of seasonal fluctuations in both U.S. imports and prices (Mazany, 1986), although these fluctuations diminished to some extent in the late 1980s.

For the estimation of supply, we use Canadian production as the dependent variable. Because there is not an observable quantity for demand, a proxy is needed, if quantity supplied and quantity demanded are specified as distinct variables. Since most Canadian production is exported to the U.S., we felt Canadian production was not an unreasonable proxy for U.S. demand for the Canadian product. Further, the alternative quantity variable to use is U.S. imports of Canadian product [4]. Use of import data requires the demand function to be specified as a semi-reduced form incorporating supply, domestic final demand and inventories. Such a specification detracts from the stability and adds to the complexity of the estimated form. For this reason, we preferred to use production rather than import data as the dependent variable in both the supply and demand equations.

A related issue is the role of inventories. Unlike fresh fish, frozen fish products can be stored. Thus, demand can be satisfied either by current production or inventories. Similarly, current production can be put into inventories if market conditions warrant. For the moment, however, we abstract from the effects of inventories [5].

4. Alternatively, Canadian exports of the product to the U.S. could be used but these data appear to be inferior to import data. For a discussion of the issue of using export versus import data, see Georgianna and Dirlam (1983).

5. There are serious data problems with inventories of fish products. First, it is not possible to distinguish among inventories of fish products from different countries. Secondly, both Canadian processors and U.S. buyers hold inventories. This complicates the modelling process even further.

## 4. DATA

We estimated the model for both frozen fillets and frozen blocks of cod, haddock, redfish, and flatfish. Because we are looking at the market at the processor-wholesaler level and concentrating on U.S. demand for Canadian products, we use as the producer price for these products the U.S. wholesale price, converted into Canadian dollars at the prevailing exchange rate. Monthly data are available for the period 1972-1987 for U.S. wholesale prices of frozen cod and haddock products, from 1974-1987 for redfish products, and from 1975-1987 for frozen flatfish products [6]. From the processor's point of view, substitutes in production include fresh product forms and, in the case of cod, salt fish. We include the prices of fresh fillets (and salt fish) in the supply equations. Since a continuous series on wholesale prices of fresh fillet products is not available, we use U.S. import prices of fresh fillets of each species for this product [7]. In the case of cod, salt cod is sold on a variety of markets, so we use the Canadian export price for this product [8]. We use as input prices the ex-vessel price of the species [9] and average hourly earnings in the fish processing industry for the Atlantic region [10]. Monthly data on landings are available [11], as are monthly production data[12].

On the demand side, prices are as on the supply side, except that substitution among products is assumed to occur not only for different products of the same species, but also for the same product from Canada's main competitors in the U.S. frozen groundfish market : Iceland and Denmark [13]. The income variable is U.S. disposable income lagged one period, and the general price variable is the U.S. Consumer Price Index for all items [14].

## 5. ESTIMATION RESULTS

The model for frozen fillets and blocks was estimated in blocks using Three-Stage Least Squares. The demand and supply equations for each species were estimated as a block. Landings and ex-vessel prices were treated as endogenous, as were Canadian product prices and production. The results are found in Tables 1 through 8.

### *5.1 Cod*

For frozen cod fillets, the coefficient of landings is significant at the 1 percent level and positive. It is close to unity, as we would expect. The coefficient of the wage rate is not significantly different from zero. The coefficient on the ex-vessel price, while significant at the 1 percent level, is positive rather than negative. One reason for this could be that the ex-vessel prices tend to be set for the season, based on the previous year's product prices and an estimate of what the product prices will be this year. Since processors buy the whole boatload from the fisherman, even if they do not need all of the fish, one would expect to find a positive correlation between the two sets of prices.

The coefficient of the own-price is significant at the 5 percent level and positive. The coefficient is greater than one, suggesting production is sensitive to changes in price. A one percent increase in the wholesale price of frozen cod fillets will cause nearly a 3 percent increase in frozen cod fillet production.

The coefficients of the prices of alternative cod products are significant and negative, as expected, except for fresh fillets. Frozen cod fillet production is elastic with respect to changes in the price of cod blocks and salt cod.

6. These were obtained from *Food Fish Situation and Outlook* and the *Bloston Blue Sheets* .
7. These are derived implicitly as value divided by volume, both figures coming from unpublished data provided by the U.S. Department of Commerce.
8. This is derived implicitly as value divided by volume, both figures from Department of Fisheries and Oceans, *Canadian Fisheries Exports and International Trade*, various issues.
9. This was calculated as value of landings divided by volume for the Atlantic Region, both figures obtained from Department of Fisheries and Oceans, *Canadian Fisheries : Landings by Month.*
10. Statistics Canada, *Employment Earnings and Hours*, cat. no. 72-002.
11. Department of Fisheries and Oceans, *Canadian Fisheries : Landings by Month.*
12. Department of Fisheries and Oceans, *Canadian Fisheries : Product and Stocks.*
13. The same products, but different species, e.g., using frozen flatfish fillets as a substitute for frozen cod fillets, were left out for two reasons. First, inclusion of too many price variables introduces severe multicollinearity, rendering elasticity calculations imprecise. Second, earlier specifications indicated little or no substitutability between products (see also, Tsoa et al., 1991). Although in the last few years Alaskan pollock has threatened to displace cod in the U.S. market, for the period under consideration, it was not a threat.
14. The U.S. Consumer Price Index and disposable income variables were obtained from U.S. Department of Commerce, *Survey of Current Business*, various issues.

The specification for the supply of frozen cod blocks differs from that of frozen cod fillets in that the specification of the supply function was better without seasonal dummies. One reason for this might be that cod blocks are more a utility product, with less specific uses than cod fillets. The coefficient of landings for cod blocks is also significant, positive, and close to unity. The wage coefficient is negative but not significantly different from zero. The coefficient of the ex-vessel price is also negative and significant at the 1 percent level. It is not entirely clear why the coefficient should be positive for cod fillets, yet negative for cod blocks.

The coefficient of own-price is positive and significant. As with the frozen cod fillet own-price coefficient, the coefficient for the price of frozen cod blocks is greater than one, again implying that production is sensitive to changes in the price of the product. The frozen fillet price is negative and significant at the 10 percent level, suggesting substitution in supply as relative product prices change. The coefficients for salt cod and fresh fillets are not significantly different from zero, suggesting these products are not substitutes in supply for blocks.

The results for the demand equations for frozen cod fillets and blocks are found in Table 2. The results for frozen cod fillets are good. The coefficient of own-price is significant at the 1 percent level and negative, as expected. The coefficient is considerable greater than one, suggesting U.S. demand for Canadian frozen cod fillets is highly price elastic. A one percent increase in the price of frozen cod fillets causes demand to decrease by 5.8 percent. This would suggest the presence of many substitutes in the market. The cross-price elasticities with respect to cod block and fresh cod fillets prices are significant at the 1 percent level and positive, with values of 1.9 and 2.6, respectively, suggesting they are substitutes, at least at the wholesale level, for frozen cod fillets. With respect to other countries' frozen cod fillets, only the coefficient of the price of Icelandic frozen cod fillets is significant. It is less than one, suggesting that changes in the price of Icelandic frozen cod fillets have a smaller effect on the demand for Canadian frozen cod fillets than do changes in either Canadian cod block or fresh cod fillet prices. This may be because Icelandic (as well as other foreign) cod products move through different marketing channels or enter different markets.

The coefficient on the Consumer Price Index and lagged disposable income are as expected. The results suggest demand for frozen cod fillets is income-elastic. The coefficient of lagged quantity is significant at the 1 percent level and lies between zero and one. This implies response in demand to changes in the market does take place over a period of time. The estimated coefficient implies half the discrepancy between long-run and short-run demand is eliminated within one month.

With respect to cod blocks, the own-price coefficient is not significantly different from zero, while the coefficient on frozen cod fillet prices is negative and significant. This anomalous result suggests there might be a misspecification of the function. The coefficients on the fresh fillet price, and Icelandic and Danish frozen cod blocks, are significant and positive, as expected. This implies that Canadian frozen cod block production does compete in the U.S. wholesale market against cod blocks from these two countries. The coefficients are less than one, though, suggesting buyers are not that sensitive to price changes.

The coefficient on both the CPI and lagged income are again significant and of the expected sign. The coefficient of lagged quantity is also significant and less than one, again implying a lag in the response of demand to changes in the market.

### *5.2 Haddock*

The results for the haddock model are found in Tables 3 and 4. The wage rate and monthly dummies were excluded from the supply equation, as this provided a better specification. For the supply of frozen haddock fillets, the coefficient of landings is significant at the 1 percent level and positive, but less than one. One possible explanation for this result is limits on freezing capacity. When this capacity is exceeded, production must be diverted to other product forms. This does not explain, however, why a similar result is not found for the other species. The coefficient on ex-vessel price is significant at the 1 percent level and positive. Again, this may reflect the market structure, as discussed above for cod.

The price coefficients are disappointing, as the signs are the reverse of what would be expected. This suggests there is some sort of identification problem, in that the price coefficients of the supply equation have signs suggesting a demand equation has been estimated. This is also true for blocks.

The demand equations are not much better. Although the coefficients on the price variables are of the correct sign, in the case of frozen fillets, only the own-price coefficient is significantly different from zero. The block equation is somewhat better, but has a calculated negative $R^2$. The results suggest that the specification is incomplete. For example, inventories have been excluded. More work clearly needs to be done on this part of the model.

*5.3 Redfish*

The supply and demand equations for frozen redfish fillets and blocks are found in Tables 5 and 6. The supply equation for blocks is not very satisfactory. Only the landings and ex-vessel price coefficients are significant. This may reflect the fact that frozen redfish blocks form only a small proportion of production. With respect to the supply equation for frozen redfish fillets, the landings coefficient is significant at the 1 percent level. and close to one, as expected. The ex-vessel price coefficient is significant at the 1 percent level and of the correct sign. Again, the preferred specification excluded the wage rate variable. The own-price coefficient is significant at the 1 percent level and greater than unity, suggesting production of redfish fillets is sensitive to changes in the wholesale price. The coefficients of the prices of alternative cod products are significant and negative, as expected, except for the coefficient on the fresh fillet price, which is just under the 10 percent level of significance. In the case of redfish products, there is no large competitor of Canadian product on the U.S. market. Frozen redfish fillet production is inelastic with respect to changes in the price of redfish blocks, but elastic with respect to changes in fresh redfish fillet prices. It is not unreasonable to think that fresh fillets are a closer substitute to frozen redfish fillets than are blocks.

With respect to demand, the own-price coefficient is significant at the 10 percent level and positive. This suggests there is some specification problem, especially as the coefficients on the prices of alternative products are negative, rather than positive. The results for blocks show similar problems. The low $R^2$ (in the case of blocks, a negative $R^2$) reinforces this conclusion.

*5.4 Flatfish*

The results of the estimation of the supply and demand equations for flatfish are found in Tables 7 and 8. With respect to the supply of frozen flatfish fillets, the landings coefficient is significant at the 1 percent level and close to unity. The wage rate coefficient is also significant at the 1 percent level and of the expected sign. The coefficient on ex-vessel price is significant at the 10 percent level and positive. This may again reflect the way ex-vessel prices are set, as discussed under cod, above. In the fillet equation, none of the price coefficients is significant. For blocks, only the own-price coefficient is significant. It is greater than unity, suggesting processors are sensitive to wholesale price changes.

With respect to demand for frozen flatfish fillets, the own-price coefficient is significant at the 10 percent level, but of the wrong sign. Part of the difficulties with the flatfish results may be because "flatfish" comprise a number of different species, so the price and production variables reflect an aggregation of over 20 different species within the category of "flatfish". The coefficient on Danish flatfish fillets is significant and of the correct sign. It is less than one, suggesting there is not much substitution between Danish and Canadian frozen flatfish fillets. This again may reflect species mix, or that the two countries sell through different marketing channels or in different markets. The coefficients on the CPI and lagged disposable income are significant, but only the coefficient on the CPI is of the correct sign. The coefficient on lagged quantity is significant, but low. This suggests only 20 percent of the discrepancy between long-run and short-run demand is eliminated within a month.

With respect to blocks, there is again a problem with the signs on the price coefficients. Given the low proportion of production that goes into flatfish blocks, and the difficulties with species mix, this suggests more work needs to be done on the specification of the model for flatfish.

## 6. CONCLUSIONS

In this paper we estimated a simultaneous equations model of the U.S. demand for and Canadian supply of frozen groundfish products. The results were mixed and indicate more work needs to be done on specification of the supply and demand equations, especially for haddock and flatfish. Our results suggest the following implications for modelling :

i) Different product types of a given species interact with one another on both the demand and the supply side, making a simulaneous approach essential.

ii) Market structure is complex and product-dependent. Some products face more competition in the market from other product forms and other countries' products than do other products.

A complete model of the U.S.-Canada trade in groundfish products must include the market for fresh and other products, since these interact with the demand for and supply of frozen products. However, data considerations would force us either to use annual data or to use import data rather than production data. Using annual data would mean a small number of degrees of freedom. In addition, it is not clear which aggregation of the price variable is the economically relevant definition. The price data used in this model are monthly series and already reflect a substantial aggregation. Taking a simple average would hide substantial variations in montly prices. If we wish to construct a weighted average, it is not immediately obvious what to use for weights.

The other alternative is to use import data for quantity. This means we are no longer estimating a supply function but an import function. This complicates the model and introduces additional estimation problems in that some of our price variables are import unit values.

Nonetheless, our model represents a first step towards building a more complete model of U.S.-Canada groundfish trade. It allows us to say something about supply responses to market changes as well as demand responses. It shows that there are differences in different product markets in terms of price responsiveness. Thus, it is not accurate to talk about effects of changes on the groundfish market as if it were a single market. The markets are connected, but still distinct.

# Price Fluctuation and Substitution in the Groundfish Market

**Torbjørn Trondsen** *

The Norwegian College of Fishery Science, University of Tromsø, N-9000 Tromsø Norway

ABSTRACT

*Prices of groundfish products have fluctuated substantially over the last few years, but the general trend has been upward. New groundfish species from the Pacific and South Atlantic oceans have penetrated the groundfish market.*

*The paper explains the price fluctuation as a function of total supply and demand for groundfish, substitution between cod, pollack, hake and hoki in the markets for frozen fillet/block/H & G, fresh, salted and surimi products. The paper also discusses barriers against substitution in the market, and technical barriers in the production which create market segments with different price developments. Understanding the marketing barriers is important when companies and countries are planning the most profitable marketing and production strategies in the long term.*

## 1. INTRODUCTION

The term Groundfish cover all white fleshed salt-water species which live in the bottom area of the sea. The main species are Cod, pollock, saithe, haddock, hake, whiting, flatfish, redfish, hoki and lings. In addition many groundfish species can be found in warm water areas as grouper, snapper and seabreams (see appendix 1).

Prices of groundfish products as fillets, salt-fish, surimi and stockfish, have fluctuated substantially in the last years, but in an upward movements. New groundfish species from both the Pacific and south Atlantic Oceans have penetrated the market.

In this paper price fluctuation is explained as a function of the total global supply and demand for groundfish and substituion between different groundfish species and products in the markets.

* The author thanks for the financial supported from the Norwegian Counsil of Fisheries Research, which has made this research possible.

Barriers against substition are focused on production, distribution and markets which create market segments with different price pictures and fluctuations. Understanding the marketing barriers is important when companies and countries are planning the most profitable marketing and production strategies in the long term.

The theoretical perspective used is based on industrial organizational behaviour (Porter 1980), which when applies in the fisheries means understanding the behaviour of the actors engaged in fishing, processing, distribution and marketing between dynamic fish stocks and markets.

## 2. DATA SOURCES AND METHODS

The research methods used are a combination of exploratory and descriptive ones and aimed at discovering ideas and insights ( Churchill 1983, p62). Catch and production data in the period 1984-1989 come from FAO statistics and 1990-1991 from different national sources. US price information comes from National Marine Fisheries Services/Urner Barry price list. Norwegian export prices comes from the new Export database at the Norwegian College of Fishery Science. Japanese wholesale information comes from industry sources in Japan. Information from trade journals, newspapers and companies are used.

In addition the analysis is based on experience survey through extensive interviews with several leaders in the seafood processing and distribution industry in the USA, Japan, France, Great Britain, Germany, Italy and Norway done through our research-program : "Competition in the groundfish market."

## 3. FLUCTUATION OF PRODUCTION AND PRICES IN THE 1980'S

In the early 1980's the demand for seafood products started to increase. Health and weight consciousness among consumers coupled with enhancing purchasing power are anticipated to be the main forces behind the increased demand for seafood. Formerly fish was seen as cheap food for low income people. On the contrary, during the 1980's, prices for high quality seafood increased so much, that seafood more and more was seen as food for the more wealthy in the society. This gave signals to processors and fishermen to increase the catch and processing efforts.

Frozen fillet block is a globally standardized product which traditionally was made from Atlantic cod, saithe and haddock. But also other kind of groundfish species have been used in recent years. Frozen fillet block can be seen as a true free market product because the global trade has few restrictions. Frozen fillet block is therefore a good indicator for the price-level of groundfish.

In the following, we will explore the correlation between the prices of cod-block, total production and other groundfish products.

Figure 1 showns the correlation between prices and production of frozen cod fillet. Both the prices and production of cod-fillets increased in 1985, 1986 and 1987 and decreased in 1988 and 1989. The production was on the decline until 1991, but the prices showed only a slight decrease until 1988, when they started rising again. The price increase from 1989 to 1990 did not cause any production growth as was the case in 1985-1987.

This figure indicates, that the processors reduced production the same year as prices started falling. The interesting pattern is that production still reduced the following year even though prices were stable and then started increasing. How can it be explained ?

A comparison between figure 2 and figure 1 shows that the production of frozen groundfish fillets as a product-group increased from the year 1987 to 1988 (when the cod fillet production went down). After 1988 the production went down and levelled off to the 1987 level. This development is logical according to economic theory. The increased prices gave incentives for increased production. But it took time between the point for production and to the point or sale. The processors act on current prices. Products go first for freezing and storage, from where it can be sold. Frozen groundfish can be stored for at least a year and still be of good quality. When most processors make products for storage at current

prices, the accumulated impact is that production increases over the quantity which can be sold at the price they were made for. Then the prices start to fall until the present products can be sold and the production decreases until the supply to current prices again is too low and the prices will again increase to stimulate production.

But opposite to cod block production, correlation is positive between the price of cod-fillet block and the total production of all frozen groundfish fillets in the period 1989-1991. This indicates that increased prices of cod-fillet block also is correlated with increased production of frozen fillet block based on other groundfish species. This can be confirmed in figure 3.

Figure 3 shows that frozen fillet has gained an increasing share of the total catch of groundfish over the period : from 5,7 % in 1984 to 6.6 % in 1991. During the same period as the fillet-production increased, figure 4 show that the share of codfish[1] used in frozen fillets decreased from 45 % in 1981 to around 32 % in 1991. Production of pollock and hake fillets grew in the same period. The share of pollock-fillet increased 1981-1991 from 4 % to 20 % and hakefillet from 13 % to 22 % of total frozen fillet production.

The changed production level of frozen fillets can be explained as a function of catch. Figure 5 shows the yearly relative change in catch of different groundfish species related to 1984. The figure shows that the yearly catch of most coldwater species (except redfish), increased from 1984 to 1989. The major contribution to the increased catch came from Alaskan pollock with hake in the second poition. But in the period 1989 to 1991 the cod catch were reduced. The catch-growth of alaskan pollock has in the same period been reduced to the 1984 level. Hake kept its gain all through the years to 1991. Flatfish contributed to the catch growth up to 1990, but was reduced in 1991.

The accumulated impact on the total production of groundfish is seen in figure 6. The total production increased strongly in 1984 -1987, but fell again. There seems to be a good correlation between catch and the prices on both cod and pollock block.

But the processors of frozen fillets have to compete with other type of processors in the raw fish market.

The situation in the early 1980's was that technical improvements in the production processes and marketing effort had made a number of groundfish species actual to be supplied into the global market for frozen fillets if the demand and prices were interesting enough. Catch and production all over the world were influenced, because of few barrier in the global trade of frozen fish.

Figure 7 and 8 show the correlation between the prices of different groundfish products.

Figure 7 show that the prices of all chosen groundfish products have the same form. It indicate that the total groundfish market influences all products. Figure 8 show that surimi lost its relative strength to cod block 1984-1990. The prices on surimi started to increase later than the other groundfishes. The reason was that the surimi factory trawlers did not have enough equipment onboard to make fillets. But when the prices of frozen fillets came up to almost the same level as surimi which only gave 60 % of the yield, the owners of the US factory trawlers started to invest in the necessary equipment and increased the production of cod and pollock fillet. The result was that the production of surimi decreased substantial, and the surimi-prices increased more than 50 % in 1991 to keep up with the competition from the fillet market.

## 4. IMPACTS ON PRODUCT-MIX FROM FISHING REGULATIONS AND THE STRUCTURE OF THE INDUSTRY

A key to understanding the competition in the product-markets is the understanding the competitive advantages of the structure of the supplying fishing industry (Porter, 1985). The present pattern of production in the market, is a result of developments in the industry over the years.

The fishing industries have faced to big difficulties during the 1980's. First, extention of the the 200 n miles Economic Zones in 1978 which started a process that changed the fishing rights to the coastal states. The resources had earlier been

1. Codfish defined as : Cod, haddock, saithe, whiting, hoki, ling, tusk, argentinas.

exploited of long distance fleets from a few nations. Second, it emerged that more and more fish stocks were overexploited. The governments had to intervene with catch restrictions, which created overcapacity in most fishing sectors. Even higher prices on frozen fillets could not compensate that catch per unit effort went down. This was a new situation in the groundfish-fishery. Increased catch effort without changing the product-mix has traditionally always been the variable by which the fishermen could regulate their income. When the quota is given, all actors had to give priority to the product-mix which could give best profit with the technology and raw materials available.

### *4.1 Supply of atlantic frozen fillets*

The distribution chain for frozen products has developed after the World War II in all industrialised countries. This gave incentive to the building up of a freezing and cold storage industry. In all north Atlantic countries, the seafood sector has made hugh investment in filleting and freezing factories. This production method combined with investment in trawler fleets, made it possible to process, store and distribute high quality products independent of seasonal catch pattern and distances between consumers and catching grounds.

Frozen fillets blocks are still a main frozen fish product in Norway, Denmark, Faroe Island and Canada. In Iceland the production is more changed to frozen single fillets (Geirson & Trondsen 1991).

Fillet blocks were used as raw material in fish-sticks production. When the blocks are cut in small sticks and breaded. The fish sticks production grew very fast in the 1950 and 1960's and can now be seen as a mature industry. But development of new frozen fish products both made from blocks, single fillets and made direct from wet fish, has contributed to a steady growth in the frozen fish markets.

Most of the fish sticks processing industry which utilize frozen fillet block as raw material, are located in the USA and EEC. The industry in Europe is dominated by big multinational companies as Nestle and Unilever (Ottesen G 1992). These companies controlled earlier their own trawler fleets in Germany and Great Britain. But after the extension of the 200 mils economic zones, this fleet lost their traditional fishing grounds to Norway, Iceland and Canada which became the winners in the resource battle.

The big multinational processing and marketing companies in the frozen food sector, had to change their strategy. Vertical integration was partly given up. The trawler fleet were scraped or sold and the strategy focused on value added processing and marketing of products made from imported fillet blocks.

On the other hand the coastal Atlantic nations which gained control over most quotas, concentrated their strategy on fillet block production for the big fish sticks processors. Relative advantages and import duties of fish sticks and similar consumer products into the EEC and US markets, may explain this development.

### *4.2 Supply of surimi*

When the European dried and salted groundfish, the Japanese washed the fish flesh and preserved it as "surimi". This methods which was invented for many hundred years ago, made it possible to keep good quality fish without chilling facilities. Over the years, the Japanese have developed hundreds of products ( mainly kamaboko products) where surimi makes a main ingredient. The latest success product is crab sticks, which also has gained popularity in US and Europe.

When the Japanese learned methods to store frozen surimi products, it became possible to develop a huge factory trawler operation in Northern Pacific mainly in the Bering Sea in the early 1960's. Yearly, the Japanese made 400.000 tons of surimi and 800.000 tons of kamaboko products from more than 2 mill tons of Alaskan Pollock.

The extension of the economic zones to 200 nautical miles resulted in restructuring of the fisheries in the Pacific. The Japanese fleet of surimi factory trawlers and processing ships in the northern Pacific, were forced out of the US-economic zone in the late 1980's. After some years survival in international waters in the Bering Sea (dough-nut hole) and JV operations in Russian and Southern Pacific waters, most of the vessels in this fleet were sold or scrapped. The main Japanese fishery companies have changed their strategy from fishing to processing and trading.

Other nations as South Korea and Poland did also operate in this area. The Korean fleet has survived by JV operations in Russian waters. The Polish fleet which mainly has made fillet block out of Alaskan Pollock, has also big economic difficulties in the Northern Pacific. The restructuring of the Polish economy, will put a stronger economic pressure on this fleet. It may result in disorganization of the fleet.

The main force behind outfacing of the Japanese, Korean and Polish fleet from the US- Economic Zone, was the build-up of an American factory trawler fleet. The entrepreneurs behind this American fleet were partly Japanese, Korean and Norwegian, because foreign ships were not allowed to fish in US Zone. Today 100 % of the US groundfish quota is caught by US-flagged vessels ( Arnarson & Trondsen 1990).

### *4.3 Supply of Pacific frozen fillets*

Changed ownership of the Northern Pacific fleet also meant introduction of new processing methods. The Norwegian fishermen who engaged in this fishery, were experienced in fillet production onboard factory trawlers. The yield to surimi from whole fish is only 60 % ( yield 17-20 %) of the yield to fillet (yield 30-35 % ). The investment needed to make fillets are lower than to surimi, but the labour cost is higher. So, when the fleet became restructured through the Americanization process in the Alaskan fisheries, the knowledge and technology were also present to change production from surimi to fillets when the prices on fillet increased to more than 60 % of surimi- price.

The first entrepreneurs in filleting and freezing operations for Pacific cod started in the early 1980's. But the cod season was too short to make good profitability. Acceptance of frozen fillet from Alaskan pollock in the market was necessary before a filleting and freezing year around operation onboard factory trawlers became profitable.

During the 1980's pollock fillets produced onboard factory trawlers were introduced. These fillets were of a much better quality than the pollock fillet earlier known in the market. But there were problems with the use of pollock fillets in catering operations, because the breading busted under cooking. But through improving and adjustment of the breading and handling process, pollock fillets are now widely accepted in certain segments in the market.

In the 1970 and 1980's it was also invested heavily in filleting and freezing operations in New Zealand and Southern America. In the late 1980's some of Norwegians factory trawlers for filleting and freezing moved over to New Zealand and Australia and participated in successful JV and trial operations. The main groundfish species in New Zealand were mainly Orange Roughy and Hoki.

### *4.4 Supply of frozen hake fillet*

Hake is another group of groundfish which are mainly caught in southern America and southern Africa. Most filleting and freezing are done on land-based plants. In the 1970's and 1980's hake became more and more present in the frozen fillet market (Cerda & Anderson 1991). Initially, hakefillet was seen as low quality products. Among other things, hake had a fat layer between the skin and flesh, which lowered the storing time if it followed the fillet. But substantial quality upgrading, both handling of the raw material and deep skinning which removed the fat-layer, made frozen hake fillet block a good substitute for cod fillet block.

### *4.5 Supply of saltfish, klippfish and stockfish (Conventional cod products)*

Figure 8 shows that the Norwegian export prices of saltfish and klippfish (dried saltfish) follow the general trend, but the relative prices have increased compared with frozen cod block.

Salting and drying of groundfish has been the traditional preservation methods in Norway. Dried cod as stockfish are a very old products invented by the first Norwegians, have been an important protein source for Catholics in southern Europe, who do not eat meat in certain periods (Lent). The production method is simply to hang the fish on a drying rack until the water content is reduced to 20 percent. This product can be stored for years without any temperature control. Before it can be consumed, it has to be put into water to swell out. This product is still very popular especially in Italy and is at present the highest paying cod product in Norway.

In southern Europe wet salt-fish and dried salt-fish (klippfish) are still very popular products. Klippfish with a water content of 30-40 % can as stockfish, be distributed and stored without any chilling facilities. Main markets are Portugal, Brazil and southern Italy.

The markets for saltfish, klippfish and stockfish have been very competitive in the raw fish market for cods. An important factor is that Alaskan pollock, hake and the other "new" species which have penetrated the frozen fillet market, have not

succeeded in penetrating the markets for conventional products. It has been impossible to make a good quality saltfish from pollock and hake. The only substitutes to Atlantic cod in the saltfish market have been Pacific cod and Atlantic saithe, ling and tusk (Asgeirson A 1992). In the stockfish markets, it is the excellent condition for fish drying, which can be found in northern Norway (Lofoten area) and to some degree Iceland, which gives this countries absolute advantages in production. These mobility barriers based on accessibility of specific kinds of raw material and production conditions, have limited the competition in these markets to the suppliers of Atlantic cod. The low degree of substitution and the strong purchasing power especially in northern Italy and Spain and to some degree in Portugal and Brazil, have pushed the prices of saltfish, klippfish and stockfish to record heights.

The industry for conventional products have consumed 50-60 % percent of the Norwegian, 30-40 percent of the Icelandic and 30-40 percent of the Canadian cod quota.

Anticipated reasons for the difference are that Iceland has a more competitive frozen fish industry than Norway, due to higher output of more diversified products as fillets for catering etc.

The Canadian has also a competitive frozen fish industry, and access to a strong US-market for fresh groundfish with limited competition (Mazany, Barrett & Apostle 1987).

### *4.6 Supply of fresh fish*

Fresh fish belongs to a separate product-market segment.

The marketing area is limited to markets which can be reached few days after catch. The markets could also be seasonal due to catch -variations. Fresh wild groundfish are mainly consumed some distance from the coastal areas which can be reached within 7-8 days. Improvements in the distribution systems as chilled trucks and airplanes, have increased the distribution distance of fresh fish. But the costs increase strongly when airplanes are used (Trondsen 1989). Almost all fresh groundfish consumed in Europe are caught in Europe and most fresh groundfish consumed in the USA are caught in North America. These barriers in the market, limit possible competitors and keep fresh fish on a high price level. Whilst the prices of frozen cod fillet in Europe is dependent on the supply of fillet in both the Atlantic and the Pacific regions, the prices of fresh fish in Europe are mainly dependent on the Atlantic catch.

### *4.7 Segmentation and positioning strategies*

The increased demand and entry of new species have increased the competition in the global groundfish market. To keep the competitive positions, the industries have developed new segmentation and differentiating strategies.

The segments were pollock and hake fillet block have gained foothold at the expense of cod fillet block, are in products like breaded fish sticks. Product labelling strategies have made it difficult for consumers to notice what kind of whitefish is used in fish sticks. Many processors label their products as "whitefish". Such labelling in the low-price market-segments make it possible to introduce frozen fish sticks made from the cheapest groundfish. In some markets for example France, there are regulations that call for labelling of the specific species used as raw material of the fish-sticks. But these labelling-law had no observable effect on the rate of consumption of frozen fillet blocks produced from pollock and hakes.

The high prices of cod fillets compared with pollock and hake fillets, have forced the processors to differentiate these products into market segments which are willing to pay premium prices.

The first step the processors of fish sticks made, was to differentiate fish sticks by labelling the products as fish sticks made from Atlantic cod, Alaskan pollock or hake. The prices of fish sticks processed from alaskan pollock and hake are much lower than those processed from Atlantic cod. Because of this price-difference, the fish sticks processors have been able to focus on different consumer groups with different price and quality preferences related to pollock, hake and cod.

The first step in this direction taken by the primary processors of cod fish block was to reduce the production of block and increase the production of frozen single fillet (IQF or layer-pack).

Frozen single fillets are sold directly to the final user (for instance to the Catering industry) without any further processing. The consumers preference for *natural* products, has favoured the single frozen cod fillets at the expense of breaded products. Especially Iceland has succeeded with this strategy (Geirson & Trondsen 1990).

Another strategy has been to make consumer packs of frozen fillets for supermarket distribution directly from fresh fish. By this production strategy, the primary processors can increase their prices of fillet and secure a bigger share of the value chain.

The increased prices of surimi block due to competition with fillet block, have forced the Japanese surimi industry to lay down several production units for low-priced traditional surimi-based kamaboko products and focus the marketing effort on more high quality and priced products. Higher prices of surimi block has also reduced the growth in the US and European crab sticks-market.

Increased rawfish prices on cod, has also forced the saltfish processors to change. Increased access to chilling facilities and demand for higher quality products have opened up markets for wet-salted codfish with shorter shelf life. Spain and northern Italy are the main markets. In Iceland processors have developed a higher quality saltfish for these markets. This product which is lightly salted and need chilling facilities during distribution, sells for 30 % higher price than traditional saltfish cod in the Portuguese market. So far there are few other processors besides the Icelandic who have succeeded in getting a foothold in the lucrative Spanish saltfish market.

Meals based on dried and salted products demand long preparation time. The main buyers of the products were housewives who had the day available to prepare dinner. Nowadays, women in southern Europe do more and more as women in northern Europe and the US : They find jobs outside home. Everyday food has to be done in short time after work. This change in buying habit, has given incentive for a substantial development of the supermarket sector in Spain, Portugal and Italy. A few saltfish processors have positioned themselves to this segment and offer diluted salt-fish in consumer packs, chilled or frozen through the supermarkets. This kind of products are also able to carry the high prices of the raw material.

New groundfish products have also been introduced into the fresh fish markets. Fresh fillets, skin-packed fillets, modified atmosphere packed fillets and Norwegian made sous vide- fresh products[2] are among new products which are under way to the market place. Common to all these products, are that they need fresh raw fish. This would give all coastal regions absolute competitive advantages on the big consumption regions in central Europe, the USA and Japan.

## 5. CONCLUSIONS

Changes in prices and production of frozen fillets are explained by the changes in total global catch during the 1980's (Figure 1-6).

Prices started to increase due to increased demand. These increased prices gave incentives to increased fishing effort and total catch. But in the 1987/88 the production was so big that the prices started to fall. At the same time, over-exploitation of the Atlantic cod stocks became evident and catch restriction was imposed in Canada, EEC, Iceland and Norway.

When the prices started rising again in 1989, the total catch of groundfish did not increase due to catch-restriction. But the frozen fillet production is kept at a high level because a bigger share of the catch is utilized in frozen fillets. The shortages in supply and high prices of cod-fish opened up the market for cheaper raw fish.

The price-curves on Alaskan pollock and cod block have the same form, but pollock prices are approximately 60 % of the cod price. It indicates that frozen fillet block of cod and pollock are substitutes. Some market segments are willing to pay a premium price for cod even if they can get pollock block at a lower price. This mean that prices influence each other even if the products are sold in different market-segments.

The same substitution and price correlation effect can be found between cod fillet block and hake fillet block.

The increased demand for groundfish products, the acceptance of new species in the market and changed ownership and access to the catching grounds, have also changed the supplying industry. The Japanese, German and British long distance trawler fleet are disorganized. The Polish and Russian fleets are in the process of disorganization. New suppliers of frozen fillets from south America, New Zealand and USA have emerged.

2. Sous vide is French and means *without air* . Pieces of fresh fish is vacuum packed and warmed to 90-100 degree Celsius. The shelf-life of cod can by this method be increased from 10 to 20-30 days and the waste in the cooking process is reduced.

When the demand and production of frozen fillet increased, the supply of raw fish to other products fell. Processors and traders of saltfish, klippfish, stockfish and fresh fish products, had therefor to pay more to be competitive in the rawfish market which affected the prices of other end- products (see also Hanneson 1991). Therefore, prices and production of all groundfish -products are influenced by the total demand, preferences and substitution of all main groundfish-products together with catch production capacity and strategies, natural stock fluctuations and governmental regulations of the groundfish fisheries (see also Johnston, Arnarson and Ziezula 1991).

To defend the price position in the markets the processors of cod-products have developed segmentation strategies. Segmentation and positioning limit the competition and create different prices on groundfish. These strategies rely on absolute, relative and competitive advantages.

Absolute advantages can be found in processing of saltfish, klippfish, stockfish and freshfish :

(i) Cod, tusk, lings and saithe have quality advantages in the saltfish, klippfish and stockfish markets.

(ii) Cod stockfish has an absolute advantage in the drying climate in Norway and Iceland

(iii) Fresh groundfish has a limited shelf-life and quality increases with increased freshness. This gives an absolute advantage for processors near the markets.

In the freezing industry the specialization between block processors and fish sticks processors can be seen as a function of comparative advantages. The fish sticks processors with limited access to fish stocks, have invested in marketing and fish sticks plants which rely on economics of scale. The primary processors in the coastal areas with access to catch, have concentrated their strategy on block and single fillet production.

Increased competition from new species, have given incentives to develop new competitive marketing strategies based on segmentation and product development. We have identified the following new marketing and production strategies in the cod processing industry :

(i) frozen single fillet-products for the catering-market.

(ii) frozen consumerpacks packed from wet fish for supermarkets.

(iii) different pieces of cod fillets (tail, centrecut and loins) for supermarkets and catering

(iv) Light saltfish for the Spanish and Italian market.

(v) Diluted saltfish in consumer packs for European supermarkets

(vi) Vacuum packed fresh fish

(vii) Sous vide packed fresh fish

All this strategies will reduce the competition and sustain price differences between the groundfish products, even if the price-trend interact over time.

It is also interesting to note that the fishing industry, which on the processing side traditional has been very conservative, now have taken use of product-development as an active competition tool. Our observations underscore Porters statement that "the rate and direction of improvement and innovation is a function of attention and effort" (Porter 1990,p83). Limited quotas and increased competition between different species, have changed the direction of innovation in the fishing industry. The attention and effort are changed from the volume of catch and processing of a given product- mix, to improvement of the product-mix based of a limited volume. This change in the direction of innovations has as Porter put it " often results from pressure, necessity, or even adversity" (ibid p49) from the changing market-forces.

GROUNDFISH SPECIES USED IN THE ANALYSES :

Alaska pollock

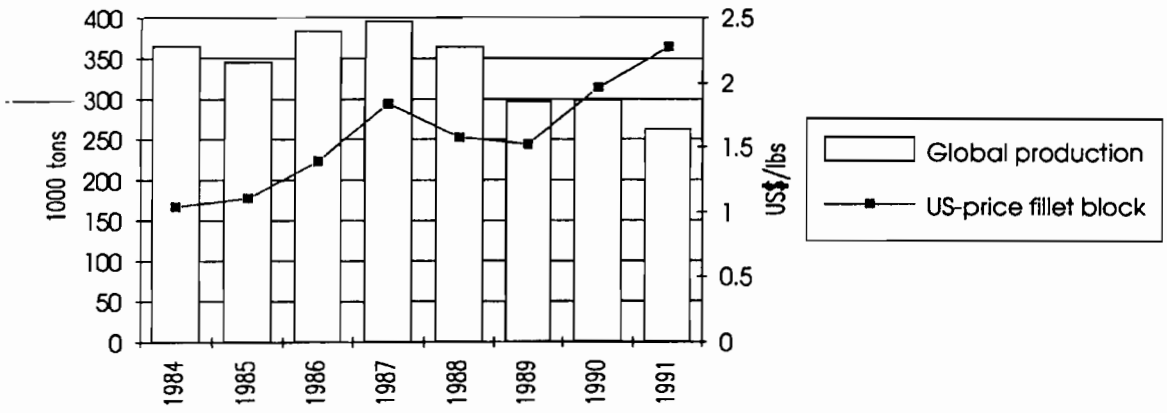
Codfish

- Atlantic Cod
- Pacific Cod
- Haddock
- Atlantic Pollock (Saithe)
- Whiting
- Hoki
- Tusk
- Ling
- Argentine (Silver smelt)

Hakes

Redfish (sebastes)

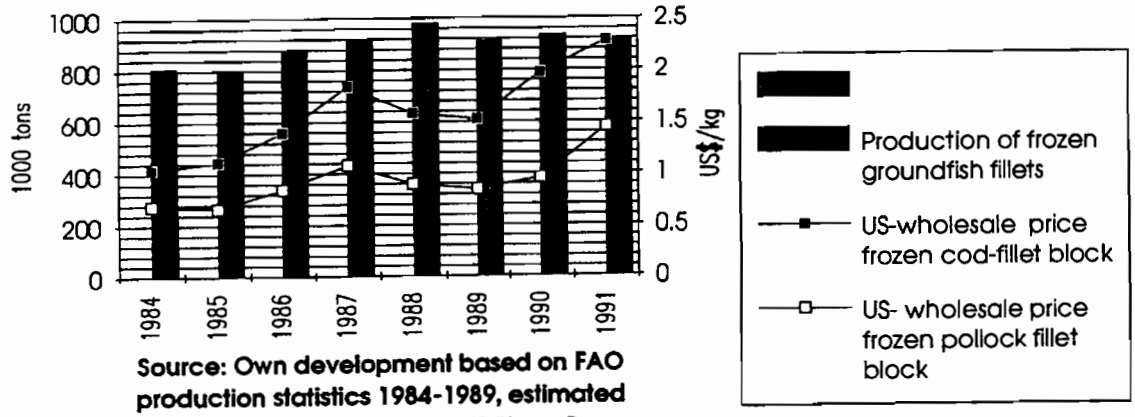
- Atlantic redfish
- Pacific redfish
- Cape redfish
- Orange Roughy



Flatfish

- flounder
- sole
- plaice
- dab
- halibut
- turbot

Warm water groundfish



- Catfish
- Dories
- Groupers
- Seabass'
- Snappers
- Croakers
- Seabream
- Kingklip
- Lingcod
- Sablefish

# The Icelandic Cod Trade : An Econometrically Based Simulation Model

**Ragnar Arnason [a] and Tryggvi Felixson[b] ***

[a]University of Iceland, Dept of Economics, 101 Reikjavik, Iceland

[b]Nordic Council of Ministers, Store Standstraede 18, DK 1255 Copenhagen, Denmark

ABSTRACT

*This study is a part of the Global Groundfish Market Research Group efforts to model the world groundfish trade. An econometrically based simulation model of the Icelandic Cod trade is developed. The model is basically structured as a collection of supply and demand relationships determining the production of various cod products, their subsequent supply to different international markets and the resulting market prices. The model, more precisely, explains the allocation of the icelandic cod catch to the freezing and saltfish production process as well as the export of fresh fish. The model comprises four markets for icelandic cod products - the fresh cod markets in the United Kingdom, the markets for frozen cod blocks and fillets in the United States and the United Kingdom and saltfish products to Spain and Portugal.*

*Altogether the model contains 43 equations. Most of these are identities of various kinds but there are 14 "behavioural" equations that have to be estimated with econometric methods. The demand equations are expressed in a price dependant form. Preliminary simulations indicate a strong negative relationship between the cod catch and the market price of cod products. Personal income variations in main market areas also appear to have a major impact on cod prices.*

## 1. INTRODUCTION

This paper reports on an ongoing work on developing an econometrically based simulation model of the Icelandic cod trade. This type of modelling obviously incorporates two distinct but related activities. The first concerns the estimation

* We would like to gratefully acknowledge the financial support of Vísindasjóður (The Icelandic Science Fund) and the excellent research assistance of Sigurgeir B. Kristgeirsson and Magnús Skúlason.

of the model. This involves the estimation of the relationships determining the production of various cod products, their subsequent supply to markets and the associated market prices.The second activity concerns the construction of a simulation model to predict the evolution of the endogenous variables in response to exogenous shifts.

The model consists essentially of a number of supply and demand relationships. It contains 43 equations. Most of these are identities of various kinds. There are, however, 14 "behavioural" equations that have to be estimated with econometric methods. The demand equations are expressed in a price dependent form. Preliminary simulations indicate a strong negative relationship between the cod catch and the export price of cod products. Personal income variations in main market areas also appear to have a major impact on cod prices.

As mentioned above, the model is still under development. In particular, as should be clear from what follows, the statistical estimation process is far from complete. Consequently, this paper should be regarded as progress report.

The paper is divided into 5 main sections. The following section provides a brief overview of the markets for North-Atlantic cod and the production and exports of Icelandic cod products. The next section contains a description of the essential structure of the model followed by a section on the estimation of the model relationships. Finally, some simulations results are presented in section 5.

## 2. CATCH, PRODUCTION AND EXPORTS OF COD PRODUCTS

The average annual catch of cod in the North-Atlantic has in recent years been around 2 million MT (metric tonnes). Iceland is one of the largest harvesters of North-Atlantic cod with about 1/5 of total landings. Thus, of the 1.97 million MT of North-Atlantic cod landed in 1988 Iceland caught 18 %, Canada 24 %, Norway 13 %, United Kingdom 5 % and Denmark 5 %[1]. Slightly more than 1/3 of the cod catch is marketed as frozen products, about 30 % is salted and 30 % is consumed fresh[2]. About 56 % of the total catch of Atlantic cod is consumed within the European Community where Britain stands for the largest share[3]. The second most important market is the United States, where the total consumption of cod is almost the same as in Britain (but considerably less per capita). Portugal and Spain constitute by far the largest markets for salted cod.

Thus, the main markets for Atlantic cod products are in the economically most advanced regions of the world with a strong transportation and communication infrastructure. As a result, cod products are traded in a highly integrated and efficient markets[4]. It should be noted, that Iceland's share in the total supply, although substantial, does not provide the country with a dominant position in the cod trade.

### *2.1 The process allocation of the Icelandic cod catch*

The annual Icelandic groundfish catch has in recent years been about 600.000 tons. About 60 % of this has been cod, 8 % haddock, 10 % saithe and 13 % redfish. Table 1. shows the evolution of the total cod catch and its allocation to different processes.

According to the information contained in Table 1, the share of the freezing industry in the cod catch declined from about 60 % in 1972 to a record low of 34 % in 1982, but has recovered to 40-50 % in recent years. The emergence of freezer trawlers, that process and freeze the catch on board, may explain this increase. Quarterly figures reveal that, while the cod catch is greater in the first half of the year, the fraction of the catch that is allocated to the freezing industry is greater in the latter half of the year that the first. This is probably due to the economic importance of maintaining a reasonably steady operating rate in the freezing plants.

1. See OECD, Review of Fisheries.
2. See e g. FAO's Globefish databank, World Fisheries data Center, Memorial University, Newfoundland.
3. See OECD, Review of Fisheries.
4. For a more complete discussion on this see Johnston (1991).

The share of fresh cod in the total catch show a rather dramatic increase during the period from 1971. Until 1980 very negligible amounts of cod was exported fresh[5]. From 1980 exports of fresh cod have increased steadily to reach 15 % of the total cod catch in 1989.

Stockfish constitutes most of the other processes listed in Table 1. The Nigerian stockfish market was accessible for a period of five years from 1978 yielding high profit to the stockfish process and a dramatic increase in stockfish production. Since 1983 this market has been largely closed, and the stockfish process has contracted again.

Compared to the other processes, the share of the cod catch allocated to the saltfish process has been fairly steady during the period since 1971 with an average share of 39 %. Table 1., however, shows a sudden jump in this share to 47 % in 1982. This increase can be explained by the unforeseen closing of the Nigerian stockfish market at the time of strong cod catches. As stockfish and saltfish are relatively easily substitutable in production a good deal of the cod catch originally intended for the stockfish process was diverted to the saltfish process.

The information contained in Table 1 shows substantial variability in the allocation of the Icelandic cod catch to processes. A major objective of this study is to explain these fluctuations in terms of exogenous variables.

### *2.2 Export of Cod Products*

In 1990 the total value of seafood exports from Iceland was about 1.3 billion USD. Cod products constituted 42 % of this export.

The most important markets for Icelandic cod products are Great Britain (UK), Spain, Portugal and the United States (US). In 1990, UK accounted for 1/3 of the total value of cod exports from Iceland, the South-European countries, mostly Spain and Portugal accounted for 30 % and the remaining EC countries for 21 %[6]. It should be noted, in this context, that some of Iceland's cod exports to Britain are later re-exported to other EC countries. The US received about 16 % of the Icelandic cod exports in 1990.

As previously mentioned the US, UK, Spain and Portugal provide the most important markets for North-Atlantic cod. Broadly speaking, the US and the UK constitute the import markets for frozen cod products, Spain and Portugal for saltfish and the UK for fresh cod.

The UK and the US import approximately the same quantity of frozen Atlantic cod products ; about 100.000 MT annually. In fact, the consumption of frozen Atlantic cod products in these two markets amounts to some 80 % of the total world consumption. This quantity represents about 30 % of the total annual North-Atlantic cod catch. The market share of Icelandic cod producers has been about 20-25 % in both markets.

The model to be described below differentiates between the export of frozen cod fillets and blocks to the US and the UK. Table 2 shows the relative shares of these two markets in the Icelandic exports. over the last 10 years.

As shown in Table 2, the US market has accounted for about 60 % of the total export of frozen cod blocks and 57 % of frozen cod fillets over the last 10 years. Corresponding numbers for the UK market are 25 % and 39 % respectively. The importance of the US market has declined dramatically since 1981. At the beginning of the period the US market account for 62-70 % of the frozen cod exports. In 1990, the US market accounted for only 24-38 % of these exports.

The UK receives almost all the frozen fillets exported to the European market. The share of UK in cod block exports has declined slightly in recent years due to an increase in block exports to France.

## 3. THE MODEL : ESSENTIAL STRUCTURE

As explained above, Icelandic cod products constitute a significant fraction of the total supply in the respective markets. For this reason, the market prices of cod products are undoubtedly dependent on the total Icelandic supply, although individual fish processing firms may well be justified in regarding them as exogenous to their own supply. It follows that a reasonably complete model of the trade in Icelandic cod products must include both supply and demand relations.

5. These statistics ignore direct landings of cod from Icelandic fishing vessels abroad.
6. This and the following export statistics are obtained from the publications of the Icelandic Statistical Bureau.

### *3.1 Supply*

To model the supply of Icelandic cod products it is necessary to have a certain understanding of the structure of the fishing industry. The essentials of this structure are as follows :

The fishing industry is characterized by numerous relatively small firms exhibiting a high degree of vertical integration in the harvesting and processing sectors and a few large organizations in the marketing sector. There are no dominant firms in harvesting and processing. In fact, apart from the marketing sector, there is little horizontal integration in the fishing industry. The revenues of the largest firms is close to 4 % of total industry revenues. The marketing organizations, on the other hand, are large relative to the size of the industry. They are not independent firms, however. They are owned by the processing firms and exist only to serve the marketing needs of the processing sector.

The typical firm in the fishing industry is based in one fishing village or town. The firm operates one or more processing plants that are capable of producing one or more of the basic output categories ; frozen, saltfish and stockfish products. The firm also runs one or more fishing vessels that usually supply most of its wetfish[7] needs. Additional needs are met by purchasing fish from independent vessels usually on the basis of implicit or explicit long term contracts. In fact, in most smaller fishing towns, the fish processing firms customarily purchase whatever volume of fish supplied by local vessels. Finally, the products are marketed by the appropriate market organization to which the firm belongs.

The key players in the supply process, therefore, are the fish processors. In the short run the fish processors have little control over the quantity of catch they process[8]. This depends largely on fishing conditions and the number of fishing vessels operated by the processor and those with which they have made a long term catch purchase contract. Given the exogenous catch quantity, the fish processors must allocate this catch to processes. This they do on the basis of relative processing costs and the prices they expect the products to fetch on the export markets.

Given the processed products, the fish processors must make decisions concerning the supply of products to markets. This they presumably do on the basis of existing relative market prices, storage and transport costs. It should be noted, however, that in the allocation of products to markets the processors are constrained by the previous processing decisions. The reason is that not all cod products are suitable for all markets. In fact, most of the products are specialized for certain markets. Thus, for instance, once cod has been turned into certain salted products there is basically only one market, i.e., Portugal/Spain.

Thus, the fish processors essentially make two decisions. First, the allocation of cod catch to processes and second, the supply of products to markets. The essential structure of this supply process is further illustrated in the figure 1.

Assuming profit maximization the aggregate process allocation equations take the form :[9]

$$q(i) = Q(q, \mathbf{p}, \mathbf{w}, \mathbf{z}, u(i)), \text{ all } i, \tag{1}$$

where q(i) denotes the allocation of cod catch to process i and q represents the total cod catch,
**p** the vector of product prices,
**w** the vector of input costs,
**z** other relevant variables and
u(i) a stochastic disturbance term.

Similarly, the market supply equations are specified broadly as :[10]

$$s(i, j) = S(q(i), \mathbf{p}, \mathbf{w}, \mathbf{z}, u(i, j)), \text{ all } i \text{ and } j, \tag{2}$$

where s(i, j) denotes the supply of product i to market j,
q(i) is as before the allocation of cod catch to process i,

7. I.e. landed catch.
8. At least not during the period under study.
9. These process allocation functions are basically derived demand functions whose derivation is fairly standard in elementary micro-economic textbooks. See e.g. Varian (1984).
10. The derivation of these supply functions is also a standard exercise in micro-economic textbooks. See e.g. Varian (1984).

the vector **p** represents product market prices,
**w** costs
**z** other relevant variables and
u(i, j) a stochastic disturbance term. It should be noted that the vector **p** contains the product prices specified in expression (1) above.

Equations (1) and (2) are theoretical derivations. In the estimation procedure, the set of explanatory variables is severely constrained by data availability. In addition it turns out that many of the available explanatory variables are not in fact statistically significant. Therefore, the final estimated equations differ from the general form above and vary a good deal across markets and products.[11]

### *3.2 Demand*

In this paper, demand is modelled in a fairly simplistic way. Three market areas are considered Ê the UK market, the US market and the Portugal/Spain market Ê and four cod products Ê fresh, frozen fillets, frozen cod blocks and salted cod. Together these 3 markets account for well over 90 % of Iceland's cod exports of the respective products. Consequently, due to trading arbitrage, the prices in these markets seem plausible representatives for the available prices for the respective products.

The fundamental demand relation employed is as follows :[12]

$$p(i, j) = P(\mathbf{q}(j), \mathbf{y}(j), \mathbf{p}(j), \mathbf{z}(j), u(i, j)), \text{ all i and j} \quad (3)$$

where p(i,j) refers to the price of cod product i to market j.
The vector **q**(j) represents the quantity of cod products in market j,
**y**(j) is a vector of income variables in market j.
p(j) and **z**(j) are vectors of other relevant prices and variables in market j.
Finally u(i, j) is a stochastic disturbance term for product i in market j.

As in the case of the supply functions specified above, the inverse demand functions in (3) are theoretical constructs. Due to data constraints and statistical considerations, the estimated demand equations differ somewhat from equations (3).[13]

### *3.3 The Model as a Whole*

The complete model consists of 43 equations. Most of the equations are either definitions or technical or numerical identities. There are, however, 14 "behavioural" equations that have to be estimated with statistical methods. These equations correspond to equations (1)-(3) above, describing the allocation of catch to processes, the supply of products to markets and the adjustment of market prices to supply and other factors.

The model equations are listed in Appendix 1.

## 4. ESTIMATION

The model contains, as discussed above, 14 estimation equations. There are 2 estimation equations describing the allocation of cod catch to processes. Due to the summing-up constraint the third allocation equation does not have to be estimated. There are 5 equations describing the exports of cod products to markets. Again, summing-up constraints reduce the number of independent equations to be estimated. Finally, there are 7 price equations, one for each market and one basic cod price equation. These equations are listed in Appendix 1.

11. The estimated supply equations are given in the Appendix 2.
12. Derivation of this type of an inverse demand function from first principles can be found in most micro-economic textbooks. See e.g. Varian (1984).
13. The estimated price equations are given in the Appendix 2.

The estimation was based on quarterly time series observations on the relevant variables for the period 1981-1990. However, as the length of the available data series differed from one variable to another, the actual number of data points used in the estimation of individual equations ranges from 20 to 39.

The functional forms employed are mostly the linear and logarithmic[14]ones. These forms are, of course, not satisfactory from a theoretical point of view. One obvious reason is that some of the dependent variables are ratios that are supposed to be constrained to the interval [0,1]. This restriction, however, is not satisfied by the linear and logarithmic functional forms although, as it turned out, they fitted the available observations reasonably well. Further estimation work employing the multiple logistic or logit functional form[15] is currently underway.

The estimation methods are also, at this stage of the work, somewhat unsophisticated. The main estimation method is Ordinary Least Squares (OLS) and variants thereof. It is clear that for this task the OLS estimator does not coincide with the Maximum Likelihood one. Among other things, the OLS estimator ignores the fact that several of the estimation equations contain endogenous explanatory variables variables. Consequently, the resulting estimates are in general inconsistent. It may be noted, however, that estimation of the model using statistically more appropriate estimation techniques [16] did not materially affect the parameter estimates. It follows that the numerical results of the simulation experiments reported in the next section are not much affected by the use of a more sophisticated estimation technique.

The OLS estimation results and some relevant statistics are presented in Appendix 2. Note, however, that although the parameter estimates appear reasonably reliable the same does not necessary apply to the other statistics not least the t and Durbin-Watson statistics.

## 5. SIMULATIONS

The main objective of this work is to construct a model that can be used to predict the effects of exogenous changes on the pattern and evolution of the Icelandic cod trade. For this purpose, a special computer simulation model has been developed based on the cod trade model and the parameter estimates discussed in previous sections.

To illustrate its workings of this simulation model, the following 4 exogenous shifts are considered :

1 : 10 % increase in Icelandic cod catch.
2 : 10 % reduction in the exchange value of the USD.
3 : 5 % increase in Icelandic real wage rates.
4 : 5 % increase in real personal income in all cod market areas.

In all cases the exogenous shift occurs in period 1 and the respective exogenous variable remains at the new level henceforth.

### *5.1 Run 1 : The Icelandic catch increased 10 %*

In simulation 1, the Icelandic cod catch is assumed to increase by 10 %. The simulated effects of this shift calculated as deviations from the base case (where no such shift occurs) are given in the Table 3.

It is interesting to note that, according to this simulation, an increase in the cod catch reduces the share of the freezing industry in the cod processing but increases that of the other processes. The reason is due to a combination of comparatively more stringent capacity constraints in freezing and the price elasticity with respect to supply in the respective markets. Notice that the share of the freezing industry in cod processing is reduced less than the increase in catch. Hence the actual quantity processed is increased.

It is also interesting that the value of cod exports increase less than the increase in the catch. This, no doubt is due to the export price elasticity and the allocation of a larger share of the catch to lower priced products.

14. Sometimes also referred to as the log-log or Cobb-Douglas form.
15. See e.g. Theil (1969).
16. I e , 2SLS and 3SLS.

Finally, it should be noted that the adjustment dynamics of an increase in the cod catch are quite long, requiring over 5 years to reach an equilibrium.

### *5.2 Run 2 : US dollar exchange rate reduced by 10 %*

In this simulation the USD exchange rate drops by 10 %. The simulated effects of this change are listed in Table 4.

According to these simulations, a reduction in the exchange rate of the USD, not surprisingly, reduces the price in IKR for frozen products. Consequently, it shifts cod production away from frozen products and reduces the US share in the exports of frozen cod products. Notice, however, that there is also a change in the combination of export of frozen products to the US with frozen block actually increasing its relative share although not volume. This is probably due to a comparatively high price elasticity of frozen block demand relative to that of frozen fillets.

Notice also that although the US is a very important market for Icelandic cod products, substitution in production and exports markets largely eliminate effects of USD currency changes on the total value of cod exports.

### *5.3 Run 3 : Icelandic Wage rates increased by 5 %*

Let us now consider the effects of an increase in the real Icelandic wage rate of 5 %. This, obviously affects the production economics and, consequently, the pattern of cod production and trade. The simulation results are illustrated in Table 5.

The simulation results reported in Table 5 show that an increase in the Icelandic wage rate shifts the cod production mix away from the freezing and fresh/other processes to saltfish production. This is readily understandable as the saltfish process is the least labour intensive of the three. The saltfish price is reduced but, the prices of the other products does not rise. As expected there is no shift in the allocation of frozen products to the two main markets. Finally, the increase in the Icelandic wage rates leads to a small reduction in the total value of cod exports. This is due to the shift to saltfish and the consequent drop in its price.

### *5.4 Run 4 : Personal income in export markets increased by 5 %*

In this simulation the effects of a 5 % increase in personal income in the market areas is considered. This may affect the Icelandic cod trade via the income term in some of the demand functions. The simulation results are listed in Table 6.

The simulation results in Table 6 indicate a quite pronounced positive income elasticity of the Icelandic cod trade. As income in the cod markets rises there is a substantial increase in the price of frozen and saltfish products. Consequently a higher fraction of the cod catch is allocated to saltfish and, in particular, frozen products. There is also a substantial increase in the value of the cod exports. In fact, elasticity of the value of cod exports with respect to disposable income in the market areas exceeds unity.

## 6. CONCLUSIONS

The model described in this paper is in many respects inadequate. In particular, it is clear that there is a need for considerable improvements in the statistical part of the model. This applies not only to the parameter estimates discussed at some length above, but also to the stochastic properties of the simulation model. At the moment, the simulation model is entirely nonstochastic. However, the stochastic features of the data generating process revealed by the econometric estimation process could be used to add the appropriate stochasticity to the simulation model. In this way, simulations could include estimates of the probability distributions of the outcomes and the associated statistics.

As mentioned at the outset, the paper reports on work still in progress. The plan is to continue to improve the model *inter alia* along the lines suggested above. The progress made so far, however, appears to demonstrate the feasibility of constructing medium-scale fish trade models capable of seemingly reasonable predictions.

**FIG. 1.**
**ESSENTIAL MODEL STRUCTURE.**

# Appendix 1: Model equations

The following lists the equations of the model and defines the respective variables.

## I. Process allocations (ratios)

| | | | |
|---|---|---|---|
| Eq. 1 | R1=F1(CA,PSPF, WPF,S3,S4,D86) | Freezing | Estimated |
| Eq. 2 | R2=F2(PRPS,WPS,S1,S2,S3) | Salting | Estimated |
| Eq. 3 | R3=1-R1-R2 | Other processes | identity |

## II. Product quantity (volumes)

| | | | |
|---|---|---|---|
| Eq. 4 | QF=CA*R1*0.3227 | Frozen products | Technical identity |
| Eq. 5 | QFF=QF*0.692 | Frozen fillets | Technical identity |
| Eq. 6 | QFB=QF*0.308 | Frozen block | Technical identity |
| Eq. 7 | QS=CA*R2*0.384 | Saltfish | Technical identity |
| Eq. 8 | QO=CA*R3 | Other products | Technical identity |

## III. Supply of Products to markets (volumes and ratios)

### Frozen fillets

| | | | |
|---|---|---|---|
| Eq. 9 | QXFF=F3(QXFF(-1),(QFF),S1,S2,S3,S4) | Total exports of fillets | Estimated |
| Eq. 10 | R4=F4(R4(-1),PEPU(-1),TRC,CAT(-1),S2,S3) | Share exported to USA | Estimated |
| Eq. 11 | QXFFUS=QXFF*R4 | Volume exported to USA | Identity |
| Eq. 12 | QXFFUK=QXFF*(1-R4) | Volume exported to UK | Identity |

### Frozen block

| | | | |
|---|---|---|---|
| Eq. 13 | QXB=F5((QXB),QFF,S1,S2,S3,S4) | Total exports of block | Estimated |
| Eq. 14 | R5=F6(PBEPBU,TRC,S1) | Share exported to USA | Estimated |
| Eq. 15 | QXBUS=QXB*R4 | Volume exported to USA | Identity |
| Eq. 16 | QXBUK=QXB*(1-R4) | Volume exported to UK | Identity |

### Saltfish

| | | | |
|---|---|---|---|
| Eq. 17 | QXS=F7((QS),S1,S2,S3,S4) | Volume | Estimated |

### Other products

| | | | |
|---|---|---|---|
| Eq. 18 | QXO=QO | Volume | Technical identity |

## IV. Price equations

### Basic Cod Price

| | | | |
|---|---|---|---|
| Eq. 19 | LP=F8(LP(-1),CDT) | UK base cod price | Estimated |
| Eq. 20 | LPIS=LP*VGB*IKRGBP/VISL | UK cod price Icel. cur. | Identity |
| Eq. 21 | LPUS=LP*VGB*USUK/VUS | UK base cod price in USD | Identity |

### Saltfish

| | | | |
|---|---|---|---|
| Eq. 22 | PSS=F9(PSS(-1),LPIS,KPO,KESP,QXS(-1)) | Saltfish price | Estimated |
| Eq. 23 | PS=VISL*PSS | Saltfish in Icel. cur. | Identity |

### Fresh Cod

| | | | |
|---|---|---|---|
| Eq. 24 | PRUK=F10(LP.VGB,UHD) | UK fresh cod price | Estimated |
| Eq. 25 | PR=PRUK*VGBP*IKRGBP | UK fresh cod, Icel. cur. | Identity |

### Frozen fillets

| | | | |
|---|---|---|---|
| Eq. 26 | PFUS=F11(PFUS(-1),LPUS,WUS) | Price of cod fillets in USA | Estimated |
| Eq. 27 | PU=PFUS*VUSD*IKRUS | US fillet price in Icel. cur. | Identity |
| Eq. 28 | PFUK=F12(LP,LCT) | UK fillet price | Estimated |
| Eq. 29 | PE=PFUK*VGBT*IKRGBT | UK fillet price in Icel. cur. | |

### Frozen block

| | | | |
|---|---|---|---|
| Eq. 30 | PBUS=F13(PBUS(-1),LPUS,WUS,VUS) | Price of block in USA | Estimated |
| Eq. 31 | PBU=PBUS*VUS*IKRUS | US block price in Icel. cur. | Identity |
| Eq. 32 | PBUK=F14(PBUK(-1)LP,LCT) | UK block price | Estimated |
| Eq. 33 | PBE=PFUK*VGBT*IKRGBT | UK block price in Icel. cur. | Identity |

## V. Export of Cod Products (Values, Icel. currency)

| | | | |
|---|---|---|---|
| Eq. 34 | VXF= QXBUK*PBE+QXBU*PBU+QXFFUK*PU+QXFFU*PE | Frozen products | Identity |
| Eq. 35 | VQS=QXO*PS | Saltfish | Identity |
| Eq. 36 | VQR=QXO*PR | Othr cod products | |

## VI. Various Price Identities and Definitions

| | | | |
|---|---|---|---|
| Eq. 37 | PF=VXF/(QXBUK+QXBU+QXFFUK+QXFFU) | Average price of frozen cod | Identity |
| Eq. 38 | PSPF=PS/PF | saltfish/frozen price ratio | Identity |
| Eq. 39 | PSPF=PR/PS | fresh/saltfish price ratio | Identity |
| Eq. 40 | WPF=KAUPM/PF | real wage/frozen price ratio | Identity |
| Eq. 41 | WPF=KAUPM/PF | real wage/frozen price ratio | Identity |
| Eq. 42 | PEPU=PE/PU | UK/US fillet price ratio | Identity |
| Eq. 43 | PBEPBU=PBE/PBU | UK/US block price ratio | Identity |

Definition of variables

### I. Catch volumes

| | |
|---|---|
| CA | Total cod catch in Iceland |
| CAT | Catch by trawlers in Iceland |
| CDT | Total cod catch in Denmark, Iceland, Norway and UK |
| UHD | Haddock catch in UK. |

### II. Costs

| | |
|---|---|
| FLUK | Freight rates for frozen products from Iceland to UK. USD/MT |
| FLUS | Freight rates for frozen products from Iceland to UK. USD/MT |
| TRC | FLUS/FLUK Relative US/UK freight rates |
| KESP | Hourly real wage rate in Spain. |
| KPO | Hourly real wage rate in Portugal. |
| W | Hourly nominal wage rate in Iceland |
| WPF | W/PF |
| WPS | W/PS |
| WUS | Hourly nominal wage rate in USA. |
| LCT | Real private consumption in UK |
| KAUPM | Real disposible income in Iceland |

### III. Price Indices

| | |
|---|---|
| VGB | UK comsumer price index (CPI). |
| VUS | US consumer price index (CPI). |
| VISL | Icelandic consumer price index (CPI). |
| IKRGPB | Icelandic UK exchange rates; IKR for GBP. |
| IKRUSD | Icelandic US exchange rates: IKR for GBP |
| USUK | US UK exchange rates: USD for GBP |

### IV. Prices

| | |
|---|---|
| LP | UK basic real cod price. Defined as the total average cod price in UK deflated by the UK CPI. |
| LPIS | UK basic real cod price in Icelandic currency. |
| LPUS | UK basic real cod price in USD |
| PBE | Average price for Icelandic cod block exported to Europe; in IKR. |
| PBUK | Average real price for Icelandic block exported to Europe; in GBP. |
| PBU | Average price for Icelandic block exported to USA; in IKR |
| PBUS | Average real price for Icelandic block exported to USA; in IKR |
| PBEPBU | PBE/PBU |
| PE | Average export price for Icelandic frozen fillets to Europe, in IKR |
| PFUK | Average real export price for Icalandic frozen fillets to Europe in GBP |
| PU | Average price for Icelandic frozen fillets in USA in IKR. |
| PFUS | Average real price for Icelandic frozen fillets in USA in USD |
| PEPU | PE/PU |
| PF | Average export price for frozen cod products in IKR |
| PS | Average export price for salted cod in IKR |
| PSS | PS/CPI |
| PR | Average price for fresh cod in UK in IKR |
| PRUK | Average real price for fresh cod in UK in GBP. |
| PSPF | PS/PF |

| | |
|---|---|
| PRPS | PR/PS |

## V. Quantities and quantity ratios

| | |
|---|---|
| QF | Total production of frozen cod products in Iceland. |
| QFB | Total production of cod blocks in Iceland. |
| QXB | Total exports of cod blocks from Iceland |
| QXBUK | Total exports of cod blocks from Iceland to UK. |
| QXBUS | Total exports of cod blocks from Iceland to US. |
| QFF | Total production of frozen fillets in Iceland, |
| QXFF | Total exports of frozen fillets from Iceland |
| QXFFUK | Total exports of cod fillets from Iceland to UK. |
| QXFFUS | Total exports of cod fillets from Iceland to US. |
| QS | Total output of salted cod products in Iceland. |
| QXS | Total exports of salted cod from Iceland |
| QO | Total output of other cod products in Iceland. |
| QXO | Total exports of other cod products from Iceland. |
| R1 | Fraction of total cod catch in Iceland allocated to freezing |
| R2 | Fraction of total cod catch in Iceland allocated to the saltfish process. |
| R3 | Fraction of total cod catch in Iceland allocated to other processes. |
| R4 | Fraction of Icelandic fillet production exported to the USA. |
| R5 | Fraction of Icelandic block production exported to the USA. |

## VI. Export Values

| | |
|---|---|
| VXF | Total value of frozen cod exports. |
| VQS | Total value of saltfish exports. |
| VQO | Total value of other cod exports. |

## VII. Dummy variables

| | |
|---|---|
| S1-S4 | Quarterly dummies |
| DCQ86 | Dummy for the introduction of trawlers equipped to process frozen cod, 1 as of 1 quarter 1986 |

## Notation

| | |
|---|---|
| Z(-1) | Variable Z lagged one period. |
| {Z} | Distributed lags of variable Z. |

## Abbreviations

| | |
|---|---|
| GBP | British pound |
| IKR | Icelandic kronur |
| USD | US dollars |
| CPI | Consumer price index |

## APPENDIX 2: ESTIMATION RESULTS

The following lists the estimation results. 14 equations were estimated. Unless otherwise stated all equations are estimated in log-log form. Estimation method was OLS. Equation numbers correspond to those in the complete model defined in Appendix 1.

**Equation 1; Function F1: Allocation of cod to freezing**

LS // Dependent Variable is R1
SMPL range: 1982.1 - 1990.1
Number of observations: 33

| VARIABLE | COEFFICIENT | STD. ERROR | T-STAT. | 2-TAIL SIG. |

# An Approach to the Management of Market and Resource Uncertainties : The Globalisation of Trade Information

**Jean-François Mittaine** *

Fish Meal Exporters Organization, 67, boulevard Haussman, 75008 Paris, France

ABSTRACT

*The fish meal industry processes about 1/3 of total world fish catches to produce over 6 million Mt of fish meal, of which about 1/2 is marketed worldwide. Although fish meal, as a commodity, represents a very small part of the world protein feed disappearance (estimated at about 135 million Mt/year), it remains an important source of high quality proteins for certain categories of animals (pigs and poultry starters, cultivated fish and shrimps). The industry is constituted of a large number of companies of all sizes, the largest of which participate directly to the world trade flows, largely from Chile, Peru and Scandinavia.The industry is submitted to uncertainties on both sides of its activity : - the supply : the fish resources destined to processing fluctuate unexpectedly from one month to the other. Thus supply variations on the market are important ; - on the demand side, fish meal traditionally competes with the dominant protein sources such as the vegetal meals (particularly soybean meals) on the feed market which, in turn, is strongly linked to the evolution of the animal productions.*

*In order to ascertain a better valorization of their products, the producers/exporters of fish meal had, 30 years ago, the first idea to globalize their information network by creating the F.E.O. in 1960 (which was then a very new approach). For many years, the institution was the "meeting point" of the fish meal producers, and allowed them to exchange views as well as to meet and know each other. Quickly, the problem of how to manage the uncertainties of the market emerged as a central point. Among the various answers, a promotion programme was launched in Germany, then the largest net-exporters market, in association with the importers. Other answers were also found particularly through new products (special fish meals) and new logistical concepts (terminals). More recently, producers realized they also had to manage the supply side uncertainties (associated with the resources). They became more interested in sharing information on the evolution of fishing. It is now becoming a central problem.*

* Prepared in association with Mr J. Bololanik, Secretary general FEO Paris France.

*With a very pragmatic approach, the presentation shows how, an organization with limited resources, can contribute to the management of some market uncertainties through an information network and market analysis. A description of its working philosophy and methodology is included, as well as some results recently obtained.*

## 1. INTRODUCTION

It is an honor to participate to this Conference. The topic of this presentation may appear quite far away from many other preoccupations discussed in this Forum. As you will see later, the fishmeal manufacturers/exporters of the world, and particularly those who are members of our organization, are very much concerned by the general evolution of their "breadmaker" : the pelagic fish. But at the same time, they are faced with another world : the commodities trading environment, a global activity of prime importance to many countries (both importers and exporters) in which fishmeal is only a small part.

Consequently, the fishmeal exporters we represent must at the same time manage the uncertainties of their raw-material and face the great risks of the protein-for-feed market. This unique position has led to unique answers. This is what I invite you to review with me.

## 2. THE WORLD FISHMEAL PRODUCTION AND TRADE A BRIEF REVIEW OF ITS STRUCTURE AND ORGANIZATION

### *2.1 Catches and Production*

The 1991 world fish catches moving into the production of fishmeal are estimated at about 30.0 Million MT representing about 1/3 of the estimated world total catches. Fishmeal production is largely, though not solely, based on the "reduction" of 4 species of pelagic fish : Anchovies, Sardines, Horse Mackerel and Capelin. Traditionnally, fishmeal was marketed within the fishing countries (like for example Japan and Germany) as a feed ingredient for monogastric animals (essentially pigs). But fishmeal started entering massively the international trade when some producing countries largely exceeded the consumption capacity of their own domestic market. It is the case of Chile and Peru. At the same time, the development of the world pig and poultry productions led to a huge demand of proteins for feed use. The fishmeal trade benefited from both situations. After some ups and downs (sometimes spectacular like in the 70's) the trade stabilized to the present level of about 3.0 million MT which is a remarkably high share of the production (more than 50 %).

Nowadays, the main fishmeal producing countries include :

(i) countries who have had a traditional usage of fishmeal consumption in their own markets : Japan, the ex-USSR, the U.S.A., South Africa, and, until recently, China.

(ii) countries who have seen production exceed their domestic requirements : Chile, Peru and some Scandinavian countries (Denmark, Iceland and Norway).

The structure of the industry is extremely diversified depending upon the fishing and trading traditions of the countries involved. For example, in Iceland, about 40 fishmeal plants buy the raw material from about 200 independent fishermen on a day-to-day basis ; in the north of Chile about a dozen plants usually own the vessels ; in Peru, the fishermen are usually independent and deliver to the about 80 plants located in the vicinity of their port of call.

Also, in terms of sales, many plants export through local and/or international buyers/brokers on a FAS or FOB basis. They frequently rely on the market informations supplied by these clients. A notable exception lies with the terminals which some producers have organized at the port of unloading within some major consuming countries (particularly in Europe).

As the situation of the market is largely dependent upon the importance of the catches, any resource uncertainty in one production area will affect the entire fishmeal market. For example, the recent outbreak of the El-Niño phenomenon has led to much uncertainties on the resource availability in South America, the largest exporting area. Thus the knowledge of all these changes have become key factors in the commercial management of the individual plants.

### *2.2 The World Trade of Fishmeal*

Tonnagewise, fishmeal is one of the "small" commodity entering the world markets of protein for feed. However, it has the richest protein level (between 64 % and 72 % protein).
Until the late 80's, Europe was the largest outlet for the major fishmeal exporters (with about one half of total world trade). As a consequence, the Hamburg market has been the site of the only worlwide public fishmeal quotation. Germany and the U.K. continue to be the largest european importers followed by Holland, Italy and France. In fact, all those countries are known for their important livestock industries, particularly for pigs, poultry and even aquaculture in the U.K., Italy and France.
Nowadays, the fishmeal trade flows have changed dramatically away from Europe toward the major consuming markets of the Far-East, particularly China (which in 1991 took alone about 1/6th of all world exports), Japan (which became a net-importer 2 years ago) and Taiwan.
The fishmeal market is much more technically oriented than for other commodities. Its origin (type of fish, mode of production, country of origin,...) gives the fishmeal an identity, if not a trade mark, which reflects in the world trade patterns in relation to usage requirements.
Also, as fishmeal is mainly used as a protein complement, i.e. with relatively low incorporation rates, its technical specifications must both adapt closely to the end-users' needs and remain constant in quality. Freshness of the raw material, digestibility are some of the characterisitics frequently required by the end-user, aside from the more traditional specifications such as protein, ash, moisture. This tendency has led the producer to adapt to individual needs and manufacture either "Special Fishmeals" or fishmeals with guaranteed specifications (such as,for example, in amino-acids, vitamins, minerals,....) in order to allow them obtain the best valorization possible of their production.
All this shows how crucial, but also how difficult, market information is.

### *2.3 The Competing Commodities*

The competing protein meals constitute a market which can be divided into three categories :

- **the oilseedmeals** constitute the bulk of it in tonnage. Total world production in 1991 reached about 133 million MT of which 52 % was soyabeanmeal. The world trade of oilseedmeals represents about 45 million MT (only 34 % of production) of which 58 % is soyabeanmeal.
  These meals differenciate themselves from fishmeal in two respects :
  (i) their protein level is generally lower than fishmeal (soyabeanmeal protein is between 44 % and 48 %)
  (ii) as year crops, they are renewable productions obbeying to the classical yearly supply/demand laws.
- **Meatmeals**, the only other animal proteinmeals obeying are becoming an increasing market factor within the consuming countries as, with the help of improved technology, it is now possible to process all meat industry by-products into meals acceptable by the feed industry. In Europe alone, for example, meatmeal production represent more than 2.5 million MT.
  However, this market factor is limited to the countries with large animal production. It is not a worldwide traded commodity such as fishmeal.
- **Synthetic amino-acids** are chemicals, not commodities but compete significantly on the markets of supplement feed.

## 3. GLOBALIZATION OF TRADE INFORMATION

### *3.1 The importance of Market Information in the Fishmeal Trade from the Producer's Standpoint*

As shown earlier, fishmeal is deeply involved in the world of commodities : the major origins are very dispersed in various parts of the world ; consumption is also very diversified both geographically and by type of use. Whether we consider the common grade fishmeal or the special quality grades, the experience shows that, overall, these products respond to the basic supply/demand laws, with price as the main selecting factor.

The fishmeal operator has to manage two major uncertainties linked, on one hand, to the resource and, on the other hand, to the market while at the same time he has to generate a return on large investments at the plants level.

As a result, he requires a host of informations which usually come from three sources :

(i) the fishermen,

(ii) the trade,

(iii) the competitors.

Since, the fishmeal market is not organized or "transparent" as in the oilseed markets, it does not participate to the classical network of price quotations and other market information networks such as those located in Chicago or in other markets. This situation explains partly the use of a private network as the F.E.O.

### *3.2 The Creation of F.E.O. and its Original Mode of Operations*

32 years ago, a private initiative of the, then, largest fishmeal exporters initiated the idea of setting up an informal and private information pool.

The main purpose of this initiative was twofold :

(i) create the opportunity for all the producers/ exporters to benefit from a structure where they could meet twice a year and exchange views on both the production side and the market side.

(ii) progressively set up a statistical base allowing a permanent and objective evaluation of the fishmeal market, particularly in terms of Supply/Demand analysis.

This very original approach to market information, the only one existing in the commodity business, led to the constitution of a small private organization, registered under the French Association laws which serves as a commodity analysis department for about 25 fishmeal groups or individual companies in six countries of the world.

### *3.3 The Present Operations of F.E.O.*

With the advent of the fax, as well as the generally improved communication networks available at a modest cost, the organization has developped a professional reporting system which, through weekly and monthly reports, allows the members to keep permanently updated on the major market trends and to permanently evaluate their positions in face of other competing commodities.

This structure also allows each individual member to compare his own activity to the group of all the members. In this respect, the organization contributes to the market transparency allowing the members to permanently adjust to the changes of supply/demand.

At last, through its market comments, the structure supplies the members with a variety of selected and objective market informations.

Through contacts with the end-users and with the major trading entities, in association with a sister organization, the International Fishmeal Manufacturers Association, as well as with international organizations (like the F.A.O.), the Fishmeal Exporters Organization is at the center of an International Information Network geared to the needs of its members, the major fishmeal producers/exporters of the world.

One important point should be stressed : the organization is, in no way, a marketing tool for the members. F.E.O. is only managing market information and analysis ; each individual member handles the marketing activity on his own.

## 4. A NEW APPROACH : THE MANAGEMENT OF INFORMATIONS ASSOCIATED WITH THE RESSOURCES

### *4.1 Over the past 18 months*

the F.E.O. has progressively developped an interest in following and, eventually, participating into the analysis of informations associated with the evolution of the pelagic ressources.

This interest grew as the 1991/1992 El-Niño developped in South America. As early as December 1990, the members started to follow the early developments of the phenomenon in the western Pacific. Through various contacts among the scientific community it was possible to assess regularly its evolution across the Pacific Ocean, until it hit the South American coast. At the same time, it was possible to evaluate, through our members, the real impact on the availabilities of pelagic resources.

Although this permanent exchange of information was based on more qualitative than quantitative informations, it led to a permanent contact between the scientific community and the fishmeal exporters. In fact, it is the first time that the latter were able to follow the developments of this phenomenon nearly in real time.

*4.2 This interest on the permanent evaluation of stocks and fishing resources*

has not been limited to the development of El-Niño along the South American coast. For example, the recent developments of the capelin stock in the North Atlantic and in the Barentz sea and the associated relationship with fishing quotas and availabilities is regularly reviewed. Also, a permanent follow-up of the government decisions concerning the management of ressources, such as the establishment of fishing bans, the launching of stock surveys or the changes in the national fishing policies, are analyzed in terms of their impact on raw material availability and more generally on the supply-side of the markets.

All these informations are integrated into the analytical tool of the Organization which is constituted of :

(i) weekly fishing, production and sales reports

(ii) estimates of the overall physical stocks situation, on a quarterly basis

(iii) analysis of the price ratio between fishmeal and soyabeanmeal, the competing protein.

This analytical tool provide some production perspectives and is regularly used by the members to manage 1) the short-term uncertainties of the trading and 2) the medium term uncertainties of the production.

*4.3 Overall*

through a better knowledge of the basic dynamics of the fish stock, the organization keeps in touch with the most important events affecting fishing. Unlike the cash crops being traded in the world, which all can be analyzed on the basis of the effective crops, this approach to the supply-side of the fishmeal market has to be continuously updated, in as much as the fish stocks are only becoming market factors when the fish has been landed, i.e. only few days/weeks prior to effectively entering the world markets. This very short notice, combined with the extreme fishing variability from one week to the other, gives importance to all reliable informations helping the producers to manage supply uncertainties.

## 5. CONCLUSION

This brief review has shown how a major part of the fish resources relates to the mainstream commodity business. It also shows how a small organization supported by active members may be the center of a dynamic information network. In this respect, at F.E.O., we believe that still a lot of useful work can be done, particularly in the analysis of raw material availabilities because we are at the cross-roads of the effective worldwide fishing/production and of the realities of the protein-rich markets. We welcome any opportunities to maintain close contacts with all the professionals (scientists, fishermen, plant operators, governments, international organizations) interested by this entire sector. We believe that the establishment of such close links with various professional categories can help feed constructive views in such a dispersed environment.

# The Market Outlook for Shrimp

**Maw-Cheng Yang** *

International Trade Division World Bank 1818 H Street, NW, Washington, DC 20433, USA.

ABSTRACT

*Shrimp is the leading product in world fisheries trade, with world imports exceeding US$4.4 billion in 1988. About 90 % of world shrimp exports originate from developing countries. Industrial countries are the major consumers, accounting for about 90 % of world imports.*

*Cultured shrimp production has grown rapidly since the early 1980s (5.4 % of total production in 1980) to reach a 22 % share of total production in 1988. This rapid increase was in response to the substantial increase in real prices in the 1970s. Shrimp prices peaked in 1979 and have been declining since then in terms of real prices. With almost all cultured shrimp produced in the developing countries, further investment in this sector should be based on a market outlook analysis. The objective of this study was to build a world shrimp model to use as a framework for analyzing the long-term outlook.*

*Simulations with the model indicate that cultured shrimp production over the 1990s will expand at 13.6 % p.a. as compared to 25.4 % over the 1980-88 period. With sea-harvested shrimp production growing at only 2.6 % p.a., cultured shrimp production is projected to exceed sea-harvested shrimp by the year 2000. With total production of shrimp growing at 6.8 % p.a. over the 1990s, US shrimp prices in real terms decline by 4.6 % p.a. If cultured shrimp production increases at 10 % per year, real shrimp prices would decline by 14 % over this projection period. But, if cultured shrimp production expands at only 5 % per year, then real shrimp prices by the year 2000 are projected to be 23 % higher than the 1988 levels.*

## 1. INTRODUCTION

Shrimp is the leading product in world fisheries trade. In 1988 total world imports of shrimp exceeded US$4.4 billion, or 20 % of international fisheries trade. Approximately 75 % of world shrimp production is by the developing countries. Over 60 % of the world shrimp consumption is in the industrial countries. Thus, shrimp is mainly (about 90 %) exported by the developing countries and most imports go to the industrial countries.

* The views expressed in the paper are those of the author and should not be attributed to the World Bank, its Board of Directors, its management or any of its member countries.

The world shrimp market over the past decade was characterized by rapid expansion of cultured shrimp production and sustained growth in catches. Cultured shrimp accounted for less than 1 % of world shrimp supplies in 1970 but its share increased to 22 % in 1988. Annual growth in cultured shrimp production over the 1980-88 period was 25.4 %. Almost all cultured shrimp are produced in the developing countries -- in 1988 Asia accounted for 80 % and Latin America accounted for 17 %. The expansion of cultured shrimp production was encouraged by increasing real shrimp prices and progress in cultured technology. However, since the mid-1980s shrimp prices have been more or less constant in nominal terms and appear to have declined a little in real terms, even though landings have been stagnant since 1985. If the expansion in cultured shrimp production continues, the trend in real prices might be significantly reversed. An earlier Bank study[1] suggested that real prices of shrimp could decline by 6-10 % annually over the next few years should supplies increase at 5-7 % annually. This marked change in the market and in the market outlook point to the need for a comprehensive evaluation of the market outlook as a guide to investment in cultured shrimp production in the developing countries.

This paper reports on the construction of a world shrimp model suitable for making long-term price projections and for investment policy simulations. The organization of the paper is as follows. The world shrimp economy is described more fully in Section II, while the model constructed is specified in Section III. Empirical results and validation of the model are discussed in Section IV. Projections and sensitivity analysis are presented in Section V.

## 2. SALIENT FEATURES OF THE WORLD SHRIMP INDUSTRY

### *2.1 Supply*

World shrimp landings increased from one-half million tons in 1960 to about two million tons in 1988, representing an average growth rate of 5 % p.a. Encouraged by the increase in shrimp prices in the 1970s and the development of cultured shrimp technology, production of cultured shrimp grew rapidly in the 1980s. It increased from 90,000 tons in 1980 to 560,000 tons in 1988. Thus the share of cultured shrimp in world shrimp supply increased from less than 1 % in 1970 to over 22 % in 1988.

Almost all cultured shrimp are produced in developing countries in the Asian and Latin American regions. Cultured shrimp production in Asia accounts for more than 80 % of the world's cultured shrimp supply while production in Latin America accounts for about 17 %. China is the leading producer of cultured shrimp with production of 180,000 tons in 1988, followed by Indonesia, Ecuador, Philippines, Thailand and Taiwan, China.

Of total shrimp production, developing countries supply about 75 %. The leading suppliers are China (accounting for 19.4 % in 1987), India (9.2 %), Indonesia (7.7 %), Thailand (6.3 %) and Taiwan, China (5.4 %). The major industrial country suppliers are the United States (7.0 %), Greenland (2.7 %), Japan (2.0 %) and Norway (1.8 %).

The shrimp life cycle is less than a year. They are harvested or die from natural causes within this time. Because of this characteristic, the shrimp yield in one year does not affect the yield in the following year. The maximum possible yield for a given year is essentially all shrimp available for harvest, given current technology. However, some time an increase in yield can be achieved by better resource management, such as closed seasons and coastal pollution control.

### *2.2 Consumption*

World consumption of shrimp increased from 677 million pounds (head-off weight) in 1960 to 3,491 million pounds in 1988. Shrimp is a relatively highly priced product. Therefore, it is usually consumed by high income earners. The United States is the largest shrimp consuming country, accounting for 729 million pounds in 1988 (21 % of world consumption). The second largest consumer is Japan, taking 654 million pounds (19 %) in 1988. Consumption growth in Japan has been much faster than in the United States, 6.6 % as compared with 3.5 %. Growth in per capita consumption in Japan has also been much faster than in the United States. In 1988 per capita consumption in Japan was estimated at 5.3 pounds as compared with 3.0 pounds in the United States.

1. World Bank, *Asia-Wide Shrimp Agro-Industry Sector Study*, September 1989.

The other major shrimp consuming region is Western Europe. Accurate estimates of total consumption in Western Europe are not available. However, it is estimated that Western Europe has accounted for approximately 12 % of total consumption in recent years.

Another, approximately 40 % of shrimp are consumed in producing countries, mainly in developing countries. Most are consumed by the high income groups in these countries.

### *2.3 Trade*

The world shrimp trade flows primarily from developing countries to industrial countries. The developing countries are best endowed with natural resources for marine shrimp as well as for cultured shrimp. World exports of fresh, chilled and frozen shrimp (the principal product in world trade) increased from 322,000 tons in 1977 to 666,000 tons in 1986, at an average growth rate of 8.4 % p.a. In terms of value, they increased from $1,353 million to $4,241 million. The major exporting countries are China, India, Indonesia, Thailand, Ecuador, Mexico, Denmark, and Taiwan, China.

World imports are dominated by Japan and the United States, though their share has been declining (from 81 % in 1977 to 71 % in 1986 in terms of value). The other major importing region is Western Europe.

For many years the increased demand for shrimp in Japan, the United States and Western Europe has been satisfied by imports. Domestic landings in Japan have been relatively stable at around 60,000 tons since 1970. During this time, net imports have increased from 90,000 tons to 422,000 tons so that the share of imports in total Japanese consumption has increased from 61 % to 91 %. Japanese imports are mostly sourced from Indonesia, Thailand, India, China, the Philippines, and Vietnam. In the United States domestic landings provided over one-half of total consumption until 1979. Since then, imports have accounted for an increasing share. Currently, imports account for over 70 % of US consumption. Net imports of shrimp increased from 137,000 tons in 1970 to 412,000 tons in 1988. Imports are mainly shipped from Ecuador, Thailand, China, India, Mexico, and Indonesia. Consumption in Western Europe has been mainly of cold water shrimp caught in the North Atlantic Ocean. However, consumption of tropical shrimp has been increasing rapidly in recent years due to shortfalls and higher prices of cold water shrimp. In recent years approximately one-half of shrimp consumption in Western Europe is cold water shrimp. The main sources of imports of cold water shrimp are Greenland, Faeroe Islands, and Argentina and of tropical shrimp are Thailand, India, Bangladesh, Senegal, and Cuba. Approximately two-thirds of shrimp consumption in the EC is supplied by imports.

### *2.4 Prices*

Shrimp prices in current dollar terms in the US market had a rapid upward trend through the 1970s until 1979. Since then the trend has been constant. In real terms (deflated by US wholesale price index) it is somewhat more obvious that there has been a decline in US prices since 1979. This appears to be because demand outstripped supply before 1979 after that supply increased substantially due to the increase in aquaculture production. Some studies (Doll, 1971, Adams, Prochaska and Spreen, 1987) have indicated that ex-vessel prices, wholesale prices, and retail prices have moved closely in the same direction and that they have been determined simultaneously in the US market. Shrimp prices in Japan, in terms of US dollars, are generally lower than in the United States except for the last few years due to the devaluation of the dollar. However, prices in the two markets have moved closely on a directional basis.

## 3. THE ECONOMETRIC MODEL

### *3.1 Demand function*

Demand for shrimp is hypothesized to be determined by income, shrimp prices, prices of substitutes, and habit. The demand function can be postulated as follows :

$$Q_i^a = f(P_i, P_{i'}^s, Y_r, Q_i^a(t\text{-}1))$$

where,

$Q_i^a$ = per capita consumption of shrimp for country i
$P_i$ = shrimp prices for country i
$P_i^s$ = prices of substitute for country i
$Y_i$ = per capita disposable income in constant $ for country i
$Q_i^a(t\text{-}1)$ = $Q_i^a$ lagged one year, a variable representing habit persistence

Per capita consumption should be negatively related to its own price and positively related to prices of substitutes and disposable income. The consumption level of the previous year is used to represent habit persistence. It should be positively related to current consumption. Total consumption of a country is the product of per capita consumption and population ($POP_i$) :

$$Q_i = Q_i^a * POP_i$$

The world demand (Q) is the summation of demand in all countries :

$$Q = \sum_{i=1}^{n} Q_i$$

*3.2 Supply Function*

There are two sources of supply of shrimp : one is marine catches, the other is aquaculture. The two sources are modeled separately. Because of the short life cycle (less than a year) of shrimp, the shrimp yield in one year does not affect the population of the next year. Therefore, production of shrimp is determined by the costs of production (for sea catches largely fuel costs, for aquaculture largely feeding costs), current and expected prices, and other factors such as technology, pollution, and rainfall. Shrimp production equations are specified as follows :

SHL = f(SHL(-1), P, P(-1), C, T)
SHCU = f(SHCU(-1), P(-1), C)

where,

SHL = shrimp landings
SHCU = cultured shrimp harvest
P = shrimp price
C = cost of production
T = time trend
(-1) = variables lagged one year

Total supply of shrimp is the sum of landings and cultured production, i.e.,

S = SHL + SHCU

In equilibrium, total demand equals total supply, i.e.,

Q = S

*3.3 Price Linkage Equation*

The average price of the two major markets, the United States and Japan is created to represent the world price. The world price, which equates world demand with world supply, is solved with the model. Prices in the United States and Japan are linked through a regression equation :

SHP$JAP = f(SHPUS)

where,

SHP$JAP = Japanese shrimp prices in US dollars
SHPUS = US shrimp prices.

## 4. EMPIRICAL RESULTS

### *4.1 Estimated Equations*

The model is comprised of three demand equations for the United States, Japan, and the rest of the world ; two supply equations, one for landings and one for cultured production ; and a price linkage equation.

The demand equation estimated for the United States is as follows :

$$\underset{}{LN(SHCAUS) = -8.297} + \underset{(-6.7)}{0.988} * \underset{(4.4)}{LN(PCEUS)} \underset{(-4.7)}{-0.380} * LN(SHPDUS) + \underset{(3.2)}{0.531} * LN(OFWPIDUS)$$

$R^2 = 0.92$ DW = 1.2 period = 1962-1988

where,

SHCAUS = per capita consumption of shrimp in the United States
PCEUS = US private consumption expenditure per capita in constant dollars
SHPDUS = US wholesale price of shrimp deflated by the US wholesale price index
OFWPIDUS = US wholesale price index of other fish deflated by the US wholesale price index

The lagged dependent variable SHCAUS(-1) was dropped from the equation because its coefficient was not significant and it did not affect the $R^2$. All coefficients in the equation are significant with the sign as expected. The equation implies an income elasticity of 0.99, an own price elasticity of -0.38, and a cross-price elasticity of 0.53.

The demand equation estimated for Japan is as follows :

$$\underset{}{LN(SHCAJAP) = -14.903} + \underset{(20.6)}{1.246} * \underset{(-24.0)}{LN(PCEJAP)} \underset{(-4.3)}{-0.360} * LN(SHPDJAP) + \underset{(3.3)}{0.347} * LN(BFPDJAP)$$

$R^2 = 0.98$ DW = 1.37 Period = 1965-1988

where,

SHCAJAP = per capita consumption of shrimp in Japan
PCEJAP = Japanese private consumption expenditure per capita in constant prices
SHPDJAP = Japanese shrimp wholesale prices deflated by the Japanese wholesale price index
BFPDJAP = Japanese beef wholesale prices deflated by the Japanese wholesale price index

All coefficients in the equation are significant with the expected sign. The lagged dependent variable SHCAJAP(-1) is not included in the reported equation because its coefficient was not significant and it did not contribute to the $R^2$. The equation implies that the income elasticity for Japan is 1.25, higher than that for the United States. The own-price elasticity is -0.36. Beef is a substitute for shrimp with a cross-price elasticity of 0.35.

The demand equation estimated for the rest of the world is as follows :

$$\underset{}{LN(SHCARW) = 11.909} + \underset{(2.8)}{0.451} * \underset{(-3.3)}{LN(SHCARW(-1))} + \underset{(3.3)}{1.528} * LN(GNPRW)$$

$R^2 = 0.97$ DW = 2.0 Period = 1965-88

where,

SHCARW = per capita consumption in the rest of the world
GNPRW = GNP per capita in constant dollars in market economies in the rest of the world

The coefficients of the lagged consumption and income variables have the expected signs and are significant. The equation implies income elasticity of 1.5. The price variable was dropped from the equation because it did not have the expected sign and was insignificant.

The estimated equation for shrimp landings is as follows :

$$\begin{aligned} LN(SHLW) = {} & 1.695 + 0.510 * LN(SHLW(-1)) + 0.094 * LN(SHPDW) + 0.209 * LN(SHPDW(-1)) \\ & (1.8) \quad (3.0) \qquad\qquad (1.2) \qquad\qquad (2.2) \\ & -0.012 * RINR + 0.017 * T \\ & (-1.8) \qquad\quad (2.1) \end{aligned}$$

$R^2 = 0.98$ DW = 2.3 Period = 1966-1988

where

SHLW = world shrimp landings
SHPDW = world shrimp prices deflated by the World Bank's manufactured unit value of exports (MUV)
SHPDW(-1) = lagged shrimp prices deflated by the MUV
RINR = real interest rate
T = time trend

All coefficients in the equation have the expected signs and are significant, except for the current price variable. Although fuel costs accounts for a large part of shrimping costs, the coefficient of the fuel variable did not have the expected sign, and was dropped from the equation. The results imply a short-term price elasticity of 0.09 and a long-term price elasticity of 0.62.

The cultured shrimp production equation estimated is as follows :

$$\begin{aligned} LN(SHCUW) = {} & -0.008 + 0.973 * LN(SHCUW(-1)) + 0.313 * LN(SHPDW(-1)) \; -0.034 * (RINR) \\ & (-0.01) \quad (40.6) \qquad\qquad (1.6) \qquad\qquad (-3.6) \\ & - 0.239 * LN(FMEALPD) \\ & (-2.7) \end{aligned}$$

$R^2 = 0.997$ DW = 1.8 Period = 1966-1988

where,

SHCUW = world cultured shrimp production
SHPDW = world (averaged US and Japanese) shrimp prices deflated by the MUV
RINR = real interest rate
FMEALPD = international fishmeal prices deflated by the MUV

The real interest rate is used to measure the opportunity cost of investment in shrimp production. With feed the major part of operating costs, fishmeal prices are used as the indicator price. All coefficients are significant with the expected signs. The results imply a short-term elasticity of 0.31 and a long-term elasticity of 11.5.

The price linkage equation for US and Japanese prices is estimated as follows :

$$\begin{aligned} LN(SHP\$JAP) = {} & 0.116 + 0.966 * LN(SHPUS) \\ & (0.7) \quad (34.0) \end{aligned}$$

$R^2 = 0.98$ DW = 1.7 Period = 1965-88

where

SHP$JAP = Japanese shrimp prices in US dollars
SHPUS = US shrimp prices

The equation indicates that both prices move closely together.

### *4.2 Performance of the Model*

In order to validate the specification of the equations as well as the overall performance of the model an ex-post simulation was run dynamically for the period 1965-1988. The simulated observations were compared with the actual

observations to derive statistics for evaluating the performance of each variable. The summary statistics from the simulation are shown in Table 1. As seen there the root mean square percentage error ranges from 3 % to 10 % for all endogenous variables except for US prices and cultured shrimp production. The Theil inequality coefficients are close to zero, indicating that the simulation values are close to actual values. The mean-square error is decomposed into the bias and regression proportions, that the values for these statistics are close to zero is an indication that there are no systematic errors. Also most of the residual proportions of the model are close to one, indicative of the good performance of the model.

## 5. PROJECTIONS AND SENSITIVITY ANALYSIS

### *5.1 Projections*

Projections of exogenous variables - including population, GNP growth for the United States and Japan, price deflators, exchange rates, interest rates, and fishmeal and beef prices - were taken from World Bank files. GNP growth for the rest of the world was taken from WEFA projections. Trend values were used for fish wholesale price projections in the United States. World population was estimated at 5.1 billion in 1988 and is expected to increase to about 6.2 billion by the year 2000, representing an average annual growth rate of 1.6 %. During the same period, population growth is projected to be 0.8 % p.a. for the United States, 0.4 % p.a. for Japan, and 1.6 % p.a. for the rest of the world. Real GNP growth is projected to be 2.3 % p.a. for the United States, 4.0 % p.a. for Japan, and 3.2 % p.a. for the rest of the world. The MUV index is projected to increase at 3.5 % p.a. during the 1990-2000 period.

World production of shrimp is projected to increase from 2.98 billion lb. (head-off weight) in 1988 to 6.58 billion lb. in the year 2000, an average growth of 6.8 % p.a. This rapid growth can be mainly attributed to the rapid growth in cultured shrimp production, projected to grow at 13.6 % p.a. Production from landings is projected to increase at 2.6 % p.a. On the basis of these projections cultured shrimp production will surpass landings toward the end of the century. Details of the projections are shown in Table 2.

Real prices of shrimp are expected to decline substantially during the 1990's as a result of the faster growth in production due to the fast growth of cultured shrimp production. The model forecasts a decline of 4.6 % p.a. in the US market and 5.0 % p.a. in the Japanese market. Without the fall in prices, world consumption would have grown at 4.8 % annually during the projection period, as compared to the projected 6.8 % p.a. growth.

### *5.2 Sensitivity Analysis*

The cultured shrimp production variable can be used as a policy variable to look at the effects of various rates of growth in cultured shrimp production on prices. The model has been simulated with two rates of increase in cultured shrimp production -- 5 % p.a., and 10 % p.a. The simulated results are presented in Tables 3 and 4. The results from the simulation indicate that if cultured shrimp production increases by only 5 % per year then real shrimp price in 2000 would be 23 % higher than the 1988 level. If cultured shrimp production increases by 10 % per year the real shrimp price in 2000 would be 14 % lower than in 1988.

# Changes in Poland's Foreign Trade Management and Impacts on the Foreign Trade of Fishery Products

**Halina Nakonieczna-Kiesiel[a] and Jolanta Zieziula[b]**

[a]Cathedral of Foreign Trade and International Economic Relations, University of Szczecin, ul Mickiewicza 64, 71-101 Szczecin, Poland

[b]Academy of Agriculture, ul Janosika 8, 70–965 Szczecin, Poland

ABSTRACT

*Since the end of the 1980s, the Polish economy has been changing towards a market-oriented system. Essential institutional changes have been undertaken by the Polish authorities in order to start to create a new basis for the economy - private ownership. The first step in that direction is the demonopolisation of state-owned enterprises.*

*The paper is organised into two main parts. First all newly-established regulations concerning Poland's foreign trade are presented, namely regulations on demonopolisation, tariff barriers and exchange rates.*

*Secondly the impact of the undertaken measures on Poland's fishery economy, especially on foreign trade, is presented. Finally, some conclusions are drawn.*

## 1. INTRODUCTION

Since the very end of 1989 Poland's centrally planned and managed economy started to transform to become market-oriented, based on principles of competition and private capital ownership. Transformation processes have been accompanied by structural and economic changes.

Poland's foreign trade is essentially affected by most of structural and economy changes. And it is obvious, that transformation processes can not be successfully carried off without a wide opening of economy for cooperation with foreign countries [1].

1. See : Polityka ekonomiczna i handlowa Polski w 1990 r. /Poland's Economic and Trade Policies in 1990/, Warszawa 1991, p.32 and the next ones.

## 2. NEW REGULATIONS CONCERNING POLAND'S FOREIGN TRADE

### *2.1 Demonopolization*

In fact, in 1989 a monopolistic position of state-owned enterprises in Poland's foreign trade was abolished. According to newly created regulations, all existing and new firms could deal with export-import transactions without the necessity to apply for a special concession, as it was before [2]. Regulations on demonopolization in the foreign trade sphere, together with previously imposed regulations on foreign investments in Poland, set up conditions of competition between firms involved in foreign trade transactions of any kind [3].

Additionally, all export and import quotas were gradually diminished. Fewer and fewer goods were on a list of products, permanently or temporarily restricted in Poland's foreign trade [4]. Generally, apart from some exceptions, any restrictions /such as import quotas/ in Poland's imports do not exist. However, there are some constraints in exports of strategically important goods or trade on intergovernmental agreements of Poland.

### *2.2 Exchange rate*

A substancial change of governmental currency exchange rate policy was the next step of transforming Poland's economy, especially the foreign trade management sphere. A principle of submarginal currency exchange rate policy accompanied with very ineffective mechanism of direct and indirect subsidies were replaced by policy of real exchange rate [5]. Initially, Poland's currency exchange rate was based on US dollar. On January 1st, 1990 the rate was worked out at 9,500 zl/1 USD. However, changing conditions of economic activities and fast growing rate of inflation in the country, made it necessary to get currency exchange rate into line. It was changed twice : in May 1991 for 11,000 zl/1 USD and in February 1992 for 13,400 zl/1 USD. Additionally, basis of currency exchange rate determination was changed. Since September 1991 the exchange rate of Poland's zloty has been based on five western currencies. It was also decided not to keep zloty at a stable level but let it gradually depreciate, according to rate of inflation, even week by week.

The real exchange rate of our currency made it possible to introduce internal exchangeability of Poland's zloty. It was the next step towards opening economy for cooperation with other countries.

Since 1991, all firms have been obliged to change all their foreing sales incomes in banks for zloties at a given rate of exchange. However, firms have been allowed to purchase foreign currencies, needed for realization of their imports, without any constraints. The new governmental policy on currency exchange rates have been accompanied by substancially restricted monetary and budget policies. Both moves limit financial flexibility of firms. According to a new requirement, firms are obliged to keep a deposit of 10 % of purchased foreign currency value in banks. This fact strengthens the tendency mentioned above.

Internal exchangeability of Poland's zloty was accompanied by a new-fixed exchange rate between US dollar and zloty, compared to transfer Rouble and zloty /it changed from 2,2 in 1988/1989 to over 4,5 in 1990/. However, it did not encourage Poland's firms to expand their exports to Western countries, instead of the Soviet Union block countries. Only, a new system of trade introduced in January 1991, first of all transaction settlements with former socialist countries - according to world prices and in exchangeable currencies - hold up firm's tendency to export mainly to former socialist countries [6].

### *2.3 Tariff barriers*

New customs regulations have been the next systemic change playing an important role in opening Poland's economy for cooperation with Western countries. Their characteristic feature was that unequal treatments of people and enterprises

4. Dziennik Ustaw No 19/90 pos. 114, No 47/90 pos. 282, No 61/90 pos. 385, No 140/90 pos. 280 and No 1/92 pos. 2.
5. Wider discussion on the problem see : U.Plowiec, Proeksportowa restrukturyzacja polskiej gospodarki /Export-oriented Restructurization of Poland's Economy/, Handel Zagraniczny /Foreign Trade/ No 1-2- 3/1991.
6. See : M. Oniszczuk, Handel Polska-ZSRR, Refleksje po czarnym polroczu /Trade Poland-USSR, Remarks after Black Half Year/, Rynki Zagraniczne /Foreign Markets/ No 85/1991.

were eliminated. Before, all state-owned enterprises were given privileges, such as tariff reductions. Apart from that, foreign trade transactions differentiated previously for trade ones and non-trade ones, become just transactions. People cannot import goods on their touristic trips without paying duties, any longer.

Construction of tariff duties has been changed. Only imported goods have been charged, according to new customs regulations, when before there were duties also on some exported goods. There is no preferential treatment of any country. Customs tariffs, introduced since August 1991, have been based on EEC customs tariff nomenclature [7]. They contain wide and more accurate lists of goods, subjects of tariff duties. According to EEC customs tariff names, foreign trade agreements as well as international comparisons are much easier.

However, successive modifications of Poland's customs tariffs since 1989 resulted in an increase of average tariff duties on imported goods. While in 1990 they consisted of less than 4 % of imported goods value and they were among the lowest ones in Europe, the new tariff construction caused an increase of average tariff duties up to 14 % of imported products value [8].

Another constraint in Poland's imports - playing a role against development of competition between firms - has been an increasing rate of import surcharge /so called border tax/. Since August 1990 it was fixed at 20 % of imported goods value and in the second half of the year at 15 % [9].

In the second part of the paper - considering all systemic changes of Poland's foreign trade management - their impact on foreign trade of fishery products is analysed.

## 3. IMPACT ON POLAND'S FISHERY ECONOMY

To open Poland's economy for cooperation with other countries, for fishery economy sphere meant abolishing foreign trade monopoly of "Rybex" - the state-owned company. Everybody could deal with export-import transactions, on condition to register the activity and to pay taxes.

At the begining, export activities started mainly private fishermen. They sold parts of their catches, mainly cod in Denmark /Bornholm Island/. Almost at the same time, private firms competing with the state-owned processing enterprises have appeared. They buy Baltic Sea fish and fresh-water fish in order to process them and to sell in Poland and/or abroad.

One of expanding private firms dealing with fish processing, exports and imports is Morawiak Corporation. It has developed since 1986 when it was small artisanal fish smoking firm. At present, Morawiak Corporation could afford to buy 81 % shares of a privatised state-owned processing firm /Centrala Rybna/ in Szczecin. They have expanded many trade contacts all over the country as well as abroad.

Other enterprises, for a long time involved in fishery activities of any kind, such as "Certa" in Szczecin, "Szkuner" in Wladyslawowo, as well as "Centrala Rybna" in Gdynia, even before 1990 - when only new state regulations on foreign capital investments in Poland came into power - then set up join ventures with foreign partners. According to mutual agreements, Polish partners most often provide raw materials for processing, location and labour. Foreign partnersusually give processing technologies and equipment as well as modern organization of work. In Poland, until 30.09.1989, the biggest joint venture company, with foreign capital share was "Schooner" Co Ltd., turned from "Szkuner" with one of US companies as a shareholder [10].

As a matter of fact, according to systemic solutions, all firms may deal with foreign trade of fish products, but all state-owned distant-water fishing firms - as it was before 1990 - still export their products by "Rybex". However, since

7. See : M.Nogaj, Przepisy prawne regulujace obrot towarowy z zagranica /Legal Regulations on Foreign Trade Markets/, Rynki Zagraniczne /Foreign Markets/ No 11/1990.

10. See · T.Malecka, Przedsiebiorstwa zagraniczne w Polsce /Foreign Companies in Poland/, Handel Zagraniczny /Foreign Trade/, No 12/1989 p. 7.

the second half of nineteen-eighties, a role of "Rybex" has changed, because distant-water fishing enterprises make export-import deals with foreign partners by themselves. They are known as "off board" transactions. Only formal documents are sent to "Rybex".

Shareholders of "Rybex" Co Ltd. /now undergoing privatization process/ are the state-owned distant-water fishing companies. They continue to keep formal monopoly of 'Rybex", because of their previous declarations and then obligations to maintain an integration of Poland's fishery economy as a whole. However, all changes in Poland's economy made "Rybex" to diminish its share in foreign trade of fish products - in 1991 to about 40 % [11].

According to data given in table 1, in the latest two years there was strong decreasing tendency in Poland's foreign trade of fish products. In fact, presented figures give only available information - the "Rybex" data, which makes the picture darker than it really is. Undoubtedly, in 1991 exports of fish products were much lower than they were in 1989. The similar tendency could be observed in imports. In the analized period, exports considerably exceeded imports.

A decrease of fish products exports /among them "off-board exports" were caused by growing difficulties in getting an access to world fish resources. Gradually diminishing opportunities of distant-water fishing [12] caused Poland's fishing fleet to be underutilized. As a result, some old fishing vessels were scrapped and some other have been sold abroad [13].

Fewer and fewer opportunities to fish brought not only problems of fishing vessels utilizations, but also some other problems. Profitability of fishery enterprises worsened and hence existing level of employment was found to be excessive. Deficit of fish raw material caused underutilization of processing equipment in many firms. Additionally, rigorous state monetary policy and high rate of interest on credits made it necessary reorganize or liquidate most of state-owned fishery enterprises [14].

As mentioned before, diminishing opportunity to fish negatively influenced exports. Exports of fish products only exist because fewer products are delivered on the domestic market. Higher prices of fish products abroad than in Poland are main stimula of exports.

Import liberalization, mainly very low tariff duties in 1989 did not result in an increase of fish imports. According to the figures in table 1 imports have been decreasing. In 1990 and in 1991 they were much lower than in 1989. There were some reasons of that. Higher prices abroad than in the country were one of them. The second one has been a deep recession, partly a result of an antiinflationary governmental policy and growing level of unemployment made domestic demand on fishery products to collapse, like it is for many other products.

Prior to Poland's association with EEC countries, since 1.08.1991, a new one column customs tariff on fish products - bringing it into line with EEC import regulations - has come into power [15]. According to the tariff, duties on imported fish products have been fixed at between 5 % and 55 % of their customs value.

However, fears of excessively rising costs of imports and decreasing quantities of imports caused that until 1.03.1992 customs duties were lowered for many fish products [16]. Mostly, they did not exceed 5 % or 10 % of products customs value. The highest duty rate was established at 25 %. Undoubtedly, increasing customs duty rates for fish products strengthened diminishing tendency in their imports to Poland.

Apart from the mentioned reasons, decreasing Poland's imports were caused by almost entirely stopped imports of canned fish from former USSR. It was strictly connected with expiries of inter-governmental economic agreements between both countries, as well as changing settlements of trade transactions, from transfer Roubles /clearing accounts in fact/ to convertible currencies.

15. See : Taryfa celna importowa /Customs Duty Tariff on Imported Goods/, Zalacznik do Dziennika Ustaw Rzeczpospolitej No 67 pos. 288 z 30.07.1991, Dzialy : 3, 11 i 16. On EEC Custom Duty Tariff construction see : J.Zieziula, Narzedzia polityki handlowej panstw jako bariery w swiatowym imporcie produktów rybnych /Trade Policy Measures of Governments as Barriers of World Fish Products Imports, Zeszyty Naukowe Akademii Rolniczej w Szczecinie /Scientific Papers of Szczecin Academy of Agriculture/ No 136/1989, p. 19-39.
16. That was until signing an agreement on trade and economic cooperation between Poland and EEC. The agreement is presented in Rynki Zagraniczne /Foreign Markets/ No 7/1992, p. 3 and 4.

Additionally, since 1988 Poland's fish imports "off board" have diminished [17] It has been caused by fewer and fewer fishing opportunities of Polish distant-water fleet. It means : smaller catches, less "off board" export and less "off board" import.

In analysed period, there existed surpluses in Poland's fish products foreign trade balance. Main reason of that was the existing high demand for fish products abroad as well as profitability of exports. The latest could be achieved because of : higher prices for fish products abroad than in Poland, especially for fillets and headed and gutted white fish /both were main items in exports/, relatively low costs of fish processing in Poland and Polish zloty devaluation.

However, a high rate of inflation in Poland without accompanying it officially changed Zloty rate of exchange until May 1991, lowered profitability of foreign trade. It made export transactions less profitable in 1991 than they were in 1990..

## 4. CONCLUSION

i) Poland's foreign trade of fish products was affected both by internal and external factors. Among them long-term cosequences of loosing access to the most valuable fishing grounds and substancially diminishing catches were of great importance. Less and less fish had to cause decreasing exports.

ii) Factors playing against above tendency were - for some time - exchange rate between zloty and US dollar, encouraging exports, as well as higher prices of fish products abroad than in Poland.

iii) Demonopolization of Poland's foreign trade enhanced mainly small and new established firms to export. However, an influence of systemic changes on exports were of less importance. Nevertheless conditions for competition among firms, some transformation processes and improvement of effectiveness in fishery economy sector have been started.

iv) Decreasing tendency of fish products imports was a result of deepening economic recession in Poland and rising level of import duties. Indirectly, diminishing distant-water catches strengthened the tendency.

ABSTRACT

*(i) Some figures*

*French Trade in Fish Products in 1991*

| *billions FRF* | | *Change 91/90* |
|---|---|---|
| *Imports* | *16.3* | *+ 7.6 %* |
| *Exports* | *5.2* | *+ 2.8 %* |
| *Balance* | *- 11.1* | *- 2.1 %* |

*(ii) The French exchanges*

*The most important products are :* fish, fresh or chilled (especially saltwater fish), crustaceans and molluscs.

*French imports come from a lot of countries, but french exports are very concentrated on two countries : Spain and Italy, which represent 61.4 % of french exports.*

*(iii) Difficulties and leading factors*

*Main difficulties are* reduction of captures and most of exported products low value-added.

*Main leading factors are* a good location, a large range, especially in fine fish, a high market-share in some markets (Spain, Italy), a growing aquaculture.

## 1. INTRODUCTION

Quelques chiffres-clés

*1.1 Balance commerciale française en 1991 (cf figure 1).*

| | Milliards FRF | Evolution 1991/1990 |
|---|---|---|
| Import | 16.3 | + 7.6 % |
| Export | 5.2 | + 2.8 % |
| Solde | - 11.1 | - 2.1 % |

*1.2 Situation de la France sur le marché mondial en 1989*

- 3ème importateur mondial après le Japon et les Etats-Unis,
- 14ème exportateur mondial et 5ème exportateur européen,
- captures 1989 : 880.000 tonnes en poids vif, soit le 4ème producteur européen.

## 2. LES CARACTÉRISTIQUES DES ÉCHANGES FRANÇAIS

*2.1 Postes prédominants (cf figures 2 et 3)*

(i) les poissons frais et congelés :

1er poste des exportations (60 %),
1er poste des importations (30 %) avec une prépondérance des poissons de mer : 55 % des exportations françaises, 15 % des importations françaises.

(ii) les crustacés et mollusques : 2ème poste des exportations (21 %) et des importations (27 %).

*2.2 Les importations françaises*

Nos 5 premiers fournisseurs (Royaume-Uni, Norvège, Danemark, Islande, Pays-Bas) en produits de la mer - non compris les préparations et conserves - représentent 49,8 % de la valeur des importations.

*2.3 Inversement, les exportations sont très fortement concentrées,*

sur l'Espagne et l'Italie qui absorbent 61,4 % des ventes françaises. En outre, cette concentration s'accentue au fil des ans.

## 3. DEUX EXEMPLES FRANCAIS : LE COMMERCE EXTERIEUR FRANCAIS EN POISSONS DE MER ENTIERS, EN CRUSTACES ET MOLLUSQUES

*3.1 Poissons entiers de mer (cf figures 4 et 5)*

Devenu positif en 1988, le solde de ce poste ne cesse de progresser, mais plus en volume : + 25,6 % qu'en valeur : + 18,6 %.

Les exportations françaises concernent une gamme assez étendue d'espèces : ainsi les 5 premières espèces ne représentent que 44 % du total.

Elles sont marquées par une valorisation insuffisante. Les ventes s'accroissent en effet pour les espèces bon marché, ou dont les cours diminuent (thon, sardine, hareng) ; tandis que les exportations d'espèces à valeur ajoutée se réduisent (soles, anguilles, roussettes par exemple), ou progressent trop faiblement (baudroie, merlu).

Les importations, bien qu'en recul, restent dominées par des produits plus chers : cabillaud (15 %), sole (15 %), baudroie (9 %).

### *3.2 Crustacés et mollusques (cf figures 6 et 7)*

Ce poste accuse le déficit le plus élevé en 1991 : - 3,2 milliards FF, et le plus brutal : + 21,8 % ; après une année 1990 relativement favorable.

En effet, les importations sont en hausse sensible : + 13,5 % en valeur, et marquées par l'importance de produits à forte valeur ajoutée : langoustes, langoustines, homards, dont les prix sont stables ou en hausse. Les exportations, au contraire, portent davantage sur des produits peu chers : crevettes, seiches, calmars, huîtres, et dont les cours ont tendance à baisser (à l'exception des crabes et tourteaux).

## 4. DIFFICULTÉS ET ATOÛTS DE LA FRANCE

### *4.1 Principales difficultés*

(i) raréfaction de la ressource, d'où des difficultés à assurer un courant régulier d'exportations

(ii) forte atomisation de l'offre,

(iii) manque d'organisation logistique par rapport à nos concurrents d'Europe du Nord (Pays-Bas, Danemark, notamment).

(iv) faible valorisation des produits exportés.

### *4.2 Principaux atouts*

(i) position géographique privilégiée, vaste façade maritime.

(ii) variété de l'offre française notamment en poissons fins, ce qui lui confère une bonne image.

(iii) position dominante sur certains marchés (Italie, Espagne), rémunérateurs pour quelques espèces (merlu en Espagne, par exemple).

(iv) développement d'une aquaculture performante, qui facilite l'accès à certains marchés de part les garanties d'approvisionnement, et élargit la gamme française.

**TABLEAU 1.**
**PRIX A L'IMPORTATION (FRF/KG)**

| | 1990 | 1991 |
|---|---|---|
| Langoustes | 113,91 | 136,44 |
| Homards | 54,11 | 59,89 |
| Langoustines | 40,80 | 39,47 |

**TABLEAU 2.**
**PRIX A L'EXPORTATION (FRF/KG)**

| | 1990 | 1991 |
|---|---|---|
| Crevettes | 58,80 | 55,89 |
| Seiches | 12,97 | 11,41 |
| Crabes et tourteaux | 57,60 | 65,85 |
| Huîtres | 13,55 | 13,47 |
| Calmars | 23,03 | 22,52 |

# Monopsony, Trade Restrictions and International Markets for Intermediate Seafood Products : The U.S.-Canada Herring Dispute

**Ali Emami[a], Lewis E. Queirolo[b] and Richard Johnston[a] ***

[a]Department of Agricultural and Resource Economics, Oregon State University, Ballard Extension Hall 213, Corvallis, Oregon 97331-3601

[b]Alaska Regional, NOAA — Alaska Fisheries Science Center, 7600 Sand Point Way NE, Bin C15700, Seattle, Washington 98115

ABSTRACT

*In much of the fisheries economics literature, it is assumed that seafood products are produced under conditions of perfect competition in both the raw fish and fish processing sectors and that free trade prevails in international markets. This paper analyzes international trade in value added products when free trade and perfect competition in the market for an intermediate product, such as raw fish, is the exception rather than the rule. The limited number of fish processors in the coastal regions of seafood exporting countries provides bases for the exercise of monopsony power by those processors vis-a-vis their raw fish suppliers. Current evidence from the GATT regarding disputes between countries such as the U.S. and Canada over trade in raw herring suggests that bilateral free trade in raw fish between major exporters of seafood products may not exist.*

*The study specifically presents analytical models showing the behavior of two rival seafood exporting countries competing in the same import market when monopsony exists in the processing sector of one of these countries, supported by export restrictions in the other.*

*The analysis illustrates how, under such conditions, trade disputes evolve. It further demonstrates how expansion of the demand for herring roe may, through trade reversal pressures, dilute the market power of the processor monopsony and make trade restriction policies irrelevant. There are lessons here for other markets as demand growth leads to trade liberalization.*

## 1. INTRODUCTION

In much of the fisheries economics literature, it is assumed that seafood products are produced under condition of perfect competition in both the raw fish and fish processing sectors and that free trade prevails in international markets. This paper analyzes international trade in value added products when free trade and perfect competition in the market for an intermediate product, such as raw fish, is the exception rather than the rule. The limited number of fish processors in the coastal regions of seafood exporting countries provides a base for the exercise of monopsony power by those processors vis-a-vis their raw fish suppliers. Current evidence from the General Agreement on Tariffs and Trade (GATT) regarding disputes between countries such as, for example, the U.S. and Canada in the matter of trade in unprocessed herring suggest that bilateral free trade in raw fish between major exporters of seafood products may not be a reasonable analytical assumption. Reasons for this include both government restrictions and market structure constraints. Indeed understanding the mechanism of trade in unprocessed herring between these two countries may yield insights into bilateral trade issues involving other pairs of countries.

The study specifically draws on features of the U.S.-Canada market to develop analytical models showing the behavior of two rival seafood exporting countries competing in the same import market when monopsony exists in the processing sector of one of these countries, supported by export restrictions in the other. The analysis illustrates how, under such conditions, trade disputes evolve. It further demonstrates how expansion of the demand for the final product — in this case, herring roe (kazunoko) — may, through trade reversal pressures, dilute the market power of the processor monopsony and make trade restriction policies irrelevant. There are lessons here for other markets as demand growth leads to trade liberalization.

The remainder of this paper is organized as follow : the first section provides an overview of the dispute between Canada and the U.S. In the second section we abstract from the specific details of this dispute and present an analytical model of U.S.-Canada trade in which Canada exports raw fish to U.S. processors and both countries export the final product, herring roe, to the Japanese market. The third section shows the results of an export embargo on raw fish from Canada to the U.S. processors in the presence of collusive oligopsonistic behavior by U.S. fish processors with respect to their raw fish suppliers. It compares the economic impacts of both market conditions (the export embargo and oligopsony behavior) with the free trade situation of the second section. The fourth section illustrates how expansion of the Japanese demand for final product (herring roe), through trade reversal pressures, dilutes the market power of the processor monopsony in the U.S. and makes restrictive trade policies (the export embargo) by Canada irrelevant. The fifth section compares the U.S.-Canada free trade equilibriums after demand expansion in Japan with the results obtained in the previous section. The sixth section presents conclusions and draws policy implications.

## 2. AN OVERVIEW OF THE U.S.-CANADA RAW FISH TRADE DISPUTE

Japan is the principal country in the world in which there is a strong consumer demand for kazunoko, considered a food delicacy and made from herring roe. [1] Historically, the major source of supply of roe-bearing herring has been the waters off northern Japan. While landings from this area have declined since 1926 (the earliest date for which records are available) a significant and abrupt drop in production occurred in 1977, from which there has been no recovery (Atkinson and Katsuyama, 1981). This occurred at the same time that many nations, including the U.S., Canada and USSR, extended jurisdiction over their respective fisheries zones. The exclusion from (or significant restriction within) U.S. and USSR waters of Japan's distant water fleets added to the decline in Japanese landings in the late 1970s.

The continued strong demand for kazunoko in Japan and the sharp decline in domestic supply provided new export opportunities for both Canada and the U.S. The response to this new opportunity elicited rather different economic and

1. Herring roe (kazunoko) is a traditional food used, primarily, as a part of the New Year's celebration in Japan. Kazunoko is said to symbolize long life and prosperity, and obtains a very high price in the Japanese market. Pacific herring is the preferred source of kazunoko by the Japanese. As a result, virtually all the U.S. and Canadian harvest of Pacific roe-bearing herring and herring roe ultimately finds its way onto Japanese markets.

political strategies in the two countries, however. Within an economic environment characterized by increasing cross-border tension, these divergent trade strategies produced conditions which ultimately brought the U.S. and Canada into direct conflict.

Since the mid-1970s, Canada has prohibited the export of unprocessed Pacific herring (*Culpa havengus pallasi*), pink salmon (*Oncorhynchus gorbuscha*), and sockeye salmon (*O. nerka*). [2] In 1984-85, Canadian buyers for the first time began to purchase Pacific roe herring directly from U.S. fishermen in the Kah Shakes herring-roe fishery (and subsequently the Sitka Sound fishery) of S.E. Alaska. Prior to the entry of Canadian buyers, U.S. processors had enjoyed a market with many of the characteristics associated with a classic oligopsony : that is, a small number of buyers and many sellers. In this case many herring fishermen, competing to harvest a highly perishable product within an extremely short period, confronted a very small number of potential buyers for their catch. Price and landings data for the years immediately preceding the entry of Canadian buyers into these fisheries suggest that U.S. processors consistently paid less per metric ton to U.S. fishermen than Canadian processors paid Canadian fishermen. And when Canadian buyers entered the S.E. Alaska herring fishery, ex vessel prices were quickly bid up, by between 50 % and 100 %, over opening offerings by U.S. processors. Under these conditions, S.E. Alaska processors understandably perceived a threat to the economic status quo. In a coordinated effort to counter the effects of Canada's entry into their market, S.E. Alaska herring processors struck back with a series of political actions aimed at what they considered to be "unfair" trade practices.[3] They expressed significant concern, to the Alaska Governor and Legislature and to the U.S. administration, about the restrictive Canadian regulations, arguing that there were inherent inequities in an arrangement under which Canadian buyers could purchase unprocessed roe herring directly from U.S. fishermen but U.S. processors could not purchase directly from Canadian fishermen.

In 1986, the U.S. Trade Representative (USTR), principally on behalf of the S.E. Alaska fish processors, initiated an action against Canada, under provisions of the Trade Act of 1974, section 301. The USTR, in consultation with the petitioners, ultimately sought relief through arbitration provisions of the GATT. While the section 301 petition cited alleged violations by Canadians pertaining to restraint of trade of pink salmon, sockeye salmon and Pacific herring, and the list of petitioners ultimately included processors from both Alaska and Washington state, as suggested above, the initial source of the dispute centered on the lucrative Pacific herring roe fisheries in S.E. Alaska and northern British Columbia.[4]

In March, 1986, the GATT panel, hearing the dispute, ruled in favor of the U.S. Subsequently, Canada "officially" revoked the offending prohibitions on export of raw herring, pink and sockeye salmon. In their place, however, Canada imposed new regulations which require that Canadian fishermen "land" their catch in Canadian ports "for inspection" before export. The effective result was that the originally offending prohibition on direct export of raw fish from Canada had been reinstated, although the new regulations were extended to include all species of fish. These new export rules were immediately challenged by the U.S., under provisions of the U.S.-Canada Free Trade Agreement (FTA), which had been entered into by the two countries during the time the dispute was being adjudicated under GATT. Presumably this dispute will ultimately be resolved within that forum under the subject of nontariff trade barriers (NTB).[5] At the present time, the two nations are evaluating an interim agreement negotiated under FTA in February 1990 and assessing options to that agreement, which is scheduled to be revisited in 1993.

2. No equivalent regulations governed the export from Canada of other unprocessed species, however, including economically important species such as chinook salmon (*O.tshawytscha*), coho salmon (*O.kisutch*), or chum salmon (*O.keta* ). Despite the availability of, among others, these latter three species of Canadian-caught salmon, there appears to have been virtually no effort by U.S. processors, operating in S.E. Alaska (immediately adjacent to the British Columbia fisheries) to import Canadian-caught fish for processing ; this despite the fact that, in some years, chinook (and on occasion coho) were in relatively short supply in S.E. Alaska fisheries. On the other hand, historical records indicate that, in some years, when pink salmon were in particularly great supply in S.E. Alaska, raw pink salmon were shipped to British Columbia plants for processing, thus relieving the glut in the U.S. fisheries. Furthermore, the U.S. did not have equivalent reciprocal restrictions on the movement of unprocessed U.S. catches to Canadian processors.
3. It should be noted that Canada had, prior to this time, not been rigorously consistent in enforcement of its regulations against export of "unprocessed" herring. It was determined by National Marine Fisheries Service, Fisheries Trade Services Division that, as late as 1977 and 1978, Canadian processors were selling unprocessed Pacific herring to U.S. firms in the Seattle, Washington area for interim cold storage and refrigeration before shipping the product back to British Columbia, Canada, where the roe was then stripped (personal communication, Matteo Milazzo, 1986).
4. The harvest of roe-bearing herring progresses sequentially up the North American west coast, beginning in San Francisco Bay (in November), proceeding through Washington state (although poor stock conditions have virtually eliminated the herring fisheries there in recent years), then northward along the British Columbia coast, to the S.E. Alaska coast. The fishery then continues north and west along the Alaska coast, terminating in the Norton Sound area, near Nome (in June). In the early to mid-1980s, the period during which the dispute arose, the U.S. harvest accounted for between half and three-quarters of the total North American catch. The S.E. Alaska fisheries, however, represented only about 15 % of the U.S. total.
5. For additional discussion, see Leitz and Wright (undated a, undated b) and McDorman (1990).

In the next section we present a highly simplified partial equilibrium trade model which allows us to analyze this intra-industry trade dispute and the likely consequences of interventions in raw fish markets by either U.S. or Canada, or both, on their domestic fishermen and processors. We believe the analysis provides insights into how demand changes can affect the sustainability of market imperfections.

## 3. AN ANALYTICAL MODEL OF U.S.-CANADA INTRA-INDUSTRY TRADE IN ROE HERRING

In this section we present an elementary model of trade in an intermediate product (raw fish) between two countries, where both are exporting the finished product (processed fish) to a third country. The model follows and modifies previous analytical models on trade in both intermediate and final goods introduced in the literature by Corden [1971], and expanded by Houck [1986], Nakamoto, Halloran, and Martin [1990], Lindsey and Johnston [1989]. However, our model differs from previous ones in that (a) it allows for three countries, (b) employs the large country assumption, (c) admits the possibility of monopsony behavior by the processors of one of the participant exporting countries, and (d) allows the other exporting country to impose restrictions on exports.

As suggested, the model abstracts considerably from the facts of this particular, complex case. Our objective is not to restrict our analysis to the U.S.-Canada dispute but, rather, to illustrate how, in general, trade disputes may be resolved through changing, often predictably, economic conditions. Thus we are somewhat selective in which facts of the case we incorporate in the model and a bit cavalier in the assumptions we impose on biological and relative cost conditions. Nonetheless we have retained many of the essential features of this particular dispute. The assumptions underlying the markets for the final product — processed fish (F) in the U.S., Canada, and Japan, raw fish (R), and value-adding, nontradeable inputs (V) in the U.S. and Canada are stated next.

We assume the world consists of three countries U (U.S.A.), C (Canada), and J (Japan). Countries U and C both produce a homogenous tradeable final product F, by utilizing two inputs of production, R and V, that are also produced domestically. Production of F is characterized by fixed input-output ratios (i.e., F is produced via a Leontief-type production function) in U and C.[6] Input R is harvested by U and C from different stocks of fish. Input V is considered to be a composite input consisting of labor and capital. Input R is a tradeable input only between U and C while V is a nontraded input. There is no domestic demand for F in either U or C ; F is demanded only by J in the world market. The final product F is not traded between U and C, but is exported by both U and C to J. All countries are "large countries" in all markets. Finally, for analytical expediency we assume that all three countries have identical currencies and that transportation costs among the countries are zero.

In Figure 1 we assume, for graphic convenience, that one unit of R is combined with one unit of V to produce one unit of F. Panels (a), (b), and (c) of Figure 1, represent fish markets in U, C, and J, respectively. In panels (a) and (b), the upward sloping supplies of raw fish, and the value adding inputs are respectively labeled $S_R$ and $S_V$ for the U.S., $S_R^*$ and $S_V^*$ for Canada (henceforth, variables for Canada are marked with an asterisk). By assumption, the intercept (the set up cost) for $S_R$ is higher than the intercept for $S_R^*$ due to the U.S. fishermen's higher access cost associated with remoteness, but the slope of $S_R$ is lower than the slope of $S_R^*$ since labor costs, landings taxes and capital costs are higher in Canada than the U.S. The supply curve of V in Canada is higher and flatter than its corresponding curve in the U.S. That is, while Canada is the more costly supplier of V at low levels of processing, at higher levels the average cost declines such that it falls below that of the U.S. for similar processing levels in part because of stricter regulations on waste from processing facilities in the U.S. This may result from higher capital costs in Canada but larger plant sizes and fewer size diseconomies in that country.[7] These curves slope upward because higher prices result in increased demand for inputs and, thus, higher input prices (for example, labor must be imported from increasingly distant locations). In panel (b), the curve labeled $S_F^*$ is the vertical summation of the curves $S_R^*$ and $S_V^*$ in that panel. In panel (c), the demand in Japan for the imports of processed fish (in this case kazunoko) is labeled $D_F^J$. In that same panel, the curve labeled $SS_R$ is the horizontal summation of the supplies of R in panels (a) and (b), and the curve labeled $SS_V$ is the horizontal summations of supplies of V in panels (a) and (b). The curve labeled $SS_F$ in panel (c) is the vertical summation of the $SS_R$ and $SS_V$ curves in that panel.

6. This assumption is made for analytical convenience only. Relaxing it would not materially affect the results.
7. Alternatively, one may consider the situation where the supply of V in Canada is everywhere above that of the U.S., largely as a consequence of higher Canadian wage rates and the private costs of social services assessed on Canadian firms. The results of this study do not change.

**U.S.-Canada Free Trade in R**

Suppose there is free trade in R between U and C, and free trade in F between U and J and between C and J. The equilibriums in each sector are found by equating $SS_F$ with J's demand $D^J_F$ at point $E^F$ in panel (c), (henceforth the superscript "F" denotes the values of variables under free trade).

In equilibrium, J imports $Q^F_{R,V,F}$ of processed fish. The aggregate production of $Q^F_{R,V,F}$ by U and C requires a total of $Q^F_{R,V,F}$ units of each input R and V in panel (c), with corresponding prices of $P^F_R$ and $P^F_V$, respectively. At equalized factor V prices of $P^F_V = P^{*F}_V$, U allocates $q^F_{V,F}$ units of V to produce $q^F_{V,F}$ units of F, and C allocates $q^{*F}_{V,F}$ units of V to produce $q^{*F}_{V,F}$ units of F. With free trade factor R prices are equalized at $P^F_R = P^{*F}_R$, U's fishermen supply $q^F_R$ units of R, and C's fishermen supply $q^{*F}_R$ units of R, of which $q^{*F}_{V,F}$ goes to domestic processors (utilization from domestic supplies of R) and the rest is exported in the round to U. To produce $q^F_{V,F}$ units of F in U requires $q^F_{V,F}$ units of R to be combined with $q^F_{V,F}$ units of V. Thus, with free trade in R, U imports $(q^F_{V,F} - q^F_R)$ units of R from C, which is equal to the $(q^{*F}_R - q^{*F}_{V,F})$ units of R exported from C.

## 4. CANADIAN EXPORT EMBARGO ON R AND THE EXERCISE OF MONOPSONY POWER BY THE U.S. PROCESSORS

In section 3 above, it was shown that, under free trade, Canada would, apparently, be an exporter of raw herring to the U.S. In fact this situation never arose. This is because Canada prevented such trade by imposing an embargo on the export of unprocessed herring to the U.S., presumably to protect its fish processing industry under the "infant industry" protection argument. This is considered next.

Let U.S. fishermen have the choice of selling their U.S.-harvested raw fish in the U.S., Canada, or both. Assume further, that Canada imposes an embargo on exports of raw herring and that, simultaneously, U.S. processors arrange a collusive oligopsony[8] in buying raw fish from U.S. fishermen (henceforth we treat this oligopsony as if it were a monopsony). Under these conditions, the new equilibrium values are indicated with superscript "M" in Figure 1, and are determined as follows.

First, we construct the residual demand for F facing the U.S. processors (labeled as $D_r$ in panel (a)) by horizontally subtracting $S^*_F$ from $D^J_F$ at all price levels. Second, we construct the U.S. processors "derived demand" for raw fish ($DD_R$) from their fishermen by vertically subtracting $S_V$ from $D_r$ at each quantity. Third, we construct the curve $MFC_R$ as the marginal factor cost of raw fish to U.S. processors. Then, the U.S. processors impose a monopsony price of $P^M_R$ (the price on $S_R$ corresponding to the quantity $q^M_{RVF}$, determined by the intersections of $DD_R$ and $MFC_R$) on their fishermen. The resulting final product is supplied to the Japanese market, in competition with final product from Canada's market. Note that this monopsony position can be sustained as long as the Canadian price ($P^{*M}_R$) is lower than that in the U.S. since, at those price levels, U.S. fishermen would have no economic incentive to ship to Canadian processors. This discrepancy, in turn, follows from Canada's preventing exports of raw fish, leading to higher utilization of domestic supplies than in free trade ($q^{*M}_{R,V,F} > q^{*F}_{V,F}$), but lower utilization in total, of Canada's raw fish ($q^{*M}_{RVF} < q^{*F}_R$) and corresponding lower ex-vessel prices.

A comparison of the value of the model's variables under a Canadian export embargo on raw fish and monopsony behavior by U.S. processors with the values of the model's variables under free trade indicates that for prices :

$$P^M_R > P^F_R > P^{*M}_R, P^M_V < P^M_V = P^{*F}_V < P^{*M}_V, P^M_F = P^{*M}_F \geq P^F_F,$$

and for quantities of V and F :

$$q^M_{R,V,F} < q^F_{V,F}, \text{ and } q^{*M}_{R,V,F} > q^{*F}_{V,F}.$$

Under these new conditions Canadian processors utilize the entire domestic catch of raw fish ($q^{*M}_{R,V,F}$) and thus export a higher volume of processed fish to Japan than the volume they were supplying under free trade. The U.S. processors are

8. The assumption that U.S. processors enter into a "collusive oligopsony" is an analytical construct and is not intended to suggest that U.S. processors actually undertook this action.

unable to import any R from Canada and utilize only their own domestically caught R ($q^{M}_{R,V,F}$), which is purchased at monopsony prices. These prices, however, are higher than what is paid to Canadian fishermen by Canadian processors and higher than the "free trade" prices to U.S. fishermen because of removal of competition from Canadian supplies. These particular price relationships follow from the assumption made here about the supply functions in the two countries. They appear to be reasonable approximations of the actual situation, however : because of the higher U.S. price, Canadian fishermen have an incentive to export R to the U.S. and, thus, to prevent this, Canada keeps in place its export embargo on R. This is consistent with a situation in which two market imperfections (monopsony in the U.S., and an export embargo by Canada) can effectively coexist and sustain.[9]

## 5. DEMAND EXPANSION IN JAPAN AND TRADE REVERSAL

This section illustrates that how an expansion of demand in the import market for the final product, i.e. the Japanese demand, can mitigate the market imperfection in both the U.S. and Canada. In fact the Japanese import demand for herring roe has increased considerably in recent years. Reasons for this include :

i) An increase in the value of the Japanese yen relative to both the U.S. and Canadian dollars.

ii) The imposition of extended fisheries jurisdiction by both the U.S. and Canada, cutting off Japanese access to the waters of these countries. This reduced Japan's domestic supply of kazunoko and hence increased its demand for imports ($D^{J}_{F}$ may also be treated as Japan's excess demand curve).

iii) An increase in personal incomes in Japan.

iv) An increase in the Japanese population.

v) An increase in the price of substitute fish products in Japan, because of (ii), above.[10]

As $D^{J}_{F}$ increases to $D^{J'}_{F}$, $D_r$ and $DD_R$ shift up to $D'_r$ and $DD'_R$, respectively. In the presence of monopsony in the U.S., and a continued export embargo on R in Canada, the new equilibrium values of the model's price and quantity variables are indicated with a superscript ('). The new levels of prices in the U.S. and Canada for raw fish indicate that $P^{*M'}_{R} > P^{M'}_{R}$. Thus, Canada's export embargo is no longer relevant since Canada shifts from having an incentive to export raw fish to being an importer of raw fish. The increased demand in Japan has made the trade restriction unnecessary and led to trade reversal. In the U.S. the processors can no longer maintain their monopsony position because the U.S. fishermen now can sell at higher prices to Canadian buyers. In summary, demand expansion has reduced the incidence of market imperfections in the U.S. and Canada and has led to trade reversal in a traded intermediate product.

Note that, the trade reversal in this model is neither because of changes in factor intensities due to the changes in the factor prices, nor due to direct domestic demand expansion in any of the exporting countries (demand based trade reversal). These are the usual explanations for trade reversal (see, for example, Ethier, pp. 134-6). With regard to the former case, our production technologies in both exporting countries are characterized by fixed proportions ; thus, any changes in the factor prices due to the existence of monopsony or the export embargo do not change the factor intensities. In the latter case, trade reversal happens because the domestic demand in an exporting country expands to such an extent that its domestic price is higher than the price in its importing partner and thus the exporting country becomes an importing country. In our model, after demand expansion in Japan, the U.S. and Canada still hold their positions as exporters of the final product, yet their pattern of trade in the intermediate product is reversed. One may label this kind of trade reversal as "foreign demand based trade reversal."

The results, once again, follow from the relationships among supply curves. Specifically, at relatively low levels of demand in Japan, and in the absence of either monopsony pricing or export controls, Canada is the low-cost producer of raw fish but the high cost processing country. Thus, Canada, with a comparative advantage in raw fish harvesting, exports to the higher cost country. At the higher level of demand in Japan, Canada's comparative advantage switches

9. Actual price relationships did not mirror those discussed here. This may be a consequence of asymmetrically-held information, a hypothesis we are currently exploring.

10. In the more general case, other factors, such as an import subsidy could also lead to increased demand facing the exporting countries.

from raw fish production to processing. At higher levels of production of the final product, average harvesting costs in the U.S. are so much lower than those in Canada and U.S. processing costs so much higher, per unit, that it pays the U.S. to export raw fish to Canadian processors.

It is not clear that these are in fact the circumstances that prevail in the two countries but the model does seem to reproduce, in broad terms, what has actually occurred. More important, perhaps, it suggests that analysis of trade patterns involving both intermediate and final goods may require examination of costs relationships beyond those associated with current production levels. For example, where cost disparities are a consequence of differences in external economies and diseconomies — certainly a strong possibility where trade is in products having a natural resource base (so that real externalities are significant) and where the exploitation of that natural resource represents a significant economic sector in a region (so that pecuniary externalities play a large role) — the results suggested here seem quite reasonable. At least, in our judgment, they merit more attention than they have received to date.

## 6. DEMAND EXPANSION IN JAPAN AND FREE TRADE IN R

In the absence of imperfections in the U.S. and Canadian R markets, as $D_F^j$ increases to $D_F^{J'}$ the equilibrium in each sector is found by equating $SS_F$ and $D_F^{J'}$ at point $E^{F'}$, and the new equilibrium values are indicated with a superscript (F'). At equalized factor V prices of $P_V^{F'} = P_V^{*F'}$, U allocates $q_{V,F}^{F'}$ units of V to produce $q_{V,F}^{F}$ units of F, and C allocates $q_{V,F}^{*F'}$ units of V to produce $q_{V,F}^{*F'}$ units of F. With free trade factor R prices are equalized at the new level of $P_R^{F'} = P_R^{*F'}$, at which U's fishermen harvest $q_R^{F'}$ units of R, in total, of which $(q_R^{F'} - {}^{F'}_{V,F}$ are exported to Canada. C's fishermen supply $q_R^{*F'}$ units of R to their domestic processors. To produce $q_{V,F}^{*F'}$ units of F in C requires $q_{V,F}^{*F'}$ units of R to be combined with $q_{V,F}^{*F'}$ units of V. Thus, with free trade in R and the absence of market imperfections, C imports $(q_{V,F}^{*F'} - q_R^{*F'})$ units of R from U, which is equal to the $(q_R^{F'} - q_{V,F}^{F'})$ units of R exported from U.

## 7. CONCLUSION

These findings are highly dependent on the relative positions of the supply curves — of both R and V — in Canada and the United States although they can be generated under a variety of assumptions about that relationship. In the above discussion, as output increases, Canada changes from having a cost advantage in fishing to having a cost advantage in processing vis-a-vis the U.S.

Suppose the R supply curves in the two countries are identical. Suppose, further, that the supply curve of V in Canada is higher and flatter than its corresponding curve in the U.S., as shown in Figure 1. In this case the results of this paper re-emerge. This means that before the demand in Japan expands, Canada, in free trade, would have an incentive to export R to the U.S. due to higher processing costs in Canada. However, as the Japanese demand increases, Canada experiences cost advantages. This leads to trade reversal, as in the example above.

Now suppose that processing costs are equal in the two countries but that the supply curve of R in Canada is lower — at low harvesting levels — than that in the U.S., as is shown in Figure 1. Further suppose, however, that this cost advantage disappears at higher harvesting levels — perhaps due to locational advantages for the Canadian fleet but higher fuel and labor costs in Canada — so that the Canadian supply curve intersects (from below) its U.S. counterpart. Again, the results of this model re-appear. In this case the explanation is that Canada, being the less costly harvester at low fishing levels, ships raw fish to the U.S. — or, at least, under free trade would have an incentive to do so. As Japanese demand expands, the U.S. emerges as the less costly fishing nation and, thus, trade reversal occurs once again.

Other configurations could be considered. The point is that this model is useful not only in understanding events underlying the U.S.-Canada trade dispute over roe herring but may also provide insights into bilateral trade patterns in intermediate products among a large number of pairs of trading partners. It demonstrates that existing trade patterns, existing market structures and existing trade policies may change significantly, not only in response to explicit government action but also in response to changing supply and demand conditions. Perhaps, then, concern about unfair trade practices could more effectively be addressed by awaiting — or even promoting — changes in market conditions than by issuing calls for retaliation.

ABSTRACT

*Many fishery markets are becoming increasingly globalized, and with the extension of exclusive economic zones to 200 miles, growing international trade is coupled with the replacement of foreign harvesting by domestic production. These trends raise questions concerning the nature of market integration and price linkages and the implications for export, market, and management policies. When domestic ex-vessel and export markets are linked by prices as well as commodity flows to central foreign markets, then domestic production, marketing, and management must consider, at least in part, developments outside of the traditional autarkic market boundaries. This paper assesses the price linkages between the United States and Japan for two species whose exports have risen considerably over the past decade : sablefish and thornyheads. The empirical results indicate segmentation of price linkages for sablefish but probable price linkages for some thornyhead markets. The findings suggest that U.S. ex-vessel markets for these species may be less sensitive to price changes in Japan than would be expected, based on commodity flows.*

## 1. INTRODUCTION

Many fisheries in the past decade have experienced increased globalization of their markets and growing international trade, as foreign harvesting has been replaced by domestic production. These changes raise issues regarding the nature of market integration and price linkages and the implications for fisheries management.

* Discussions with Jim Anderson, Clint Atkinson, Larry Jacobson, Trina Wellman, and Dick Young are gratefully acknowledged. The authors, however, are responsible for any remaining errors.

When domestic ex-vessel and export markets are linked by prices as well as commodity flows to central foreign markets, then domestic production and marketing decisions cannot be separated from events in the central foreign markets. Where strong price linkages exist, domestic fisheries management should be formulated with an awareness of developments in foreign markets, consumer taste and preferences, trade policies, and even foreign fisheries policies. In short, domestic production, marketing, and management must weigh developments outside of the traditional market boundaries.

Following the Magnuson Fishery Conservation and Management Act of 1977, United States harvesters replaced foreign producers of sablefish (*Anoplopoma fimbria*). U.S. harvesters rapidly expanded production and exports of sablefish to Japan. These factors have combined to increase the ex-vessel sablefish revenue received by Pacific coast and Alaskan groundfish fishermen to a level surpassed by only pollock and halibut. Unlike pollock which undergoes considerable processing--into surimi and fillets--soon after harvest, sablefish normally remains in a headed-and-gutted form throughout much of the market chain. Halibut seasons have typically been very short in most areas, creating time series problems for comparative market analysis. Since a very high percentage of sablefish is exported to Japan, it offers an excellent opportunity to compare prices of equivalent products in U.S. ex-vessel and foreign Japanese markets.

The nature of this market integration for sablefish was previously examined by Squires, Herrick, and Hastie (1988). This study examined the integration by prices of Alaska and Pacific ex-vessel markets for sablefish and the **Tsukiji** or Tokyo central wholesale market for 1981-1986. The study considered the pot and longline (hereafter fixed gear) sector of the sablefish fleet, because these vessels produce the higher quality sablefish desired by Japanese consumers. This study found that the Alaskan and Tsukiji markets had a form of price integration. In contrast, the Pacific coast and Tsukiji markets were segmented, so that changes in the Tsukiji market had no effect, immediate or lagged, on the prices of the Pacific coast market.

In this previous study, the Tsukiji market role was assessed as the center of a radial market for sablefish. Price was first formed in the Tsukiji market, with the Alaskan market price responding to it. Hence, the central market prices are expected to be causal to some non-central market prices, but other non-central market prices would not be causal to each other or to the central market. This previous study of sablefish markets utilized "real" rather than nominal prices, i.e. prices were adjusted for inflation. There are no theoretical reasons for the use of either real or nominal prices in testing price linkages. However, different inflation rates between two markets can create (temporary) real profit differentials in the central market. In turn, central market demand shifts and prices in the radial market are pushed up, other things being equal. Because the use of real prices may mask some of these effects, the current study uses nominal prices. Adjusting prices using the yen-dollar exchange rate fluctuations is used to account for differential inflationary variations.

The previous study also specified lag lengths up to six months based upon an assessment of the price formation process. The true lag structure may nonetheless differ, which in turn could affect the results. Hence, the present study evaluates market integration for lag lengths up to two, three, four, five, and six months. Robust results for the different lag lengths will strengthen conclusions.

The purpose of this study is fourfold. First, since 1986 the Pacific coast and Alaskan ex-vessel sablefish markets appear more closely linked to the Tsukiji market, at least by commodity flows, with possibly a form of price linkage for even the Pacific coast market. Hence, this relationship will be reexamined in the light of conditions through 1989. Second, the causal price linkages between the Tsukiji market and the ex-vessel Alaskan and Pacific coast sablefish markets for fixed gear will be assessed, thereby allowing for a more complex form of market structure than the previous study. In addition, previously unexamined causal price linkages between the Tsukiji market and the Pacific coast and Alaska ex-vessel markets for thornyheads (*Sebastolobus altivelis* and *Sebastolobus alascanus*) caught with all gear (combined fixed and groundfish trawl gears) will be evaluated. Third, recent advances in evaluating Granger causality, that surmount limitations to previous approaches, will be applied and compared to the original methodology. And fourth, the study will incorporate the use of varying lag lengths and nominal rather than real prices.

The study is organized as follows. The next section provides a background to the fisheries and markets. The third section considers causal relationships, price linkages, and presents the empirical model. The fourth section discusses the data. The fifth section examines the empirical results. The final section offers policy implications and concluding remarks.

## 2. BACKGROUND TO THE FISHERIES AND MARKETS

Domestic Alaskan fixed-gear landings of sablefish increased from 800 mt in the early 1980s to more than 13,000 mt by the end of the decade. Pacific coast fixed-gear landings fluctuated between 4,500 and 8,100 mt during this period. Coastwide landings of thornyheads increased from 3,200 mt 1981 to more than 11,000 mt throughout the 1980s, largely in response to the development of Japanese export markets, and the lure of higher ex-vessel prices. The bulk of the thornyheads landed in each year are taken off northern California and Oregon by bottom trawlers. Shortspine thornyheads (*S. alascanus*) predominate in landings, although the proportion of longspine thornyheads (*S. altivelis*) has increased during recent years.

Alaskan ex-vessel prices for fixed-gear sablefish (adjusted for inflation and measured in 1989 dollars) increased from \$0.40/lb to more than \$1.00/lb in 1988. Pacific coast ex-vessel prices for thornyheads (also in 1989 dollars) rose from \$0.17 per pound in 1981 to \$0.40 in 1990 (Jacobson, 1991). Alaskan and Pacific coast ex-vessel prices tend to be competitively formed, although short-term fluctuations in Pacific coast trawl prices are moderated to some extent by agreements between processors and fishermen. Seattle dominates as the port of export. Many of the prices received by Alaskan sablefish vessels are formed in a Seattle auction, where several processors or brokers will bid for deliveries from vessels, while other ex-vessel prices are formed directly when a vessel lands its catch at a processor. Formation of fixed prices and informal contracting occur between some processors and harvesters, but flexibility nonetheless exists in the fixed price negotiated prior to harvesting so that stochastic fluctuations in the size, quality, and composition of landings are accommodated. While wholesalers can be strung out along the coast, seemingly in a strong position to offer noncompetitive prices to vessels, competition is nonetheless stronger than initially appears among wholesalers and processors, and harvesters always have the option to land in different ports, though this may result in higher costs. In Alaska, approximately five to seven processors handle the bulk of the Alaskan product, although there are at least fifty processors in total.

We consider the Tsukiji market for reasons of data availability and because it plays an influential and increasing role in the handling of sablefish and thornyheads in Japan. Before the imposition of foreign harvest restrictions, when the Japanese fishing fleet was responsible for providing most of the sablefish consumed in Japan, the centralized market in Tokyo played a less important part in the distribution of sablefish ; it may have handled less than fifty percent of that consumed. As Japan was forced to rely increasingly on imports of sablefish and thornyheads, the clearinghouse in Tokyo has become more prominent, by providing a conduit for the imported product. Throughout most of the 1980's, the Tokyo market has generally handled an estimated 60-70 % of the sablefish sold in Japan (Hastie, 1989).

## 3. CAUSAL RELATIONSHIPS IN PRICE LINKAGES

This section defines market integration and presents the formal model used to empirically assess the causal structure of price linkages.

### *3.1 Market integration and price linkages*

Markets are integrated by prices if there is an interdependence in price movements at different spatially separate markets (Monke and Petzel, 1984). In market economies, market information to the different participating economic agents is largely transmitted by prices, so that an understanding of the manner in which markets are linked by prices can contribute to the general process of policy formulation.

Markets may be integrated by prices to different degrees and along some dimensions but not others. Geographical links or interregional trade are among the most important. Market boundaries are defined by the geographical limit of spatial price linkages. If buyers and sellers are subject to the same demand or supply conditions, they are deemed to be part of the same market (Cochrane, 1957). Hence, this study is aimed, in part, at defining the boundaries of the Tsukiji markets for sablefish and thornyheads.

### *3.2 Causal relationships*

Granger (1977) defined causality among a set of variables based upon predictability and the fact that the effect of a change in an exogenous variable upon an endogenous variable requires time. A variable X is said to cause another variable Y, with respect to a given information set that includes X and Y, if present Y can be better predicted by using past values of X than by not doing so, given all other relevant information. If the relationship is linear, this implies that in a regression context $X_{t-i}$ $(i > 0)$ and $Y_t$ are correlated. Causality from Y to X is defined in the same manner. Feedback occurs if X causes Y and Y causes X. A causal relationship between X and Y does not exist if causality does not run from X to Y or from Y to X [1].

A direct bivariate Granger test of causality is based upon the following general linear models (Holmes and Hutton, 1990) :

$$g(Y_t) = \alpha_0 + \sum_{i=1}^{k1} \beta_i\, g(Y_{t-i}) + \sum_{i=1}^{k2} \tau_i h(x_{t-i}) + \varepsilon_t + \sum_{j=2}^{4} \Omega_j D_j + \pi LT \qquad (1)$$

$$h(X_t) = \delta_0 + \sum_{i=1}^{k1} \theta_i\, h(X_{t-i}) + \sum_{i=1}^{k2} \phi_i\, g(Y_{t-i}) + \mu_t + \sum_{j=2}^{4} \Omega_j D_j + \pi LT \qquad (2)$$

where $\epsilon_t$ and $\mu_t$ are stochastic, white noise residuals, g(Y) and h(X) are strictly monotonic transformations of Y and X respectively, k1 and k2 are lag lengths (which may differ in equations (1) and (2)), LT refers to a linear time trend, and $D_j$ is the zero-one (dummy) variable for quarter j. The presence of lagged dependent variables is counted on to remove serial correlation from the estimated residuals.

The test of the null hypothesis that X does not cause Y is a test that $\tau_1 = \tau_2 = \ldots = \tau_{k2} = 0$. The test of the null hypothesis that Y does not cause X is a test that $\phi_1 = \phi_2 = \ldots = \phi_{k2}$ . Conventional parametric analysis involves least squares estimation of each of the full and null models and, assuming that $\epsilon_t$ and $\mu_t$ are generated from a normal distribution with constant variance, $N(0, \varsigma_i^2)$, subsequent calculation of F statistics with k2 and N-K (K = k1 + k2 + 4) degrees of freedom (Holmes and Hutton).

Tests for Granger causality conventionally rely on parametric analysis. The results of these statistical tests are limited by the augmenting hypotheses of a specific functional form of the variables and the homoscedasticity and normality of the errors, $\epsilon_t$ and $\mu_t$. However, an alternative to parametric testing of Granger causality employs the multiple rank transformation procedure (Holmes and Hutton 1988, 1990). The results of the multiple rank F test are invariant to monotonic transformations of all variables (and hence functional form) and are robust over alternative distributions of the errors (Conover and Iman, 1982 and Iman and Conover, 1979).

A multiple rank F test of the causal relationship between X and Y involves the variables measured in ranks, $g(Y_{t-i}) = R(Y_{t-i})$ and $h(X_{t-i}) = R(X_{t-i})$, all i, where R is the rank transformation, a strictly monotonic transformation (Holmes and Hutton). Equations (1) and (2) are then estimated by ordinary least squares for both the full and null models, and calculation of the standard F statistic based upon the residual variances from these rank regressions.

Lag lengths k1 and k2 must be selected [2]. Lagged effects in the model are likely to arise from sluggishness in price adjustment, delays in transportation, cold storage inventory holdings, and expectations formation under price uncertainty. Following Squires, et. al., a six month lag length was selected. This relatively long lag length allows for the Tsukiji market's fall prices to influence Alaska's spring prices and ex-vessel markets after Alaska harvesting has tapered off over

1. If the information set contained all the information available in the universe at time t, then $Y_t$ could be said to cause $X_{t+1}$. In practice, the information set contains considerably less information and so the phrase "prima facie" causality is used. The name is chosen to include the unstated assumption that possible causation is not considered for any arbitrarily selected group of variables, but only for variables for which the researcher has some prior belief that causation is, in some sense, likely (Granger 1988, page 201). Hence, the causality examined in this paper is prima facie causality.
2. While multicollinearity from current price and six lagged prices could present a problem in estimates and tests of significance for individual regression coefficients, the hypothesis tests in this paper are for the joint effects, requiring tests on the joint confidence region, so that multicollinearity presents far less of problem than it ostensibly might appear.

the winter months. Moreover, this lag length accommodates any possible effects of commodity flows from Alaska's spring harvests on price formation in the Tsukiji market. However, as noted above, while the preferred lag length is six months, the hypothesis test results might vary by lag length. Hence, the models were assessed for equal lag lengths in all markets up to two, three, four, five, as well as six months.

The influence of seasonality is accounted for by quarterly dummy variables for winter, spring, summer, and fall. Finally, the possibility of long-term effects from increasing United States exports are captured by a linear time trend.

## 4. DATA

Monthly price data for thornyheads and Alaskan sablefish were available from 1984 through 1989. Pacific coast and Tsukiji market sablefish prices were available from 1981 through 1989. Average monthly market price data for the Tsukiji market were obtained from the Tokyo Central Wholesale Market Yearbook. These are implicit prices formed by dividing monthly total revenues by comparable quantities. Most of the sablefish sold in this market are not homogeneous, and hence movements in average prices may reflect changes in the composition of the product form and quality. The thornyheads price includes both longspine and shortspine, and thus represents an average of the two. Since the use of averages (grouped data) can induce heteroscedasticity, the multiple rank F test rather than the standard parametric F test for Granger causality is particularly appropriate. In addition, these prices implicitly assume that different product forms and grades are perfect substitutes for each, i.e. linear aggregation is assumed. The data are in raw form, without any prior seasonal adjustments or smoothing. As noted by Sims (1974), prior seasonal adjustments or smoothing would confound the distributed lag relationships of Equations (1) and (2). Moreover, because these prices are average implicit prices, they may not be equilibrium prices. Even though spot prices are available for different size classes of sablefish, they are less suitable because corresponding quantities are not available, and because the transactions sampled may not be indicative of the entire month.

For the parametric comparisons, Japanese prices were converted to U.S. dollars per pound after adjusting for the yen-dollar exchange rate. Japanese prices were for eastern dressed weights while U.S. prices corresponded to round weight equivalent price for fish that are usually landed dressed. This difference should not affect empirical results, because the recovery rate between the two product forms is very stable.

For the rank comparisons, price series were created in both dollars and yen for each market. Transformation of these series was obtained by replacing the observations of each series with their respective ranks from 1 to N, where N is the number of observations. Ranks were generated using price values in both currencies, because application of the exchange rate to a price series can alter the rank ordering of its elements. Analyzing both sets of data allowed for an assessment of the significance of selecting a particular currency for the analysis. The dummy variables and linear time trend were unaffected by the rank transformation.

## 5. EMPIRICAL RESULTS

The full models, equations (1) and (2), for both rank data and actual (nominal) prices were estimated by ordinary least squares. The residuals were analyzed for serial correlation, the absence of which was verified with the Ljung-Box portmanteau test, or modified Q-statistic [3]. The autocorrelations were run for twenty lags [4]. Autocorrelation plots of the residuals for twenty lags were also visually inspected, and auxiliary regressions upon the residuals using various lags were also performed as informal checks on the presence of serial correlation.

The regressions using actual (nominal) prices did not exhibit serial correlation due to the lagged variables. The regressions using ranks exhibited serious serial correlation with fairly complex autocorrelated error structures. Moreover,

3. The modified Q-statistics are distributed independently as chi-squared random variables with degrees of freedom equal to the number of autocorrelations. The null hypothesis is that all longer lagged autocorrelations of the residuals are zero. See Greene (1990) for further discussion.
4. Autocorrelations are the correlation of the series, here residuals, with its own values lagged once, lagged twice, and so forth. Partial autocorrelations are the correlations measured with the series residual after all the prior lags have been removed. That is, the second partial autocorrelation is the correlation of the series lagged twice with the part of the series which is orthogonal to the first lag.

multicollinearity sufficiently serious to prohibit estimation for longer lag lengths was also experienced with the rank data. First-differencing the data and then calculating the ranks of current and lagged values of the differenced series (treating each as a separate variable) corrected for both the serial correlation and problems with multicollinearity.

The statistical significance of the linear trend and seasonal dummy variables was subsequently assessed for each unrestricted model for the a priori preferred lag structure, six months. The linear trend variable was statistically significant and retained only for the parametric regression of Pacific coast prices upon Alaskan prices for sablefish. The seasonal dummy variables were not statistically significant, and not retained, in any of the models.

The multiple rank F test is more robust over alternative error specifications than the parametric F test. Nonetheless, heteroscedasticity of the residuals remains a possibility, and the Breusch-Pagan (1979) test for heteroscedasticity was applied. If the chi-square test statistic was statistically significant for conventional levels of significance, heteroscedasticity was corrected by White's (1980) general procedure. In general, heteroscedasticity was found for most regressions, so that heteroscedastic-consistent estimates were applied when appropriate [5].

The Granger causality tests for sablefish using ranks, reported in Table 1a, uniformly indicate that the Tokyo Tsukiji and Pacific coast and Alaska ex-vessel markets were not integrated with one another by prices through 1989. These results were robust across the lag lengths examined. The Granger causality tests using actual (nominal) prices, reported in Table 1b, provided similar results, except for the model testing the influence of Alaska price on that of the Tsukiji market. Given the superior robustness of the multiple rank F test over the parametric F test, it is likely that a strong link between these markets was not present over the time period examined. Hence, despite the direct linkage known to exist for commodity flows between both U.S. fixed-gear sablefish markets and the Tsukiji market, there do not appear to be strong linkages between the prices in these markets.

These results for sablefish contradict the findings of Squires, et. al, that the Alaskan ex-vessel market was integrated by price as a radial market to the central Tokyo market. Several factors may have contributed to the difference in results. Nominal rather than real prices were used in the current study, although accounting for exchange rate fluctuations should have dampened the impact of this change. Another factor, which is largely undocumented, is the extent to which intermediaries, such as processors and brokers may be insulating each of the markets from price changes in the others.

Also, the rise in Japanese interest rates in recent years has shifted Japanese buying patterns from relatively infrequent but substantial purchases--utilizing cold storage holdings--to smaller but more frequent purchases (Dore, 1991). If this recent purchasing pattern is fairly stable and somewhat independent of Tsukiji market price fluctuations (to minimize inventory holding costs), then price changes in the Tsukiji market may not transmit to the ex-vessel level. However, a dummy variable for the months of 1988 and 1989 in the unrestricted model was not statistically significant, for each of the different lag lengths, as indicated by its t-ratio or a Lagrange multiplier test for heteroscedastic-consistent estimates. Hence, this statistical evidence suggests that significant structural change of this type did not occur. Finally, the previous study did not assess the robustness of results across lag lengths.

The Granger causality tests for thornyheads using ranks, reported in Table 2a, provide somewhat conflicting evidence that Tsukiji prices may follow Pacific coast ex-vessel prices. When the ranks were computed using prices expressed in yen, rejection of the null hypothesis was indicated for all lag lengths at the 5 %-level of significance, or better. The highest levels of significance were observed for lags of from 2 to 4 months. However, when the ranks were based on prices expressed in dollars, no significant price linkage was observed. This finding raises questions regarding the sensitivity of the rank test to the currency which is used in comparing markets within different countries. Intuitively, it may seem more appropriate to place greater weight on the results that are based on the currency of the market which is being tested for price dependence, but a solution to this problem is beyond the scope of this paper. The Granger causality tests for nominal prices, reported in Table 2b, provide some support for this interpretation, at least in this particular case. Pacific coast price was, again, observed to influence Tsukiji price, albeit with somewhat less statistical significance and over a smaller range of lags.

5. Heteroscedasticity gives a biased estimator of the variance. There is no well-established best way to test for heteroscedasticity (Greene, 1990). The most powerful tests specify a particular form of heteroscedastic process while more general but less powerful tests specify less restrictive forms of the heteroscedastic process. This study uses the more general approach of testing and correcting for heteroscedasticity. Finally, the empirical results and conclusions of this study are not changed by the heteroscedasticity correction. Finally, the relatively large number of observations are counted upon to give normally distributed residuals.

The tests using ranked data also provided moderate evidence of price integration among some of the other thornyhead market connections. Both of the models testing the influence of the Tsukiji market on Alaskan price had one lag specification for which the null hypothesis was rejected at the 10 %-level of significance. The significant lag period was 4 months for the ranks based on dollars and 5 months for those based on yen. Also, the 2- and 3-month lags were significant at the 5 %-level in the model assessing the influence of Alaskan price on that of the Pacific coast. Neither of these less robust linkages, nor any additional linkages, were indicated in the tests using nominal prices.

## 6. CONCLUSIONS

This study examined the Tokyo central wholesale (Tsukiji) sablefish market and the Pacific coast and Alaska ex-vessel fixed gear sablefish markets for the possibility and direction of price linkages between all markets. The study also assessed thornyhead price linkages between the Tsukiji market and the Alaskan and Pacific coast ex-vessel markets for all gears.

We found little evidence for market integration between the Pacific coast and Alaskan fixed gear ex-vessel and Tsukiji markets for sablefish. Price changes in any of these markets appear to have no predictable effect over a period of 6 months on the prices the other two. That U.S. prices were not found to be responsive to Japanese price changes may mean that U.S. fishermen may be better insulated from changes in foreign sablefish demand than would be expected from the magnitude of commodity flows. The Tsukiji price may not respond to supply-induced price changes as a result of the price inter-relationships with available substitutes, such as salmon. Another possible explanation for market segmentation is that processors or export brokers of sablefish may be absorbing much of fluctuation between prices in the Tsukiji and U.S. markets. If this is the case, the extent to which U.S. prices are affected by Japanese demand in the future may depend upon how far the profit margins of these intermediaries are squeezed.

As one example of the implications of these findings, Japanese policy makers might feel that sablefish imports threaten the well-being of Japanese producers domestically culturing or harvesting fish (e.g. chum salmon, a consumption substitute in Japan). In this case, because U.S. ex-vessel markets do not respond to the information in Japanese price changes, a tariff on imported sablefish from U.S. would not effectively reduce the price received by the U.S. producers and a Japanese import tariff would not impact commodity flow at the ex-vessel level. Alternatively, a Japanese import quota on sablefish would directly restrict the commodity flow, so that import quotas may be a more effective Japanese policy option to insure that commodity flows are restricted.

The Pacific coast thornyhead fishery appears to be linked by prices to the Tsukiji market. Furthermore, the evidence suggests that the Tsukiji price is likely to be influenced by changes in Pacific coast price, and not the reverse. Although some evidence was found of linkages acting from the Tsukiji market to Alaska, and from Alaska to the west coast, the strength of these linkages appeared to be weaker than that between the Pacific coast and the Tsukiji market. Since the Pacific coast is the larger producer of thornyheads, this finding indicates that the most important domestic ex-vessel markets for thornyheads may also be insulated from price changes in Japan.

Finally, another form of vulnerability theoretically facing U.S. harvesters involves a trade parameter under less direct policy control : changes in the currency exchange rate between Japan and the U.S. All prices used in this analysis are converted to U.S. dollars so that fluctuations in the exchange rate will tend to move prices of a traded good in opposite directions within the producing and consuming countries. Since the ex-vessel fixed gear sablefish markets are apparently not linked by price to the Tokyo market, exchange rate fluctuations should not impact production at the vessel level, although perhaps profit margins of processors or export brokers might be impacted. Since the Tsukiji price for thornyheads appears to follow that of the Pacific coast, much of any thornyhead price differentials caused exchange rate fluctuations may be expected to be absorbed by intermediaries or the by the Japanese market, itself.

ABSTRACT

*The Alaskan king crab industry has historically been one of the most lucrative fishing industries in the U.S. Last year the industry was staggered by low exvessel prices. An international marketing model of the Alaskan king crab industry is developed in this paper to provide insight into potential causes of price movements. Wholesale price formation and allocation for the two largest markets, Japan and the U.S., are explicitly modelled. Specific market conditions are shown to have resulted in an unusual structure to processor's price formation and product allocation. Recent events, including the deterioration of the U.S. wholesale king crab market and economic liberalizations in Russia, may have a profound impact on this industry. Model results are used to discuss the potential ramifications of these events to industry participants.*

## 1. INTRODUCTION

The Alaska fishing industry plays an integral role in the Alaskan economy. It is the state's largest employer, as well as the state's second largest private source of revenue. The fisheries have provided a steady, and even lucrative, source of income to fishery participants. However, in the past year, two of Alaska's most lucrative fisheries, sockeye salmon and Alaskan king crab, have experienced severely depressed exvessel prices. The low exvessel prices have been a cause of

* This report is the result of research sponsored by Alaska Sea Grant with Funds from the National Oceanic and Atmospheric Administration, Office of Sea Grant, Department of Commerce, under grant no. NA90AA-D-SG066, project # M/81-01, and with funds from the University of Alaska with funds appropriated by the state

great concern to fishery participants. In general, an understanding of the international markets for Alaskan fishery products is necessary if fishery participants are to gain insight into potential causes of past and future price movements, and for prudent investment decisions.

This paper examines the international Alaskan king crab market. An econometric model of historical product allocation and wholesale price formation for the two largest markets, Japan and the U.S., is developed. The detailed market structure is shown to contain unusual characteristics which have, in part, developed on the basis of Alaska being a dominant world supplier of king crab. This market structure has in the past helped support high prices to U.S. fishery participants.

The paper concludes with a discussion of how changing conditions, both within the market and in Russia, may be altering the basic market structure. These changes threaten the future stability of the Alaskan king crab industry.

## 2. BACKGROUND

Alaskan king crab are harvested during early fall in the western coastal areas of Alaska. The dominant harvest region is located in Bristol Bay. The crab fishery is managed by the State of Alaska through its Board of Fisheries and the Alaska Department of Fish and Game (ADF&). Commercial harvest of Alaskan king crab dates back to 1930, when Japanese fishers began harvesting red king crab (*Paralithodes camtschaticus*) in the Eastern Bering Sea. The domestic U.S. commercial fishery was not initiated until 1947.

The foreign fleet (comprised of vessels from Japan and Russia) were displaced through a series of Bilateral Agreements between the U.S. and both Japan and the USSR. The agreements resulted in declining annual harvests for both the Japanese and USSR fleets, beginning in 1966. The Soviet fleet had exited the king crab fisheries in U.S. territorial waters by 1972, and the Japanese fleet was completely displaced by 1976.

Harvests of Alaskan king crab by foreign (non-U.S.) vessels was further restricted with U.S. Congressional passage of the Magnuson Fisheries Management Conservation Act of 1975. Among its other provisions, the Magnuson Act extended U.S. territorial jurisdiction over all living marine resources to the 200 mile limit. Thus, the Magnuson Act, in conjunction with the earlier bilateral agreements, vastly reduced the harvest of king crab by the Japanese fleet. Since the mid 1970s, Japan's harvest of king crab has been limited to minor domestic fisheries.

Japan was a minor market for Alaskan king crab prior to 1973. However, as the Japanese harvest of king crab decreased, Japan became increasingly reliant on king crab imported from the U.S. The importance of the Japanese market increased rapidly in the 1970s. Japan's market share of U.S. harvested product was less than one percent in 1974 and 1975. By 1978, Japan accounted for one-third of U.S. king crab sales. Since that time, its market share has fluctuated between 10 percent and 50 percent, stabilizing in the late 1980s at around 44 percent. Japanese consumption of the highest valued species, red king crab, recently exceeded 90 percent of harvest.

The harvested Alaskan king crab is delivered live to either shore-based or floating processors. The processing procedure, and the subsequent market channel for the product, depends on the designated destination for the product. Crab destined for the U.S. market is brine (cooked) frozen in whole, or section and claws product forms. The frozen product is subsequently shipped to Seattle were it is reprocessed and placed in cold storage. Inventoried crab is shipped to brokers for distribution to the year-long U.S. wholesale market. The primary retail outlets in the U.S. differ by species, but include upscale restaurants (referred to as the white tablecloth trade), fish markets, supermarkets, and specialized catering. In addition, a portion of the Seattle inventoried crab is shipped to other export markets and a small portion is shipped to Japan.

Alaskan king crab destined for the Japanese market is processed in Alaska primarily in the raw (uncooked) frozen product form. It is shipped directly from Alaska to Japan. The raw frozen product form allows for secondary reprocessing to occur in Japan, where the product is subsequently processed into numerous different product forms which fill a variety of specific demand niches. It also allows the Japanese to control quality of the final products.

The Japanese retail market for king crab appears to be targeted primarily for the end-of-year holiday season. Alaskan king crab is a prestigious year-end gift item. Consequently, most of the Japanese purchases occur in the fourth quarter of the calendar year.

Thus, characteristics of both the U.S. and Japanese markets require that processors allocate live crab between the two markets early in the harvest season. Consumer preferences in Japan and the U.S. dictate that the king crab be processed in different product forms. Additionally, Japanese buyers must secure their supply of king crab early in the autumn harvest season if there is to be sufficient time for secondary reprocessing and distribution to retail outlets prior to commencement of the end-of-year holiday season.

Several market characteristics provide insight into processors product allocation behavior between the U.S. and Japanese markets. The early season designation of product to Japan allows processors to avoid shrinkage associated with holding the perishable raw frozen processed product in inventory. Second, shipment of the crab directly from Alaska to Japan allows processors to avoid transshipment costs to Seattle cold storage facilities, and also to avoid the capital costs of holding processed product in inventory. Third, early season sales to Japan firms up U.S. price by lowering available supplies throughout the remaining year. Finally, and most importantly, the Japanese pay cash at the time of sale. This provides processors with an early season cash flow that can be used to offset the cost of unprocessed crab purchases and subsequent reprocessing, holding and marketing costs. It also lowers processor risk by avoiding possible seasonal wholesale price declines.

## 3. MARKET MODELS

A model of allocation and demand for Alaskan king crab sections provides insight into how current changes in the world may impact the future health of the Alaskan king crab industry. The model represents a portion of a complete bioeconomic model of the Alaskan king crab industry (see Greenberg 1990, Matulich et al. 1991). The time periods in all models refer to the ADF&G seasonal year, July 1-June 30. The terminal time period in all models of 1987 (corresponding to July 1, 1987-June 30, 1988) was dictated by data availability.

### *3.1 Allocation*

A conventional economic treatment of allocative behavior and price formation involves arbitraging the alternative markets, where inventories buffer current and expected future prices. One would expect processors to simultaneously evaluate the price in each market and adjust allocation toward the market that has the higher net price, thereby extracting maximum profits across markets and time. Adjustments would continue until processors are indifferent between the market prices.

This arbitraging scenario involves modelling the processors' price offer to a particular market as a function of quantity allocated to that market, total available supplies, processing costs, the opportunity costs of holding inventories for future sale, and the alternative market price. However, processor behavior appears to deviate from this conventional paradigm because of the distinct market characteristics. Japanese buyers' early entry in the market, coupled with the advantages of Japanese market sales, have led to processors segmenting their price formation between the two markets [1].

Market segmentation became more formal following the fishery collapse of 1983, which severely disrupted product flow to Japan. Many of the processing firms were purchased wholly or partially by Japanese firms in the mid 1980s. This arrangement further assured Japanese access to product at a "fair" price, where fair refers ostensibly to a margin above exvessel price--the principal cost to processors. This notion of "fair" price was articulated in personal communication by many of the processors.

Equation (1) represents an unusual, simple relationship that exists in the Japanese market.

$$\underset{}{PSECTJ_t} = \underset{(2.57)}{0.40322} + \underset{(25.16)}{1.98705}\ AVEXVP_t \qquad (1)$$

$R^2 = 0.980$ df = 13

1. Conventional price arbitraging models were investigated. Estimation results were unsatisfactory, e.g. low t-values and incorrect parameter signs.

Japanese wholesale price of Alaskan king crab sections, $PSECTJ_t$ (\$/lb, FOB Alaska) is represented as function of the primary variable costs to processors, average Alaskan king crab exvessel price, $AVEXVP_t$ (\$/lb). The price offer function was estimated for the 1973-87 time period using ordinary least squares (OLS). This simple margin relationship accounts for 98 percent of all variation in the Japanese wholesale section price (t-values are reported in parentheses).

Processors' price offer was found not to be quantity responsive. Instead allocation to the Japanese market is implicitly determined by the Japanese demand at the price determined in equation (1). This suggests that the Japanese buyers may be more concerned with gaining access to a high quality product than with specific price. And that they are willing to support a price level that assures processors a fair return, in order to secure an early season supply.

One should not infer that this specification is a literal representation of the market behavior. Some brine frozen product is exported from Seattle to Japan later in the marketing year, indicating that limited arbitraging does occur. However, the influence of these sales is minor and statistically indiscernible.

In contrast to wholesale price formation captured by equation (1), the U.S. allocation equation corresponds to a more conventional market analysis, where supply and demand are determined simultaneously. The preferred log specification of U.S. section supply is given in equation (2).

$$\begin{aligned} \ln SECTUS_t = {} & -2.27711 + 1.35942 \ln PSECTUS_t - 0.78218 \ln AVEXVP_t \\ & (-2.28) \quad (3.11) \quad (-2.71)) \\ & + 0.83286 \ln(HARV_t - SECTEXPJ_t) + 0.33826 \ln(SECTHOLD_{t-1} + SECTIMP_t) \\ & (8.63) \quad (6.17) \\ & - 0.42519 \, IND83 \\ & (-3.30) \end{aligned} \tag{2}$$

$R^2 = 0.973 \quad df = 9$

where

$SECTUS_t$ is the section supply to the U.S. wholesale market (million lbs),
$PSECTUS_t$ is the New York Fulton Market frozen section wholesale price (\$/lb),
$SECTHOLD_t$ is quantity of frozen inventoried sections (million lbs),
$SECTIMP_t$ is the quantity of Russian crab imported to the U.S. (million lbs)[2],
IND83 is an indicator variable marking the year of fishery closure.
The quantity ($SECTHOLD_{t-1} + SECTIMP_t$) is treated as a separate supply variable. Russian imports did not begin until 1982, and neither variable is inventoried more than a single year.

Equation (2) was estimated for the 1973-87 time period using two stage least squares (2SLS). The model accurately estimates U.S. wholesale section supply, as indicated by the reported $R^2$ of 0.973.

The absence of the Japanese wholesale price in equation (2) highlights the recursive nature of the Japanese and U.S. wholesale markets. The Japanese wholesale market intratemporally impacts the U.S. market by reducing supply availability of king crab in the U.S. market, thereby firming U.S. wholesale price.

### *3.2 Demand*

The other side of wholesale product allocation and price formation is determined by consumer response to the wholesale price offers. According to the previously specified Japanese price offer function, processors set price on a margin basis with exvessel price. Japanese buyers then equilibrate the Japanese market by adjusting the quantity purchased according to Japanese consumer response to the price offer. Thus, price is an exogenous factor to Japanese consumers.

The Japanese demand function specified in equation (3) was estimated for the time period 1975-87. 1975 corresponds to the year that Japan ceased fishing in U.S. waters. The equation was estimated using nonlinear OLS, reflecting that price is exogenous. $SECTCONJ_t$ is set equal to $SECTEXPJ_t$ in a definitional identity. The model based on real income and prices outperformed its nominal counterpart.

2 Limited U.S. imports of Russian king crab began in 1982 under a special barter arrangement.

$$SECTCONJ_t = PSECTJ_t^{-2.01785} PCEJ_t^{2.73523} EXCHJ_t^{-2.37477} (IMPR_t + JHAR_t)^{-0.58745} SECTCONJ_{t-1}^{0.27327} \quad (3)$$
$$(-3.87) \qquad (7.25) \qquad (-6.90) \qquad (-5.00) \qquad (2.03)$$

$$\exp(-1.02920\ IND8287)$$
$$(-2.43)$$

$R^2 = 0.991 \qquad df = 7$

$SECTCONJ_t$ is expressed as a function of Japanese wholesale price and 6 demand shifters :

Japanese personal consumption expenditures, $PCEJ_t$ ($1,000) ;
the Japanese-U.S. exchange rate, $EXCHJ_t$ (¥/$, third quarter) ;
Quantity of substitute sources of king crab from Japanese harvest, $JHAR_t$ (million lbs), and
Russian imports, $IMPR_t$ (million lbs) ;[3] [4]
a measure of Japanese consumer habit formation for king crab sections ($SECTCONJ_{t-1}$).
In addition, an indictor variable, IND8287, was found to be significant, suggesting a structural break in demand beginning in 1982. In that year price more than doubled from the 1981 level. IND8287 equalled one for the 1982-87 period, and zero otherwise.

The fit is good, with 99 percent of the variation in price explained by variation in the explanatory variables. All parameters conform to a priori expectations and are significant at the 0.08 level.

The Cobb-Douglas functional form is characterized by estimated parameters representing constant elasticities. Several of the elasticities deserve examination. As would be expected for this high priced product, Japanese demand for king crab sections was found to be very responsive to changes in Japanese income. Section exports to Japan are estimated to rise (fall) 2.74 percent for a 1.0 percent increase (decrease) in personal consumption expenditures.

The elasticity associated with exchange rates is of special interest because this represents the most volatile explanatory variable in the demand function. A change in the exchange rate not only alters the effective yen price that the Japanese pay for king crab (price effect), but it also raises or lowers Japanese purchasing power in foreign markets (income effect).

The composite demand elasticity associated with these two effects can be derived from equation (3). Extracting the portion of the exchange parameter that converts $PCEJ_t$ to yen values (i.e., holding per capita consumption expenditures, measured in yen, constant), yields the cumulative price and income exchange rate elasticity. The resulting combined elasticity of -5.11 shows Japanese demand to be highly sensitive to exchange rate changes. The volatility of exchange rates in recent years translates into swings in Japanese demand, and potentially, substantial movements in the dollar price Japanese are willing to pay.

The responsiveness of the Japanese demand to both the exchange rate and income is particularly troubling to the U.S. industry given recent indications that the Japanese economy is slipping into a recession. The yen has recently weakened against the dollar, and declines in personal consumption expenditures are anticipated. These events could substantially depress Japanese demand for Alaskan king crab.

Finally, the Japanese harvest and Russian import elasticity of (-0.587) show these products to be substitutes for U.S. produced crab. Japanese imports of Russian product are of particular concern to the Alaskan king crab industry. There have been indications that Russian king crab exports to Japan have increased substantially in recent years. Time series data on Russian exports to Japan are not available. However, Russian export trends can be inferred from available data on Russian exports of all crab species to Japan. According to trade statistics reported by the Japanese Marine Product Importers Association, Russian exports between 1984 and 1988 of all crab species increased almost threefold. This trend of increasing Russian-Japan trade has continued through 1990. Russian exports of all crab species increased by 180 percent between 1988 and 1990.

U.S. demand for Alaskan king crab sections completes the market models. The demand function models the relationship between U.S. section price, $PSECTUS_t$ ($/lb) and U.S. section consumption, $SECTCON_t$ (million lbs), and demand shifters. $SECTCON_t$ is set equal to domestic supply in a definitional identity.

3. Price series were not available for either Japanese domestic king crab production or king crab imported from Russia. Instead quantities were used.
4. Historical time series data for Japanese imports from Russia were not available. The quantities used in estimation represent the quantity imported by one of Japan's largest importers.

The demand shifters fall within the same general categories as those in the Japanese demand model. U.S. personal consumption expenditures, $PCE_t$ ($1,000), are included as the measure of U.S. income. American lobster is included as a substitute for Alaskan king crab. A retail price series for lobster is unavailable. The lobster price, $PLOB_t$ ($/lb), represents an exvessel price index for lobster compiled by the National Marine Fisheries Service. It is assumed that exvessel price is linearly correlated with retail lobster price. Lagged U.S. section consumption, $SECTCON_{t-1}$, provides a measure of consumer habit formation. The indicator variable IND83 marks the year in which the Bristol Bay Fishery was closed.

Quantity and price dependent demand functions were estimated in both linear and nonlinear functional forms. The inverse demand function given in equation (4) provided the best results. Models in which income and prices were included in nominal terms consistently outperformed the real term counterparts. Simultaneity between $PSECTUS_t$ and $SECTCON_t$ required the use of 2SLS in model estimation. The linear specification of the inverse demand function provided the best results.

$$\begin{aligned} PSECTUS_t = {} & \underset{(-2.41)}{-2.06135} - \underset{(-4.46)}{0.04361}\, SECTCON_t + \underset{(1.72)}{0.00152}\, PCE_t + \underset{(2.35)}{2.15540}\, PLOB_t \\ & + \underset{(1.73)}{0.01501}\, SECTCON_{t-1} + \underset{(1.84)}{1.25166}\, IND83 \end{aligned} \tag{4}$$

$R^2 = 0.972 \qquad df = 12$

U.S. demand was modelled for the 1970-87 period. All parameters conformed to a priori sign expectations. The ability of the model to estimate wholesale price changes is reflected by the reported $R^2$.

The results from the estimated model show that U.S. consumers are highly responsive in their purchasing behavior to price changes. And that price was nearing the choke price. The estimated mean price flexibility coefficient for section consumption of -0.359 suggests that even small increases in U.S. price will severely depress consumption. This in fact occurred in 1991, one year after the model was completed. An industry report indicated that the domestic market all but vanished, in large part due to high prices (Murphy 1991).

## 4. DISCUSSION

Development of the Japanese market provided great benefits to the Alaskan king crab industry and was the primary reason why prices, both wholesale and exvessel, achieved record levels in 1990. Processors focused attention on Japan, virtually ignoring the domestic market. By entering the market early and "pulse buying" before U.S. buyers enter the market, by assuring U.S. processors a "fair" margin above exvessel price, and by paying cash, Japan has effectively segmented the market, leaving the U.S. market as a residual market. Discussions with industry representatives indicate that the U.S. market has been neglected and become perilously thin in recent years. A recent industry report stated that "... distributors (seafood) expressed a strong conviction that Alaskan king crab processors were in the process of abandoning the American market for a more profitable Japanese market (Murphy 1991)." The report further stated that recent high prices and changing consumer tastes have led to Alaskan king crab losing its position in the U.S. white tablecloth, fine dining segment. The industry will have difficulty recovering this lost market segment.

This suggests that in the near term the financial well-being of the industry is dependent on the Japanese market, and a market structure based on the U.S. being the dominant supplier of king crab. However, a structural break in the industry may be likely in the near future due to increased king crab trade between Japan and Russia.

Little is known (outside of Russia) about the Russian king crab industry. The center of the industry is Vladivistok, which is only a few hundred miles from Japan. Russian fisheries are believed to contain immense king crab stocks. This is reflected by the 1990 Russian harvest of approximately 92 million pounds (FAO 1990). In comparison, the 1990 U.S. harvest was approximately 33.4 million pounds (ADF&G 1990). Most of the harvested crab from Russia has been canned and exported to Europe. Canning of Russian product is a consequence of two dominant factors. First, the Russians lack modern freezing technology. They do process limited quantities of "blast frozen" product, but quality appears to be problematic. The Russian product suffers from "over-cooking," salt penetration and improper freezing. Thus, Russian

processed king crab is viewed by Japanese buyers as being an inferior product to Alaskan king crab. Moreover, the Russia Far East has virtually no cold storage facilities to support rigorous expansion into either the Japanese or U.S. markets. Limited technology, capital, and marketing skills have in the past restricted the Russian king crab industry, resulting in production of an unnecessarily low valued product that has not been able to fully penetrate the Japanese market. Correction of these deficiencies will greatly enhance the value of the Russian product, and permit Russian king crab to compete in markets which have been traditionally dominated by the U.S. king crab industry.

There are several reasons why this development should be expected to occur. Russia is in desperate need of hard currency. Development of the king crab industry would lead to the production of a high valued product that can be exported to the wealthy, enormous Japanese market (and potentially the U.S. market). Additionally, unlike terrestrial resources (e.g. timber and minerals), development of the king crab industry would not require costly capital investment in infrastructure.

Joint ventures between the U.S. and Russia, and Japan and Russia could provide necessary capital, technology, and marketing skills, which Russia lacks. Currently, limited joint ventures between the U.S. and Russia exist. The proximity of the Russian fishery, and the strong consumer demand for high valued king crab, provides a strong impetus for Japanese investment in the Russian king crab fishery. Increased trade linkages between capital poor but resource rich Russia, and capital rich but resource poor Japan could provide significant benefits to both countries.

We can speculate as to the consequences to the U.S. king crab industry of increased Russian production of high quality king crab. The development of an alternative king crab supply source can be expected to lead to a structural break in the Japanese purchasing behavior. Japanese buyers will be able to arbitrage across the U.S. and Russian processed product markets. The resulting equilibrium price in Japan should be substantially below the current Japanese price for Alaskan king crab, and above the current Japanese price for Russian king crab.

Increased Russian exports to Japan will result in U.S. product, previously allocated to the Japanese market, entering the U.S. marketing channel. This would depress U.S. wholesale price. Additionally, Russian product may be exported to the U.S., further depressing U.S. price. Reductions in U.S. and Japanese wholesale prices will be passed along to U.S. fishers in the form of substantially lower exvessel prices.

The 1991 U.S. fishery season may have provided a preview of future structural changes in the Alaskan king crab industry. Japanese purchasing behavior in 1991 deviated from past behavior. In the past, Japanese buyers have reached agreements with U.S. processors early in the harvest season. The agreements specified both price and quantity. As noted in the development of the market model, this price was based on exvessel price. However, in 1991, agreements between U.S. processors and Japanese buyers were delayed. This resulted in a portion of the processed product being shipped to Japan without a firm price offer. Exvessel price in Alaska dipped severely from the 1990 price of $5.00 per pound, to $3.25 per pound.

The cause of these changes in Japanese behavior can not be determined without additional information. One possible explanation is that the Japanese buyers, aware of the demise of the U.S. wholesale market, exerted increased market power--Japanese buyers took a more aggressive role in setting price.

Alternatively, the depressed market prices may have resulted from increased Japanese imports of Russian crab. There were unconfirmed reports of extremely large shipments of Russian king crab to Japan immediately preceding the opening of the 1991 Bristol Bay red crab fishery.

The emergence of Russian fisheries has implications extending beyond the king crab fishery. For example, Russia may emerge as an important source of Tanner crab and sockeye salmon. As with king crab, Alaskan fisheries have been the primary supply source of these species, and Japan has been the dominant market. Thus, gaining additional information on Russian fisheries and incorporating this information in future market models is critical to gaining insight into future performance of Alaskan fisheries. Efforts, funded by Alaska Sea-Grant, are currently underway at the University of Alaska Fairbanks toward achieving these objectives.

So what does the future hold for the Alaskan king crab industry ? The results of this analysis suggest that the outlook is less than rosy. A weakening yen, coupled with prospects of a recession in Japan, will put tremendous pressure on price. Continued growth in trade between the Russian Far-East and Japan will further exaggerate any price slippage. But the real wild card is whether processors can recapture the domestic market at a price that keeps the fleet fishing. The 40 percent drop in exvessel price last year sets the stage for a major restructuring of this fishery.

ABSTRACT

*Given the significance of the purse seine fleet to fish supplies in Java, an island in Indonesian with a population approaching 100 million, the paper analyses the relative importance of several interactive factors on Javanese purse seine vessel catch and economic performance, including the effects of vessel size, age, speed, net size, use of fish aggregating devices (FADs) and fishing lights, lunar period, season, oceanographic and weather characteristics, distance to and location of the fishing ground, the impact of navigation, fish location and communication aids, 'fleet cooperation' and 'fleet congestion', time/distance to port auction, auction size and purchasing power, general fish supply and demand conditions, etc.*

*The importance of vessel size on fishing pattern and preservation method(s) used is highlighted, as is the importance of lunar period and brightness of artificial fishing lights.*

## 1. INTRODUCTION

The Java Sea small pelagics fishery has immense biological, social and economic importance (McElroy, 1991a ; 1992a). This fishery yields over 400,000 tons/year, with an ex-vessel value in 1991 estimated at over US$ 220 million.

* The author wishes to thank the two Project Co-Directors, Thiery Boely and Johannes Widodo, the counterparts Abdull Sari and their counterpart organizations. Special thanks go to the Landell Mills Ltd. team members, Naval Architect Chris Temple and Post-harvest Specialist Ivor Clucas and to ORSTOM's Biologist Michel Potier for their advice and open discussion. Responsibility for any misconceptions and omissions remains with the author.

This work is being funded by the European Community under the 'Java Sea Pelagic Fishery Assessment Project', ALA/INS/87/17. This paper reports on 'work in progress' on vessel economics.

The Java Sea small pelagics resource base is being heavily exploited throughout its range and for many stocks throughout much of their life cycle by a variety of fishing gears, including *bagan* (lift net), gill net, *payang* and purse seine. A large subsistence economy (using small-scale gears and vessels) plus commercial enterprises (using medium-scale vessels) depend upon these resources for their own nutrition and as a source of income. Indeed, currently, the Java Sea small pelagics fishery is the single most productive fishery in Indonesia.

No empiracle study on the techno-economic performance of the Java Sea purse seine fleet has been carried out to date. Pre-1980 studies on the economic performance of both small and large Java Sea purse seine vessels have recently been reviewed (Bailey et al, 1987). These studies suffered from covering only one season, or the sample being very small. A few aggregate studies were carried out in the second half of the 1980s (see RMC/PMO, 1987 ; Bandjono et al, 1989 ; McElroy, 1991a, 1992a).

This paper chronicles changes in the fleet size, and the main technical innovations that have taken place since the introduction of the purse seine vessel to the Java Sea about 1970. The present-day vessels have evolved gradually. They remain technologically simple, with none of the current fleet of inboard purse seiners being engaged in 'active' fishing, neither using sonar in 'open water' to locate fish schools, nor power block to haul the net[1].

The fishery, today, is a 'passive' one, more closely allied to mobile 'light fishing', such as *bagan* or 'lift net' fishing operations, than the activities generally associated with modern purse seine fishing involving the hunting for and setting on schools of pelagic fish in 'open water'. However, such concepts as 'active' and 'passive' fishing are misleading in a mobile light fishery where vessels shift grounds according to the latest fleet information on the location of good fishing areas, concentrate or disperse according to the pattern of distribution of the fish, and 'filter' large volumes of water with the use of lights and *rumpon*, a fish aggregating device. The success of this fishing technique probably reflects the particular distribution patterns and behavioural characteristics of these small pelagic fish. As such, it may well be the most techno-economically appropriate.

## 2. MATERIALS AND METHODS

Primary data on vessel characteristics was collected in February/March 1992 by undertaking a 'frame survey' of nearly 40 purse seine vessels, large and small, at the two major fishing harbours of Pekalongan and Juwana (Bajomulyo). Trip data for a sample of vessels was collected at the same time, and supplemented with trip data collected by the project's permanent staff. The data covers : date of departure, date of return, main fishing ground, number of sets made, number of holds filled - sometimes with the split between fresh and salted fish given, date(s) of unloading at the auction, and volume and value of the fish auctioned for the period January 1990-March 1992. In addition, data was collected on queuing times, species composition, quality grade and unit price for a sample of vessels.

Cost and earnings data for a sample of twelve large purse seiners (over 20 m keel length) and five small purse seiners (below 20 m keel length) was collected from vessel owners, and verified/supplemented with data collected by the harbour administrations, etc. This data covers the same period, namely January 1990 - March 1992, although data for some (new) vessels is of a shorter duration. This data analysis is not yet complete. Consequently, the results reported here should be taken as indicative rather than definitive.

Where secondary data is used, the source is indicated.

### *2.1 Catch and Economic Performance*

A number of factors affect both the catch and economic performance of any small pelagic purse seiner fleet 'light fishing'. The principle factors affecting catch performance of a vessel are likely to be : vessel size (grt or hold size), age, power

1. Active fishing', using sonar and power block, have been tried in the Java Sea. Indeed, a State-owned fishing company, PT. Tirta Raya Mina, was set up with the purpose of introducing this technology into the Java Sea in the 1970s. Whilst catches were reported to be satisfactory, the economics of this method of fishing were unfavourable for this company at that time. Since then, at least one private company has attempted to introduce purse seine fishing using sonar and power block, on traditional wooden vessels. This attempt was abandoned after two years, again reportedly due to unfavourable economics compared to the traditional 'passive' fishing method, using large crews to haul the net. These vessels may still be using sonar, however, to select suitable locations to fish using fish aggregating devices, notably rumpon and artificial lights.

(Hp) and speed ; number and size (or fishing power) of Fish Aggregating Devices (FADs), namely rumpon, and fishing lights used ; net and mesh size ; other fishing equipment and communication systems used ; crew size and skill ; abundance and distribution of the fish stock(s) ; lunar period ; season ; oceanographic factors (current and wind, direction and strength) ; weather ; location of and distance to the fishing ground ; 'fleet cooperation' and 'fleet congestion'. These factors are interrelated, some being more important than others under specific circumstances.

The principle factors affecting the economic performance of the vessel include all of the above, as each affects catch performance, while factors related to fish quality and fish price need to be added. These factors include : preservation method used (ice, salt) ; the effect of trip duration (including time spent in port waiting to unload) on fish quality and remaining 'shelf life' ; insulation ; quantity, application and quality of ice and/or salt used ; time/distance to port auction ; auction size and purchasing power, etc.

### *2.2 Technical Innovation*

According to Cunningham et al (1985), technical innovations are concerned with improvements in the technique of fishing or in attempts to find the optimum combination of gear, equipment and operating procedure. They are essentially directed at maximizing vessel profitability, either by increasing catch and/or revenue or reducing the cost of fishing. However, technological change in fisheries is a two-edged sword (Bell, 1978). That is to say it may have a favorable or detrimental effect on economic performance, depending on the circumstances. Essentially, while a particular innovation may be of benefit to the innovating vessel, if adopted by a significant proportion of the fleet, it may increase the catch efficiency of the total nominal effort, which in a normal fishery of limited productive capacity may have one of two outcomes :

i) total catch increases, or

ii) total catch is reduced.

In the measurement of fishing effort, nominal fishing effort (number of vessels, total fleet horsepower, total days at sea, total time spent searching) is related to effective fishing effort by the catchability coefficient, or the measure of how much fish can be caught per unit of nominal effort. We can measure the impact of technological change by measuring changes in the catchability coefficient. However, whether output goes up or down as a result of technological change depends upon the level of exploitation of the fish stock(s).

### *2.3 Measures of Fishing Effort*

To date in the Java Sea purse seine fishery, all authors have suggested or used the single parameter 'days spent at sea' as a practical measure of fishing effort. This measure has also been converted to 'standard effort units' by adjusting for changes in the propulsive power of the fleet (i.e. total main engine horse power) (Potier and Suherman, 1991). At best, this adjustment may be considered a proxy for changes in vessel size. But, given that the method of fishing is essentially 'passive', relying on the power of attraction of rumpon and fishing lights, the best measure of fishing effort in this fishery remains to be found.

The number and size of vessels, fishing technology and fishing techniques employed, have all changed since the early 1980s, and the measure 'days spent at sea' may no longer be, if it ever was, the most appropriate.

This paper attempts to analyse the impact of changes in fishing technology and technique upon catch efficiency (catchability coefficient) over the past 12 years, which incidentally coincides with the rapid expansion of the Java Sea small pelagic fish catch.

As Figure 1 illustrates, the measure 'days spent at sea' has been fairly insensitive to large changes in light fishing power, which may have increased between 2 to 4 fold over this period on average.

## 3. HISTORICAL DEVELOPMENT OF THE FLEET

Four phases in the development of the Java Sea purse seine fleet can be distinguished to date (information based largely on Atmadja and Sadhotomo, 1985 ; Nurhakim et al., 1987 ; Potier and Suherman, 1991 ; and Potier and Boely, 1991).

*Phase 1 (1970-1975).* The *introduction and widespread adoption along the north coast of Java of purse seine vessels,* with a variety of different engine (inboard, outboard) and gear arrangements, size of nets and fishing methods, including active daytime searching. The inboard powered vessels mostly operated from bases along the north coast of Central Java province. Trip lengths were 1-5 days long, extending to 3 - 6 days by the end of this period, with fishing grounds between 3-16 hours from port. The vessels, mostly between 5 - 20 grt, were active for about 8 months each year, with night-time fishing concentrated in the new moon period. Other purse seine vessels, particularly in East Java province, were powered by outboard engine. No 'assist boat' is used.

*Phase 2 (1976-1981).* This period is characterized by a *second pulse of new vessels* , with conformity in the size of new vessel (20-30 grt), engine (120 or 160 Hp) and net (typically 400m x 60 m) ; the shift to 'passive' rumpon fishing, with Petromax lights being used at night. The fishing grounds remained within 1 day's journey time, and trip lengths averaged 3-7 days. The number of new vessels and the average vessel size in the fleet increased dramatically in 1978 and 1979 as a result of the new additions. In 1981, some of these vessels were venturing further from Java, which resulted in some fish being preserved at sea in an ice-brine mix.

*Phase 3 (1982-1986). Expansion of fishing area to cover the whole Java Sea followed by a third pulse of new, larger vessels, particularly in 1985 and 1986,* resulting in a further expansion in fleet capacity. The trawl ban came into effect in the Java Sea in January 1981 and had spread throughout the area by the end of 1982. Grants were provided to change to other fishing methods, and purse seine fishing was promoted as a suitable method as the small pelagic fish stocks were underutilized in areas far from the north Java coast and offshore islands. As more vessels entered the fleet between 1983 - 1987 to take advantage of the higher catch rates available, they got progressively bigger in size, and fished further from Java, by the end of this period operating throughout the Java Sea proper, and extending into the South China Sea (Pejantan) and Makassar Strait (e.g. Lari-larian) at certain times of the year, in their search for productive year-round resources to fish. Besides the continuing expansion in vessel size and fleet capacity (though not vessel numbers), this period is also characterized by the widespread adoption of wet salted fish preservation at sea, introduction of the first electric-powered lights (about 1983/84) and SSB radios (about 1985/86). Trip durations had also risen, by the end of this period of up to 40 days during trips to fishing grounds four to five days one-way journey time away.

*Phase 4 (1987-present). Increased emphasis on technical innovation, widespread adoption of electric fishing lights and SSB radio, the consolidation of vessel numbers over the period, with a fourth pulse of new vessels, particularly in 1991 and 1992, to take advantage of the better port facilities.* This period is characterized by the consolidation of vessel numbers as old vessels are withdrawn and new vessels added, the dramatic increase since 1988 in the number of 'fresh fish' purse seine vessels, making shorter trips of 7 to 12 days at sea, a general increase in vessel engine power (ranging from 250 - 360 Hp for the largest, new vessels of 100 - 130 grt), the growth in size of the mixed fresh/salt fish purse seiners as port facilities (water depth, length of unloading wharf, size of auction area, etc) improve. Technical innovations and adoption have also become more important, with the widespread use of radio, an increasing emphasis on the use of more powerful electric lights and generators, the introduction of halogen lights, the decreasing reliance on *total numbers* of rumpon for fishing, the increasing use of polyurethane for improved fish hold insulation in place of polystyrene, etc.

## 4. VESSEL OPERATING PATTERN

### *4.1 Large purse seiner*

#### 4.1.1 Preparing for Departure

A large purse seiner normally spends *two days* to load fuel, water, ice, salt, rumpon, food. One of these two days is set aside to take ice onboard. Fifty tonnes of ice represents 1,000 50 kg blocks, each of which is, in part, man-handled into the vessel's holds. Time spent preparing for departure ranges from 1 - 2 days in the peak season, to 2 - 5 days in the low season. Total port turnaround times, after waiting-to-unload and unloading the catch which can take between 2 - 5 days, is normally less than 7 days.

### 4.1.2 Selecting fishing ground

Selection of the target fishing ground commences before the vessel leaves port and is largely based upon information received by radio from vessels of the same company (or, on the 'open waveband' radios, from other vessels) which are still at sea fishing. In general, though, the seasonal distribution of small pelagic fish in the Java Sea is nowadays well known, so the target fishing ground or grounds for a particular period will normally be the same from year to year. During the journey, regular updates of success on different fishing grounds is received, particular attention being paid to the good fishing grounds, as the location of these within a general area may change over a short period.

### 4.1.3 Outward Journey

The vessel normally sets off on a rising tide, and at night. Typically, fishing grounds are 1.5 - 4 or 5 days journey time for these vessels, which have speeds of 6 - 7.5 knots (laden). Navigation is by compass bearing and time, making use of the many island groups and peaks for waypoints. Normally, no chart is used. The Nakhoda (captain) and boswain remember the course bearings to the different grounds. Indeed, less than half the vessels appear to carry charts with them. None use position fixing equipment such as radar or Global Satellite Positioning (GSP), the other feasible options. Almost all vessels today have 'open band' Single Side Band (SSB) (mostly ICOM) radio for communication between vessels and with home port/company. Although not a legal requirement for vessels officially registered as below 100 grt (which basically covers over 90 percent of the present fleet), the use of radio has been officially encouraged as an important safety feature.

### 4.1.4 Locating good fishing grounds

Once the vessel arrives at the fishing ground, she will normally use rumpon of vessels from the same company for setting upon the first night. Alternatively, she may use rumpon she placed on the previous trip. If the area is good, she will place about 5 rumpon of her own the next morning. A number of features are considered in setting the rumpon. Water depth of between 40-80 m, ideally between 50-65 m is chosen. Water colour is also used. Areas with turbid or murky water are avoided as they have low water transparency for light fishing and are not good fishing grounds ; areas of clear, transparent water are chosen, where the rumpon show a good fish presence. The presence of fish schools in the early morning and mid to late afternoon is another indicator. The presence of small pelagic fish is thought to be related to different water masses which move into and out of an area seasonally. But within a given water mass, current streams and particularly their interfaces are good indicators. Areas of upwelling, close to islands, underwater features, and especially near the edge of the continental slope are often favourable.

### 4.1.5 Fishing Operation

The fishing operation has been described recently (Wijopriono et al, 1991 ; Dremiere and George, 1991 ; and Temple, 1992)

The 'fishing operation' starts in the afternoon by checking individual rumpon, using a handline with about 12 small, unbaited, hooks (*brandil*). From those which indicate a good school of fish near the surface, one or two are chosen for setting upon that night. New rumpon will normally have a school of fish after 3-4 days of setting out. Sometimes, if a good fishing ground is found, newly set rumpon can be used immediately (the same night) because fish are already schooling nearby.

After checking wind and current direction, the vessel manoeuvers into position, and drops its anchor, drifting back to within 10-20 m of the rumpon, normally positioned either to starboard or to stern of the vessel. (The actual position changes over the tidal cycle). A line is normally attached to the rumpon to 'hold' the vessels position near that of the rumpon.

The electric lamps are switched on towards nightfall (at sunset). The spotlights are directed to the area of the rumpon, the objective being

(i) to concentrate the fish already schooling around the rumpon into a tight group, and to bring them near to the surface, and

(ii) to attract other fish, passing in the current within visual distance of the vessel during the next several - to ten -hours, to the vessel's lights.

Normally only one set is made a night, and this is carried out in the early morning, commencing at between 03.30-04.30 h., to allow the maximum time for light fishing. But sometimes two sets and, occasionally, three sets per night may be made, each on a different rumpon, especially if the fishing ground is poor or over the full moon period when catches can be more erratic. One strategy here is to fish over deeper water to help offset the high background illumination of the moon. If two sets are made, the first set is normally commenced between 20.00 - 22.30 h. for the large purse seiner, with the second set still being made between 04.00-04.30 h (Wijopriono et al., 1991).

As no 'light vessel' is used, the purse seine vessel's lights must be switched off before the net is set. Also, the *rumpon*'s anchor must be lifted across the vessel before the purse rings are closed. Yet at the same time, as far as possible, the fish attracted to the light and *rumpon* should not be disturbed !

The procedure currently in use is as follows. Before the electric lights are switched off in turn, they are replaced using a floating raft holding a bank of kerosene lamps, attached to the *rumpon* by a line, and held in place by a swimmer. Next, the *rumpon*'s anchor line is lifted on deck. The anchor section of the line is untied. A stone used to weight the floating coconut leaf section is tied on, before this end of the line is returned to the water. The *rumpon*'s bamboo float is now held in position by two swimmers wearing inflated rubber inner tubes, with the float-mounted kerosene fishing lamps attached. The vessel moves off and manoeuvres into position, with the '*juruarus*' (literally, current specialist) in the water signaling updates to the skipper on the position, and if moving off, the direction the school of fish is swimming in. Only then is the net set.

Setting the net depends upon its size, and the vessel's maximum speed ; for one large purse seiners it took on average just under 4 minutes, while for a mini purse seiner two minutes was sufficient. Next, the rumpon and floating lamps are pulled to the side of the net furthest away from the vessel as the purse rings are being closed by winching in the purse line. This is to avoid fish being attracted by any lights on the vessel and escaping through the open net under the vessel. After the bottom of the net is closed and the bunt formed (which took on average 13.5 minutes on the large purse seiner) the lamps and rumpon are brought to the side of the vessel and hauled on deck. The headrope and body of the net are hauled on deck by the large crew, totalling 35 - 40 men. Later, two derricks, one forward, one aft, are used to lift the headrope out of the water and towards the vessel's side, while a scoop net is attached to a third aft derrick for scooping up the catch in the net, before bringing it over the side, and tipping its contents into a fish hold.

Typically, catches range from 0 - 10 tonnes per set, though average catches are generally less than three tonnes per set.

### 4.1.6 Catch rate

To date, only a small amount of catch rate data per set, per night, per lunar day or quarter, per month and season has been collected for individual vessels, although considerably more effort in this area is planned (Figure 2). Currently, more extensive data is available for vessel catch rates/trip, where the number of days at sea, main fishing area and reported total number of sets is recorded, allowing the average catch per set and per night to be calculated (McElroy, 1992b).

To date, the most intensively studied trip data covers a 23 day trip made by KM Mustika Sakti, a large purse seiner, between mid-September to early October 1988, in the eastern part of the Java Sea in the peak fishing season (Wijopriono et al., 1991). The following data was calculated :

| No. of sets | No. of Zero Set | Total catch (tonnes | Average (catch/set) (ton/set) | No.of nights fishing | Average catch/night fishing (tonnes/night) |
|---|---|---|---|---|---|
| 23 | 1 | 26.96 | 1.17 | 19 | 1.42 |

Figure 3 presents a cumulative distribution of this small sample of data. The narrow range in both catch/set and catch/night is noteworthy, respectively 0 - 3.5 t/set and 0 - 3.5 t/night. Both the median (50 percentile) catch/set and catch/night was just 800 kgs, indicating the weighted distribution towards below average catches. However, too much should not be read into this particular distribution, as most fishing took place in the second and third lunar quarters (i.e. with the full moon period occurring in the middle of the trip). Nevertheless, it does indicate this period coincides with the period of lowest catches, even is the main fishing season.

*4.2 Mini purse seiner*

The main differences between the operating pattern of the mini purse seiner and the large purse seiner relate to their different product targets. While the large purse seiner generally will remain at sea until its fish holds are full (with most of the fish normally heavily salted, and only the last 3-5 fish holds retained for 'fresh' fish) or until supplies such as food and ice are nearly used up, the mini purse seiner aims to bring back fish of 'fresh' quality only. Its maximum trip length is fixed by the keeping characteristics of the small pelagic fish species in ice. This is put at between 9 to 12 days, after which they are suitable for the production of salted dried fish up to a maximum limit of 16 days (Clucas and Reilly, 1992). As fresh fish achieves a considerable price premium, depending upon its quality grade, trip lengths for mini purse seiners are normally restricted to a maximum of 10-12 days at sea, with trips of 7-10 days being normal.

For most of the year, the most productive fishing grounds in the Java Sea are too distant for the mini purse seine vessels to fish. With catches likely to be lower/set and more erratic, mini purse seine vessels attempt to overcome this shortfall by generally fishing two rumpon per night, with a maximum of three being fished. They also favour grounds which, on a seasonal basis, yield a higher proportion of the higher value small pelagics, such as mackerel, trevally and little eastern tuna (tongkol).

Interestingly, as a general rule the mini purse seiners have been slower to adopt useful innovations adopted quickly by the large purse seine fleet, such as electric lights to replace kerosene lamps and radio. This is at least in part a result of the difference in their ownership, they being owned typically by small family businesses, with limited capital resources of their own. Some of the large company groups operate a fleet comprising both fresh fish and mixed fresh/salt fish purse seiners. Their vessels tend to be better equipped.

## 5. CATCH PERFORMANCE

Catch performance is affected by both endogenous and exogenous factors.

*5.1 Exogenous or 'non-controllable' factors*

The main exogenous factors in this fishery are environmental, namely :

(i) weather

(ii) oceanographic factors

(iii) lunar cycl

### 5.1.1 Seasonal factors

Rainfall and salinity are probably the main environmental factors affecting seasonal fluctuations in small pelagic fish distribution and abundance in the Java Sea (refer Potier and Boely, 1990). These are affected in turn by the general movement of air currents across the Java Sea and of sea masses into and out of it, which has a definite seasonal pattern.

The peak fishing seasons in the Java Sea occurs between September, October and November in the eastern part, around Masalembo and Matasiri. A second, smaller peak normally occurs around June and July, off the north coast of Central Java and its offshore islands of Karimunjawa.

Between December and April in recent years, most large vessels have fished off south-east Kalimantan, around Lumu-lumu and Lari-larian. Between May and June, some vessels venture to the islands near Pejantan, west of Kalimantan, in the South China Sea. Generally, it is uneconomic for the smaller vessels to make these longer trips. Even for the larger vessels, the lower catch rates result in long trips with a larger portion of the catch being preserved in salt, generating lower incomes and higher costs for the vessels.

### 5.1.2 Lunar cycle

The lunar cycle affects the 'local' behaviour of small pelagic fish, with higher catches associated with the use of fishing lights during the two lunar quarters centred on the new moon, and lower catches during the two lunar quarters centred on the full moon, irrespective of the season.

## *5.2 Endogenous or 'controllable' factors*

The most important 'controllable' factors on the catch performance of the Java Sea purse seiners 'passive' method of night-fishing are the number and size (or fishing power) of Fish Aggregating Devices (FADs), namely *rumpon*, and fishing lights used.

During the 1980s, the method of purse seine fishing has shifted from relying on fixed physical fish aggregating devices (FADs), with kerosene lamps when fishing at night, to the increasing, even total, reliance on 'fishing with light', which, traditionally, probably accounted for the greater of the catch taken by most purse seiners. Today, in Indonesia, some vessels have dispensed with FADs in good fishing areas, relying solely on the power of attraction of high illumination artificial lights. Normally, though, both FADs and light attraction techniques are still used in combination.

### 5.2.1 Fish Aggregating Devices

These devices are designed to exploit the behaviour of small pelagic fish. The use of bamboo and coconut FADs as a method of fishing small pelagic fish dates back at least to the 19th century (Zerner, 1991).

Today, the *rumpon* FAD typically consists of a bamboo float and weighted anchor line, into the top part of which is interwoven branches of coconut leaves every 0.2 - 0.3 metres, forming a structure resembling an underwater 'christmas tree', somewhat bent by the current near the surface. Fish are attracted to such fixed structures in the sea. No-one is sure exactly why.

Between 10 - 20 *rumpon* are taken on board each trip, depending upon season, and whether the vessel is returning to a ground it recently fished. More rumpon are taken during poor fishing periods.

### 5.2.2 Light Fishing

But probably the most important innovation during this decade was the introduction of ever-more-powerful electric-powered lights to replace pressurized kerosene wick lamps, and, thereby, increase catch per night.

As one observer recently stated, "at night the area of sea around a vessel is lit up like a floodlit playing field, which from a distance, with vessels strung out in a line, resembles an illuminated section of highway out at sea !"

While a fishing lamp, which can be seen miles away in air, will be visible at a distance, at most, of a few tens of metres underwater because of the high extinction of light in water, nevertheless, brighter fishing lights have a greater fishing efficiency because of their increased radius, and hence volume, of attraction. In the sea, which is subject to currents, brighter lights translate into a greater volume of water 'sieved' for fish.

Fish are attracted to light. The effectiveness of an artificial light source is greater (1) the lower the background light, and (2) the brighter the artificial light source. Thus a given artificial light source is most effective attracting small pelagic fish at night during the new moon (dark) phase compared to the full moon phase (when background illumination is relatively high). Lift net (*bagan*) fishermen, using kerosene wick lamps at night, have exploited this characteristic behaviour of fish to catch anchovy and sardine for many years.

Electric lamps, apparently first introduced about 1983-84 by Pekalongan vessels, were adopted quickly as standard equipment. Virtually all the large purse seine vessels based at Pekalongan employed electric lights (standard or mercury lamps) by the end of 1987, although smaller purse seine vessels have been slower to adopt this technology.

The lamps are powered by an auxiliary diesel engine and generator. Since their introduction, both the size of generator and total power input of the lamps has continued to increase. Generators producing 10 Kw of power have been in use

on some vessels since 1986. Typically, by 1992, the total power input of the banks of electric lamps located port, starboard, and sometimes aft, of the wheelhouse and on the forward mast of the large purse seine vessels ranged from about 6.0 - 12.0 kilowatts, with individual lamps ranging between 250 - 1,500 watts. This compares to 200 - 300 watts for the standard Petromax kerosene lamp, amounting in total to about 1,500 watts per float with 6 units.

Also, there has been a shift, since 1990, towards using some 'Galaxy' halogen lamps, which are enclosed in sealed units, have better reflectors and a more focussed beam, with a higher power rating, and possibly emit a better frequency spectrum for attracting fish.

Normally four to six halogen lamps are fitted, located high up on both port and starboard sides of the forward part of the wheelhouse and forward mast, from where they can be directed to the area of the *rumpon* and passing shoals of fish. Indeed, by the start of 1992, in apparent recognition of their greater effectiveness, several of the newest vessels were fitted with 'all halogen' lamps. Some older vessels had also been converted.

Such 'all halogen' lamp purse seine vessels are understood to be common now in Malaysia and Philippines also.

### *5.3 Net and mesh size*

Based on a small sample of vessels, there does not appear to be a marked relationship between net size (length, depth) and catch performance. Net size is not considered a critical determinant of catch efficiency. Indeed, in most setting situations the nets are considered to be 'oversized'. Typical sizes are : large purse seiner 450 m x 100 m ; small purse seiner 350 m x 75 m.

Mesh size, which is 3/4" (19.05 mms) only in the two net pieces which make up the bunt and 1" (25.4 mm) in the main body and wings (Barus et al, 1991), is sufficiently large to allow many juvenile fish to escape.

### *5.4 Crew size and skill*

The number of crew on a purse seiner is determined by the skipper, but essentially depends upon the net size, as the function of most of the crew is as labour to haul the net. Crews range in size from 25 for a small purse seiner to 40 for a large purse seiner.

Fishing skill is notoriously difficult concept to assess objectively. Ultimately the skipper is responsible for selecting his crew. Certain skippers have 'good reputations', and their vessels tend consistently to land 'above average' catches from 'below average' trip lengths. As a result good skippers tend to complete a high number of trips per year and achieve high earnings.

It is not surprising, therefore, that the top skipper(s) within a company are given command of the new vessels ; it is often their ideas that are incorporated into the new vessels (more lights, halogen bulbs, larger generators, etc). Also, the owner is keen to see a good return on his latest investment.

### *5.5 Communications, fleet cooperation and coordination*

While of obvious relevance for the analysis of fishing effort, nevertheless it is difficult to evaluate the importance of improved radio communications on fleet catch performance. It undoubtedly reduces 'searching time', but to what extent is not known.

If the activities (location, catch last night) of a large part of the fleet covering a wide area are provided freely over the radio for all to hear, and this information is reasonably accurate, then we can presuppose that with two thirds of the fleet at sea at any time, the fleet follows the drift or migration of the small pelagic fish in a relatively informed and concentrated way. For example, as the stocks concentrate, the fleet has the capacity also to concentrate on them. And as the fish disperse, the fleet also will disperse over a wide area, searching out the next concentration to form or pass through the area.

The standard SSB radio in use, Icom 700 series, is an 'open channel' radio telephone system, with individual companies or groups allotted a single frequency, into which anyone else can tune if they wish (and they do). The radio is on continuously, and up-to-date information is, in principle, available to all.

Obviously, within the one company using the same radio frequency and having fixed call-up times, information on the location and performance of each vessel is available to all the others in the company at least twice a day.

An analysis of the pattern of fishing of one company with eight large vessels active over the course of one year did not show a marked difference to the distribution of the general fleet. However, there was a tendency to have a minimum of two company vessels operating on the same fishing ground at any one time. However, the vessels did not show a strong pairing or teaming up from one trip to the next. The best fished alongside the worst and on one trip and with the mediocre on the next. It was noted that when the general fleet was spread out between several fishing grounds, the company vessels were also. Further, some would switch grounds, from ground A to B, then back to A again on successive trips, while others would spend their three trips over the same period on the same gounds. While a small company has the ability to coordinate its fleet's activities with information generated internally, it would appear in general to benefit more by 'cooperating' with the larger group of non-company vessels in determining the best grounds to fish at any point in time.

## 6. DISCUSSION

The paper is concerned primarily with determining the technical and operating characteristics of the Java Sea purse seine fishing system. In other words, the factors affecting catch per trip and those which underlie vessel income and cost. It is necessary to understand these well before undertaking an economic analysis.

The essential parameters are catch/trip and earnings/trip. Surprisingly, the two often show little obvious relation-the same level of earnings being achieved for widely differing catches. The difference in value is attributable largely to

(i) differing species composition of the landings, and

(ii) differing fish quality, generally the latter being the more important. (Obviously, other factors, such as total fish landings that day and where the fish is landed, the fasting month, etc play an important part too).

This analysis has proved necessary because little reliable published information exists on the characteristics of the current fleet of Java Sea purse seine vessels and their fishing technology, their method of fishing, their operating pattern, factors affecting catch performance, etc, at a level of detail sufficient for operational analysis. In other words, all the factors which determine production cost and income. The European Community funded 'Java Sea Pelagic Fishery Assessment Project' clearly appreciates the value of this information, as much of the relevant information is recorded on a routine basis and efforts are being made to obtain other necessary data, e.g. trip log book data using independent observers onboard.

Nevertheless, it does appear that the essential point about this fishery has been largely overlooked in the literature to date.

The Java Sea fishery for small pelagics, as elsewhere in SE Asia, is essentially a *'light fishery'*, and this light fishery makes use of the most effective means of catching fish using light, which is purse seining.

In principle, the fishing method relies upon the *visual attraction of small pelagic fish*, passing in the current, *to a fixed point* (actually a large number of fixed points) *in the sea*

(i) using *rumpon* , an anchored coconut leaf fish aggregating device or FAD, for daylight attraction and

(ii) artificial light from an anchored light vessel (purse seiner) for attraction in the dark (at night or at depth, if using underwater lamps).

Having attracted a passing 'school' (which may actually have been passing as dispersed fish), next the attractant must work to keep them there. A rumpon tends to work better in seawater when it has been colonized by filamentous algae and other micro-organisms, a process which takes several days and is called 'ageing'. These micro-organisms attract small (juvenile) fish which in turn attract larger fish. But the food available at the rumpon is insufficient on its own to sustain the fish (whether grazers or predators) for as long as they may stay at the rumpon (which can be several days). Other factors obviously play a part, too.

The second attractant, and generally more important for achieving good catches, is artificial light. Different animal species show different reactions to light. Ben Yami (1976) has characterized four behavioral patterns or behaviour 'types' for the dominant component small pelagic fish. But even within the same fish species, its reaction to light may change with age, prior to spawning, just after feeding, when its gut is full, etc.

Current strength (which changes on a seasonal basis, also its direction) and the impact on it of tidal ebb and flow (which is highest just after new moon/full moon and at the equinoxes) also play an important part in determining (a) the volume of water (and hence fish) passing the light beam and so 'filtered' by it and (b) the length of time the fish can swim against the current, and still stay in the light or at its edge.

The effectiveness of artificial light works best in the dark. (Also important for the transmission of light through water is its transparency : the water should have a high transparency). As noted above, this can be at depth or at night. The main efficiency factor is the level of background illumination. Low background illumination boosts the range over which an artificial light source attracts ; high background illumination reduces its effective range dramatically. Hence, the phase of the moon and the time it rises and sets during the night affect fishing success and, hence, the timing of fishing trips, and fishing strategy once on the fishing ground.

For example, most fishing vessels fish one rumpon per night, setting the net about 04.00 h, some ten hours after they start light fishing. But during the full moon phase, they will make a first set (if possible) before the moon rises, and a second, at a different rumpon site, also about 04.00 h (i.e before first light). The longer the lights are left on before setting, the higher the potential catch per night. Fishing two rumpons per night cuts down the light fishing time and, generally, the catch.

This demonstrates that it is the volume of water fished on a dark night that has the greater impact on the catch size, rather than the initial population 'resident' at the rumpon site.

Variations in other fishing technology factors, such as net size (length, depth, mesh size), hauling system, vessel size and speed, etc, are of marginal significance relative to the brightness of the vessel's lights used for fishing.

Vessel size (i.e. fish hold capacity) is important in determining the duration of a fishing trip. Carrier or freezer/carrier vessels have not been adopted up to now.

Maximum vessel speed is important in determining journey times for getting to and from the fishing ground. It is important in determining the time it takes to set the net, although this is considered generally of marginal importance in determining catch size. Of much more importance here is the speed at which the purse line and rings are brought onboard after setting the net, thereby cutting off the main escape route for the fish inside the net. While this operation is being carried out, the escape route is under the vessel. Hence, between the time the vessel has switched off its fishing lights until the purse line is onboard it is important that no vessel lights are used to attract the fish away from the Petromax lights, which if the current allows are normally held by line near the far end of the net from the vessel during this operation.

These are some of the main 'endogenous' or controllable factors affecting catch performance in this fishery.

### *6.1 Price formation at the auction*

The main factors affecting price formation at the auction are briefly reviewed here. This system has two components ; the supply of fish and factors which affect this ; and the demand for fish and factors which affect that. The present concern is with factors affecting price formation at the auction.

In principle, there are two types of purse seine fishing vessel supplying the market, (i) fresh fish only and (ii) mixed fresh and wet salted fish (*gereh*). The price of fresh fish is determined by quality and species. There are three quality grades in current use for fresh fish. These grades are based on physical appearance.

The price achieved for first grade fish is typically between 2-3 times the price of third grade. Second grade lies between the two. Apart from appearance, these price differences reflect remaining shelf-life of the fish (if it is to be sold as fresh fish). Comparing first and second grade fish at Pekalongan auction, first grade fish, which achieves the highest price, is dispatched to Jakarta and a few other major cities in Java.

Meanwhile, second grade fish marketed fresh is sold within the local area and province. (However, most is processed into 'pindang', a light to heavily salted product before sale). This fish distribution pattern reflects income distribution and the concentration of high earners within a few major cities. The 'ability to pay' a higher price and the price competitiveness of small pelagic fish compared to other 'white' fish, meat and chicken ensures a good demand. Only first quality fish (and shrimp) is on display in supermarket fresh fish counters in Jakarta (and, presumably, Java's other major cities).

### *6.2 Future Technical Innovations*

The following list of technical innovations are likely to be economically justified and so are likely to be introduced before the end of this decade.

Navigation Aids. GPS, and possibly radar, for steering a straight course, avoiding obstructions and relocating FADs.

Improved light fishing technology and techniques, such as using underwater lamps from a series of small 'light vessels' which the purse seiner sets on in the course of the night. This would vastly increase fishing effort.

Improved onboard insulation which retains its water tightness and hence its insulation properties better.

Freezer and refrigerated carrier vessels serving groups of purse seiners for improving fish quality and for supplying the fresh fish market and, possibly, canneries in times of low supplies

## 7. SUMMARY AND CONCLUSIONS

The two most significant developments of the last decade in the Java Sea purse seine fishery for small pelagics were :

i) locating new, more productive, distant fishing grounds which allow a vessel to be operated year-round ; and

ii) the use of more powerful electric lights to attract and concentrate small pelagic fish at night near the sea surface around a vessel, which improves the catch rate per night, even during the full moon period.

The Java Sea purse seine fishery has seen steady step-by-step technical advances introduced in recent years, the most significant of which has been the introduction of powerful electric fishing lamps, followed by the use of radio telephones which allow up-to-the-minute fishing conditions in this fishery to be transmitted around the fleet on its open airways.

However, the impact of these significant increases in fishing power are masked out by the standard measure of 'days spent at sea' used in this fishery to measure nominal changes in fishing effort.

The major technological advances predicted over the next decade will concentrate on improvements in light fishing and fish quality.

Une grande partie de la littérature concernant la gestion des pêches porte sur les questions principales de détermination de tailles optimales de stocks et de flottilles. Toutefois il y a une prise de conscience croissante du fait que pour résoudre ces questions d'ajustement, les autorités responsables de la gestion ne doivent pas considérer seulement leurs propres tactiques, stratégies et objectifs mais également ceux des pêcheurs. Autrement il faudra faire face à un nombre important de problèmes. En premier lieu il est difficile de prévoir la réaction des pêcheurs aux différentes mesures de gestion et en conséquence il est difficile d'assurer que les bonnes mesures sont engagées. En second lieu, les stratégies de gestion qui s'opposent à des stratégies des pêcheurs peuvent avoir des effets inattendus et rencontrent aisément des résistances.

Les textes présentés dans cette session se focalisent sur ces questions. La plupart traitent des pêcheurs eux-mêmes, alors que certains considèrent les questions qui se posent au niveau industriel, et d'autres enfin discutent des problèmes qui apparaissent face aux autorités de gestion.

McElroy et Wijopriono abordent un des effets importants au niveau des pêcheurs : l'impact de l'innovation sur les performances en pêche dans le cas des pêcheries pélagiques de la mer de Java. Comme ailleurs dans le monde l'innovation technologique augmente l'efficacité d'un niveau donné ou d'une définition donnée de « l'effort de pêche » – dans ce cas, les jours de mer. Dans les pêcheries de la mer de Java, les changements dans la distribution spatiale de l'effort (exploitation de zone plus distante des côtes) et l'introduction de puissances d'éclairage plus grandes (comme technique d'attraction des poissons) sont les principaux facteurs qui agissent sur F pour un niveau donné de f. Squires considère le même problème sous l'angle de la mesure de la productivité pour les pêcheries chalutières côtières du Pacifique. Il trouve que les estimations d'amélioration de productivité sont biaisées sauf si la capacité d'utilisation, l'abondance des ressources et le coefficient de capturabilité sont pris en compte. L'estimation exacte de l'accroissement de la

Much of the literature concerned with fisheries management concentrates on the key issues of identifying optimal stock and fleet sizes. There is increasing recognition however that in resolving these issues, the management authority must consider not only its own tactics, strategy and objectives but also those of the fishermen. Otherwise, a number of problems will have to be faced. First, it may be difficult to predict the reaction of fishermen to different management measures and hence difficult to ensure that the correct measures are implemented. Second, management strategies that cut across fishermen's strategies may have unintended consequences and are likely to meet resistance.

The papers presented in this session concentrate on these issues. Most focus on the fishermen themselves, although some consider industry-level issues, whilst others discuss the problems facing the management authority.

McElroy and Wijopriono discuss one important effect at the fisherman level: the impact of innovation on fishing performance in the case of Java Sea Pelagics. As elsewhere around the world, technological innovation increases the effectiveness of a given level, or a given definition, of "fishing effort" – in this cas, days spent at sea. In the Java Sea Fishery, changes in the spatial distribution of effort (the exploitation of more distant grounds) and the introduction of more powerful lights (as fish attractors) are the main factors increasing F for a given level of f. Squires considers the same problem from the point of view of productivity measurement in the Pacific Coast trawl fishery. He finds that estimates of productivity improvement are biased unless capacity utilisation, resource abundance and the catchability coefficient are taken into account. Accurate estimation of productivity growth is especially important in licence limitation programmes that limit the number of vessels.

A number of papers discuss the behaviour of fishermen and the way in which this may impinge upon management. Rey applies the concept of hysteresis to fishermen behaviour, arguing that investments do not depend simply on the state of fish stocks and the exploitation rate of

productivité est particulièrement importante dans des programmes de limitation par licence qui tendent à contraindre uniquement le nombre de bateaux.

Certains textes évoquent le comportement des pêcheurs et les voies par lesquelles ils peuvent se heurter aux systèmes de gestion. Rey applique le concept d'hysteresis aux comportements des pêcheurs montrant en quoi l'investissement ne dépend pas seulement de l'état des ressources et du taux d'exploitation de celles-ci mais également d'autres variables comportementales. Hillis et Whelan considèrent le rôle d'escompte dans la réhabilitation de stocks surexploités. Au travers d'une enquête, ils ont tenté d'approcher le taux d'escompte utilisé ou implicite entrant dans le processus de décision des pêcheurs. Ils constatent ainsi qu'un taux très élevé semble le plus courant. En conséquence directe de cela, les programmes de réhabilitation de stocks qui se fondent sur des pertes de court terme en retour de gains de long terme ont peu de chance de satisfaire les pêcheurs. Résultant de cela, les autorités de gestion auront à mettre en place des méthodes qui garantissent que le pêcheur pourra être amené à accepter de tels programmes. Roy *et al.* prennent en compte quant à eux l'impact d'une prime de chômage et la durée de la saison de pêche dans les pêcheries du Newfoundland. Ils développent un modèle de revenu des pêcheurs et considèrent alors l'effet de l'introduction d'une assurance chômage. Il n'y pas de relation simple entre les deux ; les résultats dépendent du nombre de semaines travaillées avant même l'introduction des bénéfices et des bénéfices particuliers de la régulation (nombre de semaines à prendre en compte). La conclusion principale est que rien ne peut être déduit de l'utilisation de la moyenne du nombre de semaines travaillées mais que l'assurance chômage est propice à réduire la variance autour de la moyenne.

D'autres textes traitent des stratégies des pêcheurs. Campbell *et al.* s'intéressent au thon comme cas d'étude de stratégies de gestion multi-espèces. Ils trouvent que l'aptitude du pêcheur à cibler différentes espèces est une clef caractéristique des pêches. S'il est impossible de cibler sur une espèce, alors le contrôle de n'importe quelle espèce peut causer une chute inacceptable des captures associées à cette espèce. Des conclusions identiques sont obtenues par Hanna, et Lantz *et al.* Hanna considère le comportement des pêcheurs en terme de portfolio présentant une sélection de stratégies de pêche. Elle montre que les pêcheurs privilégient volontairement une stratégie pluri-espèce pour réduire le risque. Le résultat est que la gestion d'un stock unique est généralement inappropriée puisqu'elle ne prendra pas en compte les effets induits sur les stocks liés. En fait l'unité de gestion a besoin d'être définie en intégrant les comportements de ciblage. Lantz *et al.* analysent également la ressource, mais aussi les variables comportementales. Hillis et Whelan considèrent le rôle d'escompte dans la réhabilitation de stocks surexploités. Au travers d'une enquête, ils ont tenté d'approcher le taux d'escompte utilisé ou implicite entrant dans le processus de décision des pêcheurs. Ils constatent ainsi qu'un taux très élevé semble le plus courant. En conséquence directe de cela, les programmes de réhabilitation de stocks qui se fondent sur des pertes de court terme en retour de gains de long terme ont peu de chance de satisfaire les pêcheurs. Résultant de cela, les autorités de gestion auront à mettre en place des méthodes qui garantissent que le pêcheur pourra être amené à accepter de tels programmes. Roy *et al.* prennent en compte quant à eux l'impact d'une prime de chômage et la durée de la saison de pêche dans les pêcheries du Newfoundland. Ils développent un modèle de revenu des pêcheurs et considèrent alors l'effet de l'introduction d'une assurance chômage. Il n'y pas de relation simple entre les deux ; les résultats dépendent du nombre de semaines travaillées avant même l'introduction des bénéfices et des bénéfices particuliers de la régulation (nombre de semaines à prendre en compte). La conclusion principale est que rien ne peut être déduit de l'utilisation de la moyenne du nombre de semaines travaillées mais que l'assurance chômage est propice à réduire la variance autour de la moyenne.

A number of papers looked at fishing strategy. Campbell *et al.* discuss tuna as a case study of multi-species management. They find that the ability of fishermen to target different species is a key feature of the fishery. If targeting is not possible, then the control of any one species may cause unacceptable declines in catches of associated species. Similar conclusions are reached by Hanna and Lantz *et al.* Hanna considers fishermen behaviour in terms of portfolio selection of fishing strategies. She argues that fishermen deliberately target a diverse range of species as a way of reducing risk. As a results single stock management is generally inappropriate since it will have unintended side effects. Instead management units need to be defined taking account of targeting behaviour. Lantz *et al.* also look at fishing strategies. They discuss the concept of the "metier": a combination of area, species and gear. They show that although a fleet catches many species and uses many gears, it is possible to identify metiers based upon 1 or 2 gears and at most 4 species. They conclude that management needs to consider the impact of regulation on sub-sectors of the fleet as well as the inter-relationships between different sub-sectors.

These papers indicate the need for the fishery management authorities to take into consideration at least the following issues when developing management plans:

(i) the relationship between fishing mortality and fishing effort;

(ii) the response of fishermen to behaviourial and institutional variables;

ment les stratégies de pêche. Ils mettent en avant le concept de « métier » : combinaison d'une zone d'activité, d'espèces cibles, d'engins utilisés pour leur capture. Ils montrent bien qu'alors qu'une flottille de pêche capture plusieurs espèces et emploie plusieurs types d'engins, il est possible d'identifier des « métiers » en fonction d'un ou deux engins et au plus quatre espèces. Ils en concluent que pour la gestion, il convient de considérer l'impact de la régulation sur les autres aires d'actions de ces flottilles ainsi que les interactions entre les différentes sous zones.

Ces textes mettent en avant le besoin pour les autorités de gestion de prendre en compte pour le développement de plans de gestion au minimum les questions suivantes :

(i) les relations entre la mortalité par pêche et l'effort de pêche ;

(ii) la réponse des pêcheurs aux variables comportementales et institutionnelles ;

(iii) les stratégies d'exploitation des ressources qui ont été mises en œuvre par les pêcheurs.

Dans tous les cas il est nécessaire de surveiller la façon dont les variables changent au fil du temps ainsi que le chemin par lequel les pêcheurs réagissent. Le fait de ne pas prendre en compte ces variables conduit communément à une stratégie de gestion défectueuse avec des effets imprévisibles et pervers.

Au niveau industriel, Wilson *et al.* développent un modèle bioéconomique de réensemencement des stocks de coquilles Saint-Jacques au Québec. Ils mettent en exergue la nécessité d'arrangements institutionnels appropriés si de telles initiatives veulent être couronnées de succès. Dreyer et Vassdal proposent un modèle prédictif portant sur la probabilité de faillite par anticipation jusqu'à cinq ans. Des modèles similaires sont développés pour être appliqués aux entreprises norvégiennes de transformation de poissons.

Deux textes portent sur les stratégies de gestion au niveau même des institutions responsables. Mickwitz et Hilden analysent l'emploi d'incitations dans le cadre de la théorie des jeux. Ils démontrent que quelques catégories d'incitations peuvent encourager les collusions entre pêcheurs qui n'auraient pu exister sans cela. Avec Whitmarsh nous nous sommes intéressés à la question de savoir si oui ou non un Etat côtier devrait développer sa propre flottille ou compter plutôt sur des flottilles de longue distance. On constate que plusieurs pays ont privilégié trop vite la première option sans considérer pleinement l'impact que pouvait avoir une telle politique surtout sur la rente générée par les ressources et l'échange au niveau des services attachés à l'activité de pêche.

(iii) the resource exploitation strategies that have been developed by the fishermen.

In all cases there is a need to monitor the way in which variables change over time and the way in which the fishermen respond. Failure to consider these variables is likely to lead to a flawed management strategy with unpredictable and perverse effects.

At the industry level, Wilson *et al.* develop a bioeconomic model of stock enhancement of giant scallop in Quebec. They stress the need for appropriate institutional arrangements if such activities are to be successful. Dreyer and Vassdal develop models to predict the likelihood of bankruptcy up to 5 years before the event. Reliable models are developed which are applied to the Norwegian fish processing industry.

Two papers consider strategic issues at the level of the management authority itself. Mickwitz and Hilden analyze the use of subsidies in a game theoretic context. They demonstrate that some types of subsidy may encourage collusion between fishermen that would not other wise have existed. Cunningham and Whitmarsh consider the issue of whether a coastal state should develop its own fleet or rely upon distant water fleets. It is argued that many nations have opted too quickly for the first alternative without fully considering the impact of such a policy especially on resource rents and trade in fishing services.

# Coastal State Fisheries Management : Fleet Development Versus Trade in Fisheries Services

**Stephen Cunningham and David Whitmarsh**

Centre for the Economics and Management of Aquatic Resources, University of Portsmouth, Locksway Road, Portsmouth, PO4 8JF, U.K.

ABSTRACT

*The problem of deciding what proportion of available catches should be allocated to Distant Water fishing fleets is one which continues to pre-occupy many Coastal States. The paper suggests that much of the debate surrounding this issue is misplaced, since it draws attention away from the more important question of how exploitation rights should be allocated in order to ensure that resource rents are maximised. The paper highlights the drawbacks inherent in the essentially 'administrative' approach to fisheries management adopted by most Coastal States, and suggests that a market approach would help avoid many of the distortions and contradictions which typically arise.*

## 1. INTRODUCTION

Following the extension of fisheries limits worldwide, many Coastal States (CSs) face the difficult problem of deciding what, if any, proportion of available catches should be allocated to Distant Water (DW) fleets. A fair amount of economic research has been directed towards resolving this problem, and this Conference Paper is intended to be a contribution to that debate. Our aim is to explore the extent to which the catch allocation problem arises due to management failure following extended fisheries jurisdiction (EFJ) rather than due to any inherent feature of EFJ itself.

The paper is organised as follows. In the first section we assess the effects of EFJ and examine how far it has generated benefits to CSs. We next consider the problems of CS fisheries management, focussing on the bioeconomic aspects of attempting to regulate a fishery which is exploited jointly by a domestic and a foreign fishing fleet. This leads onto a discussion of the distortions and conflicts which may arise when a CS loses sight of what is arguably the principal source of benefit from the fisheries, namely the rent which the natural resource is capable of generating. It is suggested that because CSs have tended to take decisions that favour their domestic fleet, some quite complicated administrative decisions are required. The nature of such decisions is outlined and their impact on key variables such as the trade in services, employment and income is discussed.

## 2. THE AFTERMATH OF EXTENDED FISHERIES JURSIDICTION

### *2.1 Assessing the effects of EFJ*

It is now 15 years since the majority of the World's coastal states declared EFJ, and a clearer picture is beginning to emerge of the impact which this has had on World fisheries. In some areas of economic activity, such as trade in fisheries products, the effects of EFJ became apparent within a fairly short time. For example, Copes (1982) highlighted the increasing internationalisation of fisheries markets and showed that between 1976 and 1979 the World volume of fish exports increased by over 22 % compared with a much more modest increase in global catch of only 2 % over the same period. Other effects have taken longer to identify, and this in part is due to the difficulty in isolating the specific influences of EFJ from other factors. An illustration of this is given by Garrod (1990) who argues that EFJ has had a destabilising effect on international markets, and this has been reflected in greater year-to-year volatility in fishery product prices since 1977.

The one area in which it has been especially difficult to establish the effects of EFJ concerns the net economic gains to different countries, and such evidence as we have is far from conclusive. Pontecorvo (1988) selects 9 of the leading fishing nations and compares their annual catches in the period 1970-72 with those in 1983-5. The change in the capitalised value of gross revenue is then used as an approximate indicator of the economic gains to the CS resulting from the annexation of what had formerly been 'marine commons.' With the exception of Japan and Peru, all countries selected were shown to have gained substantially from EFJ. A recent paper by Juda (1991) looks in more specific detail at the distribution of world marine fish catches since EFJ, and in particular the partition of catches between developed and less developed countries. The paper concludes that while developing CSs as a group have probably benefitted from EFJ in terms of increased catches, these have tended to be concentrated in a sub-set of states and that for many other developing coastal nations EFJ has not resulted in particularly large absolute increases in the volume of landings.

This begs the question of how economic gains to the CS ought appropriately to be measured. Juda's study focusses on national catches, but it is admitted that these may not be fully reflective of the benefits attributable to EFJ. While Juda makes no attempt to evaluate rents (associated with access fees, etc) he acknowledges that these "may be quite significant." (p.17). Evidence from other sources suggests that such rents may indeed be very important to a CS, which on crude indicators (e.g the weight of fish harvested by the domestic fleet) may not appear to have gained much from EFJ. In this paper we take it as axiomatic that economic rent is the *principal* source of benefit which may accrue to a CS who can be assumed to be the de facto owner of the marine resource. In the next section we briefly consider the way in which EFJ has created the opportunity for capturing resource rent and the reasons why in practice CSs have not always taken full advantage of such opportunities.

### *2.2 Coastal State benefits from EFJ*

As Queirolo and Johnston (1989) have pointed out, a CS which has declared EFJ enjoys two sources of increased production. On the one hand, expanded oceanic dominion increases the production possibilities open to it by virtue of its ownership of a valuable natural resource. On the other, the CS now has the opportunity to manage these resources more effectively and to deal with the open-access problem which had been a feature of the pre-EFJ era. Most economists would argue that a CS which takes advantage of both these opportunities will, in theory, enjoy higher real national income. This improvement has its counterpart in the rents which the natural resource should be capable of generating under the new regime and which will necessarily accrue to the CS as resource owner. It may well contended that a third source of potential gain to the CS stems from its ability to displace foreign effort from its newly created EFZ and to increase its share of whatever the total harvest might be. Such a benefit would, however, be at the expense of the DW fleet ; and, as many observers have pointed out, such a strategy may not be to the advantage of the CS in the long run. We return to this point later.

Though EFJ creates opportunities for resource rent capture by the CS, experience suggests that in practice many CSs fail to capitalise on such opportunities. Firstly, it may the case that a CS chooses to trade off rent for some other 'benefit'. This appears to have happened in Newfoundland, for example, where economic efficiency in resource management has deliberately been sacrificed in favour of employment creation within its fishing communities. Secondly, even in situations where the CS attempts to maximise economic benefits from its fish resources, this may not be achieved because of

weaknesses in the fisheries management regime itself. Robb (1984) estimates that in the early 1980s the Pacific Islands were receiving only about 2 % of the value of the resources in their fishing zones. This was attributable to a failure of compliance by foreign fleets, stemming in turn from an inability by CSs to exercise full control over their proprietory rights. Another kind of problem is illustrated by the EEC where, despite the declaration of a 200 m EEZ in 1977, the potential gains have been largely negated by the inability to restructure the fleet and to control over-capitalisation.

It is clear therefore that management is essential if a CS is to reap the full benefits of its newly acquired marine resources. Experience suggests, however, that this is far from easily achieved. In the next section we discuss some of the particular difficulties associated with managing a fishery which is exploited by both a domestic and foreign fleet.

## 3. MANAGEMENT PROBLEMS

### *3.1 Bioeconomic issues*

Figure 1 illustrates some of the bio-economic interdependencies. The CS management authority is assumed to wish to earn a certain level of rent from its EEZ, which can be a source of funds for use either outside the fisheries sector or in developing domestic fleet capacity. The fishery may be exploited either by domestic or foreign vessels, and we can anticipate that in any given time period the amount of effort from each will be dependent on profitability. This is unlikely to be the same for both fleets, however, if only because of differences in technical efficiency. If profitability should differ between the two fleets, this will have major implications for the development trajectory of the resource since what will tend to happen is that over time the more efficient vessels will drive out the less efficient. For the sake of argument let us suppose that the foreign fleet enjoys lower costs than the domestic fleet, and that they jointly exploit a fishery which is unregulated. The tendency will be for the fish stock to be reduced to a level at which the least cost vessels make only a normal profit. At this stock size, however, the domestic vessels will not be able to operate profitably and will exit from the fishery.

A less dramatic version of this scenario may occur in a situation where the CS adopts the 'surplus' principle proposed by the Draft Convention of UNCLOS III. Under this principle a CS is entitled to set a TAC for a fishery within its 200 mile EEZ, but is then expected to allow a DW fleet access to any fish which are surplus to its own domestic harvesting and processing needs. The fundamental flaw in this whole arrangement, as Garcia et al (1986) have pointed out, is that it is bioeconomically unrealistic. Unless each fleet is limited in the absolute amount it can remove from the jointly-exploited resource, stock depletion will occur and the less efficient of the two fleets - which we are assuming will be that of the CS - will gradually be expropriated from the fishery. Essentially what happens is that the harvesting capacity of the domestic fleet will become increasingly uncompetitive as stock depletion causes catch rates to fall and unit harvesting costs to rise. Where this uncompetitiveness results in a cutback in catching capacity and a drop in total CS catches, it implies that the amount that the DW state is permitted to catch automatically increases. Clearly, the 'surplus' principle may become the thin end of potentially very large wedge by which a foreign fleet gains entry into a coastal fishery. What is likely to happen, of course, is that the CS management authority will feel obliged to alter the terms of the access agreement or else introduce financial support measures for its domestic vessels.

For this reason a CS management authority may choose to employ a number of other regulatory instruments besides TACs and quotas. Of these, possibly the most important are royalties which may be levied on the quantity of fish landed. Differential royalty rates may be imposed, and indeed it is not uncommon for a CS to levy a low (or even negative) royalty rate on its indigenous fleet and a considerably higher one on foreign vessels. It is important to understand that, within the context of CS fisheries management, royalties serve two distinct but complementary functions. Firstly, they can be used to regulate the flow of effort to the fishery by altering the absolute and relative profitability of the two fleets. If we continue to assume that domestic vessels have the higher operating costs, the management may, if it chooses, attempt to offset this cost disadvantage by the imposition of lower royalty rate on the indigenous fleet. In this way royalties may be used as an instrument for curtailing the expansion of one fleet relative to another. The other purpose of imposing royalties is, of course, to act as a vehicle for capturing the rent from the resource. However, setting a royalty rate for each fleet which will maximise total rent is a particularly complicated task for the management authority. This

is because the harvests which generate the rents, and on which the royalties have to be paid, are themselves a function of past and present royalty rates. The information requirements involved in setting the optimum royalty rate are thus quite formidable.

### *3.2 Administrative versus market approaches to the management problem*

It is suggested therefore that a CS that is intent on maintaining some sort of balance between its domestic and foreign fleet capacity - and specifically where it is trying to support and develop the indigenous fleet in the face of competition from foreign vessels - faces a very difficult management task. The difficulty is compounded where an administrative rather than a market approach is being pursued. Quite complex decisions must be made by the Fisheries Ministry in relation to the number of domestic vessels to allow into the fishery, how much investment is required in such vessels, as well as the key issue of what royalty rates to impose on each fleet.

We would contend, however, that to see the management problem in these terms is to misunderstand what is required. The question to ask should not be : 'what is the appropriate balance between domestic and foreign vessels ?' but rather : 'how should exploitation rights be allocated to ensure that rents to the CS are maximised ?' If this is accepted, it immediately follows that there should be no presumption in favour of either the domestic or the foreign fleet, since the relevant consideration becomes one of employing factors of production with the lowest opportunity cost. Subject to an explicit statement that the CS retains ownership of the resource, exploitation rights (e.g. in the form of ITQs) should be allocated to those who will bid most for them.

In practice, most CSs have not chosen to follow a strict economic maximization approach but instead have used EFJ to opt for a long-run policy aiming either to exclude foreign vessels or at the very least to maintain a domestic fleet presence. The reasons for doing this are largely political and/or socio-economic. Charles & Yang (1991, p.292) state that " coastal state objectives go beyond strict optimization of royalty revenues, to include the desire to create employment and shore-based economic activity through domestic fleet development". This statement probably commands widespread support, certainly among policy makers. However, we argue that even if such objectives are considered legitimate, they do not necessarily imply that domestic fishermen should be favoured. In particular, the implication that an inefficient domestic fleet should be developed at the expense of an efficient foreign one in the name of employment creation seems misguided. Policy makers who argue that the development of the domestic fleet is necessary in order to create jobs for CS fishermen and onshore workers - jobs which would not have existed had the competitive activities of the foreign fleet not been curtailed - are in danger of confusing economic *impact* with economic *value*. The impact of CS fisheries development, measured by its multiplier effects, may indeed be very great. The net economic value will be negative, however, if the resources tied up in the fishing sector could have been put to better use elsewhere in the economy. If the comparative advantage lies with the foreign fleet, then it would be in the interests of the CS to employ the services of DW vessels. The real economic benefit can then be taken in the form of resource rent, which the CS can use in whatever way it wishes.

As well as this general issue about confusing economic impact with economic value, we can also point to more specific problems which arise from trying to favour domestic fishermen using an administrative approach to fisheries management.

## 4. DISTORTIONS, CONTRADICTIONS AND CONFLICTS

Where a CS management authority is not prepared to allow the market to decide the allocation of exploitation rights, perverse effects may arise in a number of specific areas.

### *4.1 Effects on trade in fishing services*

At the level of the fishery, two effects, at least, can be discerned. First, joint ventures tend to proliferate. This occurs to the extent that comparative advantage lies, for reasons explored in Munro (1985), with the DW fleet. If the more efficient

foreign fleet is excluded and exploitation rights are granted to domestic fishermen, then it is to be expected that such fishermen will try to charter foreign effort as a way of minimizing their costs. Hence many joint ventures probably represent disguised trade in fishing services between CS and DW states. Second, CS companies are likely to be very keen to acquire the managerial expertise of foreign skippers. Trade in individual labour services may also be expected to flourish therefore. Such trade is likely to be difficult to detect in balance of payments data.

If the effort level of the domestic industry is not controlled, the quantity of trade is likely to be higher than in the case where it is controlled. In part this is simply due to the fact that the effort level will be greater. Partly however it will result from the intensity of competition between domestic companies to obtain the best inputs, be they foreign or domestic. Ironically, therefore, the immediate consequence of a regime intended to favour CS fishing interests is likely to be increased purchases of fishing services supplied by the DW state.

### *4.2 Effects on investment in domestic capacity*

Another interesting issue is the assumption that resource rent should be re-invested in the fishery, hence building up domestic capacity. However, the payoff to the CS of such a strategy is likely to be zero if domestic capacity simply displaces foreign capacity. In such circumstances there would be no capacity increase and therefore no increase in resource rents ; in fact, since by hypothesis efficient fleets are being displaced, there is good reason to believe that rents will be lowered. The question has to be asked : why should the CS invest in its domestic fleet ? Surely the fact that rents are generated from fishing does not mean that they have to be reinvested in it. Where capital is so severely rationed that the industry can only obtain investment funds from rents generated from the fishery, one would have thought that the country would have many potential projects awaiting funding. The idea of using resource rents merely to displace foreign fishing effort seems somewhat profligate in such a situation.

### *4.3 Effects on employment*

The issue of employment is also important. Frequently the idea is to ensure that employment exists for domestic fishermen. A number of points must be made. First if rights are initially allocated to domestic fishermen then the problem might be resolved although at the cost of giving away much rent. If rights are granted to domestic companies we have already argued above that this is likely to generate trade in fishing services rather than protecting local employment. One way of protecting such employment would be to attack the problem directly - eg by making it a condition that all vessels having an exploitation right should employ a minimum number of nationals. Of course, if such employees are less efficient, then their extra costs will have to be met by reduced rent receipts by the CS as fish stock owner. This may nevertheless be regarded as a legitimate use of rental income. An alternative, and perhaps ultimately more profitable, approach would be to consider supply-side policies for the domestic industry. If domestic fishermen are less efficient due to a lack of experience or a lack of qualification, then the CS might use some rent to establish training programmes so that domestic fishermen might become as efficient as their foreign competitors.

### *4.4 Effects on income*

Another frequent management goal that is cited in support of management measures that discriminate in favour of domestic fishermen is to increase incomes and welfare of fishermen and their regions, especially where the regions are disadvantaged in some way (eg locationally). This argument relies on a view that fishermen's incomes are determined from within the fishery. We would deny that this is the case. This is not the place to develop a detailed argument but we would hold as a general principle that the incomes of fishermen depend on the opportunity cost of labour in the relevant region. An increase in anticipated incomes from fishing is likely just to increase the number of fishermen, thereby depressing incomes again. An increase in opportunity costs on the other hand is likely to reduce the number of fishermen thereby inducing a permanent rise in incomes. A property rights system will certainly affect the wealth of fishermen but it seems most unlikely of itself to alter their incomes.

Once more we come to the conclusion that meeting the objective does not depend on eliminating foreign fishermen. Moreover, eliminating such fishermen reduces resource rents and therefore represents a disguised subsidy given to the domestic fishing industry by society in general, usually without anyone explicitly taking such a decision.

*4.5 Effects on wealth distribution*

Part of the debate concerning domestic versus foreign fleets seems to relate to the issue of wealth distribution. For instance, suppose freely transferable exploitation rights were initially to be given to (by hypothesis) less efficient domestic fishermen. It is to be expected that more efficient foreign producers would purchase the rights, so that the fishery would end up being exploited by the least cost producers, who happen to be foreign. Domestic fishermen could be counted upon to support such a scheme since the resource rents would accrue to them rather than to the CS itself.

Wealth effects may also materialise in the form of a power struggle between the management authorities representing society (the resource owner) and domestic fishermen (politically-important resource exploiters). It is to be presumed that the owner of the resource should wish to capture the rent, but rent-seeking behaviour on the part of the exploiters is also to be expected. The policy to exclude foreign fishermen comes about perhaps as a result of political pressure exerted by domestic fishermen as part of this power struggle and as an illustration of Cushing's famous dictum that the best policy from the point of view of the individual fisherman is 'to sink all vessels but mine'. In this case foreign fishermen are selected precisely because they represent an easy target since generally they lack political power in the CS.

The point is, therefore, that so long as an administrative solution is sought, the management authority is likely to find itself in an impossible position. Foreigners are usually sacrificed partly in a misguided attempt to achieve non-economic objectives but also as a way of buying off domestic fishermen. However, much of the problem has been created by the CS management authorities themselves. A market-based management system would provide them with the flexibility to favour domestic fishermen (eg in the allocation of rights) without having explicitly to exclude more efficient fishermen simply on nationality grounds.

## 5. CONCLUSION

This paper has argued that much of the debate about whether a coastal state should develop its own fleet or use foreign vessels is misplaced. It arises from a series of confusions, most notably a failure of management authorities to understand (or at least to act as if they understood) the difference between the economic value of a fishery and its impact. The economics profession seems to have some work left to do if the message is to be brought home. Another difficulty concerns the fact that the resource, though publically owned, is exploited by private companies or individuals. Many of the problems of fisheries management stem from a confusion between ownership rights and exploitation rights. It needs to be stressed that, except where specific laws state otherwise, fishing firms do not *own* the resource ; what is granted to them is the right to *exploit* it. Fishermen's exploitation rights are awarded by public authorities, whose role should be to manage the resource for the benefit of society as a whole ; and that, in the first instance, requires the explicit recognition that it is rent which gives the resource its value. In this context we would draw a parallel between fishing industry and the oil industry. Few, if any, commentators now propose that foreign oil companies should be excluded and that domestic capacity should be built up. Countries which followed such strategies in the 1970s (eg Algeria, Libya) are now inviting the foreign oil majors to return as a way of obtaining least cost inputs. They have learnt the hard way that it is extracting resource rent rather than oil that matters for the country. As economists it is our role to help CSs learn the same concerning their fisheries without facing the difficulties currently being experienced by some OPEC countries.

ABSTRACT

*A question which is becoming pertinent in fisheries management is how species might be saved from extinction in a manner which is consistent with economic rationality, by in situ management of the natural production process. How to do this seems straightforward ; in effect, the "how" part of the problem has been addressed in places like Japan, Alaska, and Norway, where there are already attempts at the enhancement of coastal fisheries. However, management which is "consistent with economic rationality" poses a more difficult problem. The conditions for the optimal extinction of a species in an extractive industry has already been demonstrated in the economic dynamics literature. However, the motivations for investment in renewable resource stocks, apart from issues concerning comparative rates of return on capital stocks, have been less thoroughly explored. The conditions for the optimal public or private investment in stocks*

* Cette étude est financée par le Ministère des Pêches et Océans.
Nous remercions les étudiants du cours Micro-économie des ressources maritimes (automne 91), et en particulier Eduardo Klein Salas et Thomas Noël du Payrat, pour leurs commentaires. Contacter les auteurs avant de citer.

*and habitat in situ (as opposed to aquaculture) seems to be an important intermediary link between those cases where hunters exploit naturally occurring processes, and those cases where this natural process is altered within a well-defined ownership context.*

*The optimal investment in the enhancement of the Sea Scallop fishery in Québec, Canada is explored using dynamic analysis with multiple controls. One control is the level of effort expended in the fishery, and the other controls are the levels of investment in the stock and in the habitat. This problem is then changed to one where the fishery is in open access, where enhancement of stock or habitat is a collective endeavor, but harvest takes place by individual entrepreneurs. Finally, the question of overinvestment in natural processes is addressed. Density-dependence (including depensation effects and self-thinning) is identified as an important factor which exacerbates investment errors, if habitat is a binding constraint. At extreme levels of stocking with habitat constraints, chaotic stock behavior obviates potential benefits to the investment.*

## 1. INTRODUCTION

Bien qu'il existe des études concernant l'extraction optimale des ressources maritimes, très peu a été écrit sur les conditions optimales qui guident l'investissement dans la récupération des ressources vivantes en mer. Les études actuelles font principalement référence aux techniques de récolte optimale et aux problèmes de rotation optimale en forêt.

L'ensemencement de certaines ressources aquatiques est déjà une réalité sur le globe. Les techniques aquicoles développées profitent du comportement migratoire de certaines espèces. Ces techniques consistent à lâcher des juvéniles en milieu naturel et à recapturer les adultes en mer ou lors de leur migration de retour pour le frai. Les pays où l'on retrouve une importante industrie d'ensemencement sont le Japon, l'ex-URSS, les États-Unis (en particulier l'Alaska) et le Canada. Cependant, un débat subsiste concernant la rentabilité de ces activités du fait que les espèces en question sont en pleine mer, et donc hors contrôle des investisseurs, pendant une grande partie de leur vie.

Les premiers essais réalisés en Amérique du Nord remontent aux années 1930, lorsque le Secrétariat au Trésor des États-Unis a tenté de mettre en place un programme d'ensemencement du saumon en Alaska financé par des investissements privés (Orth et al., 1980). Durant les années 1970, lors de la crise dans la pêcherie de saumon, l'Alaska a développé le programme "Fisheries Rehabilitation Enhancement and Development Program" (FRED) qui visait le rétablissement des stocks de saumon. Les résultats de ces investissements ont été prétendument très favorables, malgré les questions qui se posent concernant les évolutions à long terme de la productivité des océans. L'État d'Orégon possède également des programmes visant à l'ensemencement d'espèces aquatiques et l'amélioration des habitats de certaines ressources perturbées par les activités de pêche. Ces programmes sont largement supportés par des contributions volontaires.

En ce qui a trait aux études économiques sur les programmes de repeuplement des espèces en mer, les travaux sont très limités. Clark et al. (1979) abordent le problème d'irréversibilité dans l'investissement du capital et ses conséquences sur les politiques d'exploitation des stocks de pêche. Whoriskey (1991) et Wilson (1991) décrivent les projets publics qui touchent les aspects de repeuplement des stocks ainsi que les conditions socio-économiques nécessaires pour réaliser un ensemencement. Chaudhuri (1988), Bjorndal (1988) et Polovina (1991) ont réalisé des évaluations économiques des programmes publiques d'ensemencement en utilisant une approche de modélisation mathématique.

Les expériences réalisées dans l'île de Man au Royaume-Uni suggèrent que la gestion des stocks de pétoncle, en combinant les activités de repeuplement dans des zones fermées à la pêche et sous un système de rotation, produisent des résultats très positifs (Brand et al., 1991). Les résultats indiquent aussi que le repeuplement doit se réaliser à des tailles comprises entre 60 et 70 mm pour éviter la prédation par d'autres animaux (en particulier le crabe).

Les études qui traitent des effets des activités de repeuplement ou de l'aménagement de l'habitat sur la croissance d'une population semblent inexistantes. Les conséquences d'un sur-investissement dans la croissance des stocks contrôlés ainsi que les problèmes de "densité-dépendance" et de "self-thinning" sont rarement discutés en dehors du contexte de l'agriculture et de l'aquiculture. Ces derniers points devraient être traités lors de l'élaboration des politiques concernant les activités d'ensemencement d'espèces en milieu aquatique et naturel.

L'objectif de notre communication est de développer un modèle bioéconomique pour dériver le niveau optimal d'investissement dans une activité d'ensemencement. Les résultats de cette étude seront utilisés dans une étude empirique

sur l'économie de l'ensemencement de pétoncle géant (*Placopecten magellanicus*) aux Iles-de-la-Madeleine (Québec) afin de déterminer la valeur optimale des captures des adultes obtenues grâce à l'ensemencement. L'objectif ici est de fournir les fondements mathématiques permettant de réaliser l'évaluation économique de l'activité de rétablissement des stocks de pétoncle dans des conditions institutionnelles bien définies. L'objectif principal du projet REPERE (Recherche sur le Pétoncle à des fins d'Elevage et de Repeuplement) vise à développer une source stable d'approvisionnement en juvéniles de pétoncles aux Iles-de-la-Madeleine par le développement de technologies d'élevage rentables dans le contexte québécois. La réalisation d'un projet pilote permettant l'exploitation de l'espèce à l'échelle commerciale constitue un des principaux buts de ce programme.

## 2. LA PÊCHE DU PÉTONCLE AU QUÉBEC

L'exploitation commerciale du pétoncle au Québec a débuté dans les années 1960. Les pêcheries ont été développées principalement dans cinq secteurs maritimes. Les Iles-de-la-Madeleine occupent le second rang en termes de contribution aux captures totales de la Province.

D'après les statistiques du Ministère des Pêches et des Océans (MPO), les débarquements de pétoncles provenant des Iles-de-la-Madeleine ont subi une réduction significative depuis 1971. La cause de cette diminution est principalement la sur-exploitation des stocks naturels. Selon le MPO, les stocks semblent réduits et difficiles d'accès avec les techniques conventionnelles de dragage. Par ailleurs, les observations de Giguère et Legaré (1989) suggèrent que la présence de pré-recrues dans la zone est variable mais plutôt à la baisse. Les méthodes de gestion des pêches ne sont pas suffisantes pour rétablir les faibles rendements de la pêche. Pour ces raisons, une nouvelle stratégie basée sur le repeuplement des stocks épuisés a été adoptée.

Depuis les années quatre-vingts, des essais de capture de naissains sauvages et d'élevage de juvéniles ont été entrepris au Québec. Bien qu'il existe actuellement une expansion du marché du pétoncle, les travaux de Gilbert et Leblanc (1991) démontrent que la culture de cette espèce peut dans certains cas ne pas être rentable. Mais en regardant les technologies proposées, ce résultat n'est pas étonnant. Ils proposent la capture de juvéniles sauvages et l'élevage pendant une période de cinq ans jusqu'à la taille commerciale, en utilisant des techniques de culture différentes. Ces résultats incitent à une réflexion sur les modes de cultures autres que l'aquiculture proprement dite. Une stratégie de rentabilisation des opérations de culture peut être dans l'ensemencement d'une espèce, soit par la capture de juvéniles, soit par l'aquiculture de naissains. Ces produits d'une entreprise aquicole peuvent être ensuite utilisés pour l'ensemencement du fond. L'utilisation du fond par l'ensemble des pêcheurs est un contexte institutionnel de propriété qui n'est ni strictement privé ni d'accès libre.

Le pétoncle est une espèce attrayante pour l'ensemencement en milieu naturel car le problème de la mobilité est largement restreint. De plus, c'est une espèce de haute valeur commerciale. Enfin, grâce à sa mobilité limitée, l'espèce semble adaptée à des institutions d'ensemencement collectives dans le cadre d'une pêcherie en propriété commune. Ceci est spécialement vrai lorsque le terrain utilisé pour la production (dans ce cas le fond de la mer) est la propriété exclusive de la collectivité. Dans ce cas, la question de l'investissement en ensemencement pour le pétoncle s'avère plus pertinente que l'investissement dans l'ensemencement du saumon atlantique par exemple. Cependant, parce que ceci est un problème d'investissement collectif dans une ressource vivante, le problème est de trouver la combinaison des niveaux annuels de captures et d'ensemencement qui maximisera la valeur présente nette au fil du temps. Ceci est donc un problème dynamique à deux variables de contrôle. La détermination de la valeur optimale de l'investissement dans l'ensemencement de pré-recrues ($E_t$) de pétoncle géant et de la récolte postérieure des adultes (Yt) dans la pêche commerciale permettent de répondre à la question suivante : existe-t-il une stratégie permettant de rentabiliser les opérations de pêche par l'intermédiaire d'activités telles l'aquiculture, tout en sachant qu'un *sur-investissement* est possible ?

## 3. MÉTHODE

L'investissement optimal pour l'ensemencement de pétoncle est analysé à la lumière de la théorie du contrôle optimal en cas discret. L'application de ces principes et théories permet de trouver, pour un intervalle de temps défini, le contrôle

optimal pour chaque période de temps qui maximisera une fonction objectif. Le principe maximal donne les conditions nécessaires qui doivent être satisfaites pour l'application optimale des variables de contrôle. Pour des exemples pratiques de l'application de ces principes en économie, le lecteur pourra consulter Kamien et Schwartz (1981) et pour des applications économiques à la pêche et aux problèmes forestiers, Clark (1976).

Nous présenterons d'abord un modèle général et analytique concernant le problème de l'ensemencement et de la récolte. Pour une application empirique en cas discret avec deux variables de contrôle, on peut se référer à Bjorndal et Conrad (1989) sur la capture du phoque de l'Atlantique Nord dans les stades juvénile et adulte. Nous en dérivons le résultat dynamique, sans prendre explicitement en compte les effets de la densité sur la dynamique de la population (i.e. self-thinning). Cependant le sur-investissement comme phénomène économique n'est pas lié nécessairement à l'observation de self-thinning ou de dépendance lié à la densité, mais surtout à la forme de la fonction objectif, qui dépent du signe et de la valeur des paramètres estimés.

## 4. LE MODÈLE BIOÉCONOMIQUE

Les décisions de repeuplement dépendent étroitement de la dynamique de la population en question et des facteurs qui contrôlent sa taille. Les mécanismes associés aux limitations de la présence de recrues sont généralement le manque de nourriture, le manque d'espace, ou la modification de l'habitat naturel de l'espèce. La présence des adultes est plutôt limitée par le manque de ressources alimentaires dans une population.

Le modèle bioéconomique ici proposé suppose une population simple, composée d'individus de taille inférieure à 30 mm que nous appelons pré-recrues. Par recrutement à 30 mm, nous entendons l'entrée dans la population des individus qui ont atteint la maturité sexuelle. L'ensemencement sur le fond est le déversement en milieu naturel des individus qui sont matures sexuellement. Le recrutement à la pêcherie s'opère deux ans après. L'élevage des pré-recrues est fait dans des collecteurs pendant deux ans. Après déversement il faut que les pré-recrues croissent encore pendant deux ans avant de rentrer dans la pêcherie. Pour explorer le modèle en toute simplicité, on suppose que le déversement est fait d'une manière aléatoire et que le recrutement à la pêcherie est en "lame de couteau" (c'est-à-dire que le recrutement partiel est nul).

Le revenu net d'une association de pêcheurs qui ensemence à l'année t est fonction de l'amplitude de l'ensemencement en pré-recrues ($E_t$), de la récolte des adultes ($Y_t$) et du stock ($X_t$). Pour une description purement théorique, il suffit de décrire les propriétés fonctionnelles de la forme en considération. Cependant notre objectif est de décrire des relations qui pourront ensuite faire l'objet d'une estimation économétrique avec les données réelles. La relation considérée est une fonction de revenu net séparable de la forme :

$$N(E_t, Y_t, X_t) = pY_t - cE_t^{\alpha} - eY_t^{\beta} X_t^{\phi}; \qquad \alpha > 1; \quad \beta > 1; \quad \phi < 0.$$

Dans cette expression, $Y_t$ représente la capture à l'année t ; $E_t$ le nombre de juvéniles de 30 mm déversés sur le fond à l'instant t ; $X_t$ est le stock adulte à l'instant t. Le premier terme est le revenu brut provenant de la capture et p est le prix au débarquement. Le deuxième terme est la fonction de coûts totaux d'élevage des individus jusqu'à 30 mm. On suppose explicitement que l'entreprise confronte des coûts croissants pour l'ensemencement ainsi que pour l'activité de récolte. Le premier terme est une fonction linéaire, le second terme est toujours croissant avec l'argument $E_t$. Le dernier terme est une fonction de coûts qui est croissante en captures ($Y_t$) et décroissante en stock ($X_t$).

Il faut souligner que dans la formulation proposée, le prix est considéré comme un paramètre plutôt que comme une variable. La raison est que l'analyse est basée sur des données annuelles, dans un contexte où les pêcheurs des Iles sont considérés comme "price takers". Une condition plus restreinte serait de supposer que l'association confronte une demande à pente négative. À noter aussi que l'existence d'une solution unique repose sur l'hypothèse de concavité de la fonction objectif, qui implique des fonctions de coûts croissants si le revenu brut est considéré linéaire et croissant.

## 5. DÉRIVATION ANALYTIQUE

Pour le problème d'optimisation abordé ici, nous supposons deux activités différentes : l'ensemencement de pré-recrues de 30 mm ($E_t$) et la récolte des adultes ($Y_t$) à un âge supérieur à 4 ans. L'ensemencement est traduit par une augmnentation au taux intrinsèque de croissance de la population ($r_{30}$ : nombre d'individus survivants générés par un couple de pétoncles et qui atteignent une taille de 30 mm). Pour cette analyse, nous utilisons deux cohortes : les pré-recrues ($R_t$) dont la taille est comprise entre 30 et 70 mm et les adultes ($X_t$) qui possèdent déjà une taille commerciale c'est-à-dire 70 mm. Il est nécessaire de souligner que les pré-recrues sont des individus qui ont déjà atteint la maturité sexuelle, tout en n'étant pas encore recrutés à la pêche.

La maximisation de la valeur présente du revenu net s'exprime mathématiquement par la fonction suivante :

$$Max\ J = \rho^t N(E_t, Y_t, X_t)\ ;\quad \text{où}\quad \frac{\partial N}{\partial E_t} \leq 0\ ;\quad \frac{\partial N}{\partial Y_t} > 0 \tag{1}$$

Dans cette équation, $\rho = 1 / (1 + i)$ représente la fonction d'actualisation (i : taux d'actualisation). La fonction de revenu net est linéaire quant à la récolte $Y_t$. L'ensemencement $E_t$ s'apparente à des coûts de la période courante effectués dans l'espérance d'un remboursement ultérieur sous forme de récoltes des adultes.

Les contraintes biologiques qui s'imposent sont les suivantes :

$$X_{t+1} = (1 - M_0) R_t + (1 - M)(X_t - Y_t) \tag{2}$$

$$R_{t-1} = r_{30}\left(X_t + R_t - \frac{(X_t + R_t)^2}{k}\right) + E_{t+1} - (1 - M_0) R_t \tag{3}$$

Les termes $M_0$ et M sont les taux de mortalité respectifs des juvéniles et des adultes. La capacité de charge du système est exprimée par k.

Le Lagrangien s'écrit :

$$\begin{aligned}\mathcal{L} = \sum \rho^t N(E_t, Y_t, X_t) + \\ + \rho^{t+1}\lambda_{t+1}\left(r_{30}\left(X_t + R_t - \frac{(X_t + R_t)^2}{k}\right) + E_{t+1} - (1 - M_0) R_t - R_{t-1}\right) + \\ + \rho^{t+1}\mu_{t+1}((1 - M_0) R_t + (1 - M)(X_t - Y_t) - X_{t-1})\end{aligned} \tag{4}$$

La formulation précédente représente un problème d'optimisation dynamique avec deux variables d'état ($R_t$ et $X_t$ ) et deux variables de contrôle ($E_t$ et $Y_t$ ).

Les conditions de premier ordre nécessaires pour le maximum sont :

$$\frac{\partial \mathcal{L}}{\partial E_t} = -\rho^t[c\alpha E_t^{(\alpha-1)} + \rho\lambda_t] = 0 \tag{5}$$

$$\frac{\partial \mathcal{L}}{\partial Y_t} = \rho^t[p - \beta e Y_t^{(\beta-1)} X_t^{\theta} - \rho\mu_{t+1}(1 - M)] = 0 \tag{6}$$

Les deux équations adjointes sont :

$$\mu_{t+1} = \frac{p - \beta e Y_t^{(\beta-1)} X_t^{\theta}}{\rho(1 - M)} \tag{7}$$

$$\lambda_t = \frac{c\alpha E_t^{(\alpha-1)}}{\rho} \tag{8}$$

Les dérivées partielles par rapport aux variables d'état pour les adultes sont exprimées comme :

$$\frac{\partial \mathscr{L}}{\partial X_t} = \rho^t\left[-\theta e Y_t^{\beta} X_t^{(\theta-1)} + \rho\lambda_{t+1} r_{30}\left(1 - \frac{2(X_t + R_t)}{k}\right) + \rho\mu_{t+1}(1+M) - \rho\mu_t\right] \tag{9}$$

Celles pour les pré-recrues sont exprimées comme :

$$\frac{\partial \mathscr{L}}{\partial R_t} = \rho^t\left[\rho\lambda_{t+1} r_{30}\left(1 - \frac{2(X_t + R_t)}{k}\right) - \rho\lambda_{t+1}(1-M_0) - \rho\lambda_t + \rho\mu_{t+1}(1-M_0)\right] \tag{10}$$

Pour garantir une trajectoire optimum, les ensemencements et les récoltes seront faits ensemble, en respectant la condition :

$$\begin{aligned}\lambda_{t-1} - \lambda_t &= -\frac{\partial \mathscr{L}}{\partial R_t} \\ &= -\rho^{(t+1)}\left[\lambda_{t-1} r_{30}\left(1 - \frac{2(X_t + R_t)}{k}\right) - \lambda_{t+1}(1-M_0) - \lambda_t + \mu_{t-1}(1-M_0)\right]\end{aligned} \tag{11}$$

Il est à noter que les conditions dérivées de cette manière prennent compte des ajustements vers l'équilibre dynamique et donc englobent cette solution et les ajustements. La substitution des termes $\lambda_t$ et $\mu_t$ exprimés en (9) et (10) et la résolution postérieure du système d'équations permettent de trouver l'expression optimale pour l'ensemencement $E_{t+1}$ :

$$E_{t-1} = \left[\frac{E_t^{\alpha-1}(1+\rho^{-(t+1)}) - c\alpha^{-1}\left(\frac{1-M_0}{1-M}\right)(P - \beta e Y_t^{(\beta-1)} X_t^{\theta})}{1 + \rho^{-(t+1)} + r_{30}\left[1 - \frac{2(X_t + R_t)}{k}\right] + M_0}\right]^{\frac{1}{\alpha-1}} \tag{12}$$

Dans cette équation, l'activité d'ensemencement $E_{t+1}$, est liée de façon positive avec la valeur future du coût marginal de l'ensemencement. Ce n'est pas surprenant de noter que le profit marginal des récoltes aura un effet négatif sur la décision d'ensemencer. Par ailleurs, avec un taux de survie plus élevé des jeunes, par rapport aux adultes, les effets négatifs seront plus prononcés. Par contre, lorsque le taux de mortalité des juvéniles augmente, $E_{t+1}$ diminuera. Les effets négatifs sont aussi évidents lorsque la croissance naturel du stock est à la hausse. Enfin, en regardant le terme $\rho^{-(t+1)} = (1+i)^{(t-1)}$, il est évident que la hausse du taux d'escompte diminuera l'ensemencement aux périodes futures. Mais cet effet est minime par rapport aux effets de la valeur future et des coûts de l'ensemencement sur l'ensemencement en période t+1.

Une application similaire du principe maximum dans le cas discret permet de dériver les récoltes optimales à travers le temps, $(Y_t)$ :

$$\begin{aligned}\mu_{t-1} - \mu_t &= -\frac{\partial \mathscr{L}}{\partial X_t} \\ &= -\rho^t\left[-e\theta Y_t^{\beta} X_t^{(\theta-1)} + \rho\lambda_{t+1} r_{30}\left[1 - 2\frac{(X_t + R_t)}{k}\right] + \rho\mu_{t-1}(1+M) - \rho\mu_t\right]\end{aligned} \tag{14}$$

Cette équation n'a pas une solution unique pour $Y_t$, sauf dans le cas où $\beta = 2(\beta\text{-}1)$. Dans ce cas, et en faisant la substitution des termes $\lambda_t$ et $\mu_t$ et la simplification de l'équation (14), $Y_t$ peut être exprimé comme :

$$Y_t = \left[ \frac{-B \pm \sqrt{B^2 - 4AC}}{2A} \right]^{\frac{1}{\beta - 1}} \tag{15}$$

avec

$$A = e\theta X_t^{\theta - 1} \qquad (<0)$$

$$B = [1 + (1 + i)^{t+1}(1 - M)^{-1}]\,\beta e X_t^{\theta} \qquad (>0)$$

$$C = c\alpha E_{t-1}^{\alpha - 1} r_{30}\left[1 - \frac{2(X_t + R_t)}{k}\right] + P\left(1 - \frac{1}{1 - M}\right) + \beta e Y_{t-1}^{\beta - 1} X_{t-1}^{\theta}(1 + (1 + i)^{t+1})$$

La racine négative à été sélectionnée pour notre analyse car les valeurs provenant de cette racine sont positives. Il est à noter que le terme A (les effets du stock) est négatif à cause du signe du paramètre θ. Mais dans la racine négative de l'équation (15) ces effets sont directs et positifs. Le terme B est toujours positif, avec une relation inverse entre sa valeur et le stock. La valeur future de ces stocks pondérée par le taux de survie est évidente. Lorsque le taux d'intérêt augmente, $Y_t$ augmente aussi. Lorsque le taux de survie est important, il y a moins d'incitation à effectuer la récolte immédiatement. Le terme le plus complexe est C. Le premier terme de C suggère que les captures à la période t sont directement liées aux coûts marginaux de l'ensemencement planifié en période t+1 et au taux de croissance de la biomasse. Le deuxième terme est le prix pondéré par le taux de survie. En effet, on voit que le prix, s'il varie, affectera les captures directement, mais cet effet est diminué par la valeur de $1\text{-}(1\text{-}M)^{-1}$, toujours négative. Si le prix augmente, la façon de maintenir la trajectoire qui maximise le flux de profits est de réduire les captures. La valeur future du coût marginal des captures affecte les captures courantes de manière positive. Pour les taux d'escompte très petits et les taux de survie très élevés l'effet du prix peut devenir négatif. Le troisième terme de C suggère que les décisions de capture en t sont déterminées par la valeur future à t des coûts marginaux des captures en t-1 et la valeur du coût marginal en t-1 escomptée, le tout pondéré par le taux de survie. Ce terme est positif.

La racine négative de l'équation donne des valeurs positives pour $Y_t$ et la forme de la fonction quadratique préserve les interprétations de B et C. Cependant, il est à noter que la signification du terme A est ambiguë. Au dénominateur, une grande population d'adultes dans une période donnée entraînera nécessairement une augmentation des captures. Le numérateur suggère une certaine minimisation des effets directs de C et une importance de l'existence du stock sur les décisions sur $Y_t$ . Une interprétation plus exacte de cette fonction n'est possible que par les méthodes numériques avec des données réelles. La prochaine étape de cette recherche vise l'estimation des fonctions des coûts de captures et des coûts d'ensemencement dans un effort de démontrer plus clairement ces effets et d'expérimenter avec les autres formes fonctionnelles.

Il existe un niveau d'ensemencement qui permet le rétablissement de la population à long terme, avec les objectifs fonctionnels en profit qui sont concaves. D'autre part, la solution suggère aussi que l'ensemencement optimal est sensible aux variations dans l'état des stocks, aux coûts de l'ensemencement, et aux valeurs futures du profit provenant des captures.

## 6. EXTENSIONS POSSIBLES

Le modèle décrit ci-dessus, bien qu'il semble complexe, est très simple en termes de construction et d'hypothèses de base. Parce que le modèle est conçu avec seulement deux cohortes limitées par k (la capacité du système), la compétition intra-spécifique n'est pas prise en compte. De plus, le modèle suppose que les pêcheurs sont capables de se regrouper en association et ont des droits d'usage exclusifs concernant le fond autour des Iles-de-la-Madeleine. On suppose que l'association distribue les juvéniles de 30 mm de la même manière que la production naturelle ; une situation qui n'est pas tout à fait raisonnable sur le plan réel. Enfin, les auteurs ont supposé que le recrutement à la pêche est "en lame de couteau" ; le recrutement partiel n'est pas considéré. Malgré l'utilité des approches analytiques, le vrai projet

d'ensemencement aura à prendre en compte ces éléments. Les auteurs proposent un agenda de recherche pour étendre les résultats présentés. Un premier groupe d'extensions doit traiter les problèmes duaux de densité et self-thinning d'une manière plus réaliste. Le deuxième groupe d'extensions doit traiter des stratégies possibles d'ensemencement et des implications institutionnelles de ces stratégies. Cependant, la prise en considération d'une technologie dans un contexte institutionnel spécifique risque de rendre impossible l'utilisation des approches analytiques pour la modélisation.

### *6.1 Ensemencement, densité, et self-thinning*

Il est bien connu que la densité, exprimée en biomasse par unité de surface, affectera le taux de croissance de la biomasse. Aussi la densité dans un contexte aquicole est une variable de contrôle qui peut entraîner des réductions par une augmentation du taux naturel de mortalité.

D'après la formulation du modèle, une augmentation très forte de la densité de la population ensemencée engendrera une baisse de rentabilité des opérations de récolte. Le travail de Mallet et Carver (1991) indique qu'une forte concentration des individus ensemencés engendre une compétition pour la nourriture et pour l'espace. Les densités élevées entraînent aussi une diminution dans la capacité de fixation des juvéniles et par conséquent une augmentation de la mortalité. Watanabe (1986) indique que les opérations de repeuplement introduisent des changements au plan de la stabilité de la population. Une augmentation du taux de reproduction de l'espèce peut occasionner de grandes fluctuations de densité et par conséquent provoquer un effondrement de la population. Il insiste sur la nécessité de développer des études sur la reproduction des espèces avant de s'engager dans des activités de repeuplement.

Berryman (1991) souligne que des cycles chaotiques pour certains crustacés, en particulier le crabe, sont occasionnés par l'interaction entre la dynamique de la population et la pêche. Selon cette hypothèse, la population de crabe oscille autour d'une densité d'équilibre qui est sensible à l'augmentation de l'effort de pêche. De ce fait, l'accroissement des captures entraîne une diminution de la population. Si la pression de la pêche est maintenue longtemps, le crabe peut subir des périodes de très faible abondance et "éclater".

Conséquence des limitations d'espace ou de nourriture ainsi que de la nature compétitive des animaux, les individus ensemencés peuvent subir des effets comme le "self-thinning", où la taille ou biomasse moyenne de l'individu montre une relation négative avec la densité. Les individus restant dans la population continueront à croître, en remplaçant la biomasse perdue par la mort des autres individus (Begon et al 1986). D'après les observations de Hugues et Griffiths (1988) et de Fréchette et Lefaivre (1990), les effets de "self-thinning" sont observés dans différentes populations de mollusques dont la densité atteint des niveaux très élevés.

D'après la littérature, on peut souligner que la densité initiale d'ensemencement aura un effet sur la vitesse de croissance des individus. Ces effets se font sentir à travers les processus de mortalité naturelle, provenants de la dynamique entre l'environnement et la population, mais aussi à travers les effets directs et indirects de la compétition intra-spécifique. Il est assez clair que l'investissement en ensemencement ne doit pas dépasser la capacité de charge du système sous peine d'entraîner une situation non-rentable voire de détruire le stock complet. Cependant, la taille et la gestion de la taille des individus devient une considération importante car le prix varie souvent avec la taille. Ces considérations soulignent l'importance d'une connaissance de la mortalité naturelle ainsi que des dynamiques de compétition, dans un système fermé et également dans un système ouvert.

### *6.2 Institutions et stratégies de repeuplement*

Pour bien gérer les opérations d'ensemencement-récolte et maximiser les bénéfices des participants, la nature des institutions de gestion doit être considérée. Quelques États et provinces utilisent un système de location du fond aux particuliers. Un excellent exemple de ce type d'institution existe dans la Baie Chesapeake parmi les producteurs d'huîtres. En Alaska, les associations régionales de pêcheurs commerciaux de saumon engagent des gestionnaires pour des projets d'ensemencement dans la région qui sont auto-financés par la production des saumons qui reviennent aux rivières après leur migration. Ceci est possible car les pêcheurs régionaux ont des droits exclusifs de pêche dans la région.

Un point de discussion très important est alors le type d'institution de propriété qui accompagnera les activités d'ensemencement aux Iles-de-la-Madeleine. Cette institution, soit une coopérative des pêcheurs soit une formule

individualiste, doit tenir compte des activités de pêche et d'élevage autant que des réalités de la gestion publique des pêches en vigueur. Il semble qu'il n'y a pas au Canada d'infrastructure en place permettant l'octroi de droits pour exploiter le fond de l'océan. Cependant, les coûts et l'échelle de l'élevage d'espèces peuvent devenir intéressant pour la coalition des pêcheurs. Une innovation de ce système serait la passation de contrats entre le secteur public et l'industrie pour exploiter certaines parcelles de l'océan. Ces contrats peuvent être passés avec des individus ou avec les membres d'une coopérative ou d'une association, en utilisant les méthodes de culture adaptées au milieu.

Les études réalisées au Japon ont démontré l'importance des coopératives de pêche dans les activités de rétablissement des stocks épuisés par la pêche. D'après Mahmoud et Masuda (1991), plusieurs coopératives de pêcheurs sont directement responsables des activités de déversement et de capture du saumon. Une partie des fonds provenant de l'activité de récolte est utilisée pour couvrir les coûts de repeuplement. Il est important de remarquer que les niveaux de remontées de saumons au Japon semblent étroitement liés avec les nombres de poissons relâchés dans les années précédentes.

La gestion de la population de pétoncles avec ensemencement et captures est prometteuse parce que la culture de pêcheur est préservée et les pratiques de l'aquiculture sont utilisées en conjonction avec les processus naturels. Par contre, l'adoption des techniques de la mariculture nécessite une vision d'aquaculteur. La possibilité de sur-investissement en ensemencement est toujours à craindre lorsque les contraintes, que l'on regroupe sous le terme générique "k", sont fixes. D'une part la population s'accroît par le déversement d'individus, mais cet acte peut générer des problèmes de compétition, de limitation d'espace et de nourriture et donc une augmentation du taux de mortalité. Ceci n'est rien que le principe économique des rendements décroissants. D'autre part, la pêche des adultes enlève une partie de la population ce qui peut avoir des effets nuisibles selon l'effort appliqué. La combinaison de ces deux facteurs peut très bien entraîner une situation de chaos écologique et subséquemment la non-rentabilité du projet.

ABSTRACT

*All programmes to rehabilitate run-down fisheries by enhanced conservation measures incur immediate losses to allow increased fish survival, and the pattern of immediate losses and long-term gains is routinely modelled by biologists using inputs of growth-rate, mortality and recruitment. This paper discusses the effects of including in the model fishermen's time discounting rates, price elasticity and price-size effects (price per unit weight being generally higher in large fish than in small) in influencing the predicted outcome and reports on the results of a questionnaire survey in the Irish Sea Irish fishery undertaken among other things inter alia to establish the fishermen's time discount rates applicable in rehabilitation calculations.*

## 1. INTRODUCTION

The run-down state of most technologically well developed fisheries close to large markets is by now well-known, and in the case of the north-western Irish Sea, as in many other areas, the situation has been deteriorating progressively for many years, despite the efforts of national governments and since 1983 the European Communities to conserve them so as to stabilise yield at maximum sustainable level.

In this area, the three most important species traditionally are *Nephrops* (Dublin Bay or Scampi prawn), cod and whiting, which are exploited by Republic of Ireland and Northern Ireland boats, and plaice and sole, fisheries for which are largely confined to the Republic whose fishery is the subject of this paper. The composition by value of the Irish catch in 1991 (IR#m) was as follows : Nephrops 2.97 (56.5 %) ; Sole 0.52 (9.9 %) ; Cod 0.46 (8.8 %) ; plaice 0.45 (8.5) ; whiting 0.44

(8.4 %) ; all other species 0.42 (7.9), giving a value of IR#5.26m. All five main species are known to be overfished to varying extents, and in recent times there has been some evidence of the situation changing as boats diversify to avoid constraints imposed by EC quotas, catching monkfish, while catches of hake may be increasing due to gradual warming of the climate. There is also a very small herring fishery between the Mourne coast and the Isle of Man. The area of the main fisheries is shown in Figure 1. The amount of effort to which a fish species should be subject to yield maximum profit has been discussed by many, including Hillis (1989) and is indicated in Figure 2, which shows the zone of fishing mortality (F) values within which profit is maximised, i.e. between the values of F where profit is maximised with nil costs (i.e. Fmax where yield is maximised) and that where it is maximised with costs equal to 100 % of revenue at current F value (i.e. nil profit), also the F values at which profit is maximised using typical variable and fixed costs at current F values, and deeming all costs to be variable (as is the case where fleet size is reducible).

Profit Maximising Fvalues - which are dependent on the amount of fishing effort deployed - can be shown from the Reports of the ICES Irish Sea and Bristol Channel and Nephrops Working Group (Anon. 1991a, 1991b, 1992) to fall short of current Fvalues for the main NW Irish Sea species shown in Table 1. The extent to which Fe is exceeded by Fcurrent has increased in recent years, particularly for cod.

Due to the fact that the Irish Sea was a relatively discrete area fished by relatively few countries and with, as far as could be ascertained, relatively sedentary fish stocks, it was selected by the authors' institutes, together with the Sea Fish Industrial Authority, Fishery Economics Research Unit, Edinburgh, and the Irish Sea Fisheries Board, Dun Laoghaire, for a joint bioeconomic study, which was chosen for funding by the Commission of the European Communities under the Fisheries and Aquaculture Research (FAR) Programme. In discussing the issues involved in attempting to rehabilitate fisheries run-down by overfishing, this paper reports on the findings of a questionnaire survey carried out in the Republic of Ireland to establish the time discounting rates held by the fishermen and underlying their business thinking and decision-making. This is probably the most important of the factors influencing cost benefit analysis of any programme of improved fishery management through stock rehabilitation.

## 2. EFFECTS OF REHABILITATING FISH STOCKS BY REDUCING EFFORT

Typically, recovery of catches after reduction of fishing effort (and hence fishing mortality) is preceded by initial losses which persist until the extra fish spared realise enough growth to raise volumes caught with the reduced effort beyond their initial level. This effect, which is modelled routinely in fisheries biology, is shown in Figure. Also shown is the effect of gradual, stepwise reduction, which reduces the severity of the initial losses, but by spreading them at a lighter level over a longer period delays the onset of long-term gains.

Several biological and economic effects exist which may influence the modelling of effort reduction ; these are as follows :

i) Density-dependent growth. As a stock increases in numbers, competition for food will tend to reduce individual growth rates, slightly reducing the level of returns expected from an improved conservation programme.

ii) Multi-species effects. For fish preyed on by other species, reduction of fishing all round may well expose the prey species to increased natural mortality,a s survival of the predator increases. This is a very laborious topic to quantify, normally requiring sampling of predator stomachs ; it also depresses level of expected gains.

iii) Price-size effect. During most of a fish's life its value per unit weight increases, so increased fish age at capture will cause an increase in catch value greater than that in catch weight. This effect raises the levels of expected gains. (It reverses in extreme old age but the numbers of individuals involved are very small).

iv) Price elasticity. This tends to reduce slightly expected changes in both initial losses and long-term gains. However effects may be negligible where initial losses and long-term gains are confined to a pilot area fishery small in extent compared to all fisheries in the same market.

v) As will be shown, a most important effect, since it may strongly influence decisions on conservation measure is that of future (time) discounting. The effect of future discounting on effort reduction calculations is to reduce expected gains since expected immediate losses being close to the present, are less reduced by this effect than the long-term gains.

## 3. QUESTIONNAIRE SURVEY

To assess the fishermen's views on the state of the Irish fishery and examine its amenability to rehabilitation by conservation measures, an interview survey was undertaken during 1991. Its main aim was the acquisition of information on the Irish fleet and its operating expenses in the north-western Irish Sea fishery. Views of skippers on the state of the stocks and as to which measures could best improve catches were also sought as well as the future discounting rates held by them and their attitudes to certain specific Conservation measures, notably individual boat quotas, non-transferable and transferable.

The population surveyed was that of all boats of over 12 metres overall length registered as belonging to owners with addresses on the NW Irish Sea coastline. Of 107 boats on the register, 21 had ceased working in the area, 21 owners could not be located and 10 declined to participate, leaving a sample of 55 respondents. These comprised 39 boats, mainly fishing for Nephrops fourteen mainly fishing for Whitefish (Cod, Whiting etc.) mostly with a minority component of *Nephrops* activity, and two boats beam trawling for sole (Table 2). As these last were so very different from all others (Brake Horse Power of 1260 and 2000 respectively, whereas the other 53 boats lay in range 90-700 BHP range), it was felt that they would distort any size-category in which they were included with others and that since they on their own form a small category, their data should only be reported for non-contentious subjects. In some other cases sample size is slightly reduced by inability or reluctance of respondents to answer specific questions. Mean profitability of most boats is given in Table 3 which suggests positive correlation with size and better levels for nephrops fleet than for the whitefish fleet. Some preliminary results of the survey have already been reported (Hillis and Whelan, *in the press*). The skippers' views on the degree to which the main species were overfished are shown in Table 4, showing responses in respect of the five main species plus the next two in importance in 1991. Replies, which omit the very few "don't knows", show that a majority of all respondents ranging from 62 % for "plaice and other flatfish" and for ray/skate to 91 % for cod thought each species to be overfished. From 7 % (for cod) to 36 % (for plaice and for ray/skate) thought the species involved to be about optimally fished, whilst from 2 % to 6 % of respondents were optimistic enough actually to consider each species underfished. Interestingly whitefish respondents were considerably (10-31 %) more pessimistic about whitefish (except for ray/skate) than were nephrops respondents, who in turn - despite 8 % who thought nephrops underfished - were on balance more pessimistic about nephrops than were the whitefish respondents, i.e. (apart from the two sole beamer respondents) each fleet thought its own species in worse condition than those of the other fleets.

Further responses noted by Hillis and Whelan (*op.cit* ) very strongly indicate that the fishermen are under no illusion but that the NW Irish Sea is severely overfished ; 88.9 % of respondents think present policy inadequate to ensure survival of overfished species and 72.7 % think regulations should be enforced more strictly. 72.7 % also responded to the effect that a reduction in total catch for a few years would lead to a permanent increase in future profits, with the reasons given by the dissenting 27.3 % ("I could not survive the few years' reduction" and "It could not be implemented/cheating could not be eliminated") showing that they were not, in fact responding to the question as put, but to an implicit question on practicality of such a course perceived as underlying the question put.

## 4. TIME DISCOUNTING RATES

### *4.1 Money*

To investigate the question of the perceived importance amongst skippers of events and values int he non-immediate future compared to their importance in the immediate future, respondents were asked whether they would prefer to receive IR# 1000 now, or sums of IR# 1050, IR# 1100, IR# 1200, IR# 1500, IR# 2000, IR# 2500, IR# 3000 or IR# 5000 after elapsed periods of 1 year, 2 years and 5 years. This gave ranges within which respondents' time discounting rates could be assumed to lie, and composite values were obtained from means of the three lengths of period arbitrarily weighted by 3,2 and 1 for 1,2 and 5 years to account for a slight decrease in consistency of results observed with increasing period length.

The resultant values were very variable, ranging from under 2 % to over 60 %. Table 5 shows that their distribution related to engine BHP indicated an inverse relationship of values to engine size with a marked bimodality of distribution

of values clearly apparent with the smaller boats, implying a minority element, nearly all with boats of under 400BHP with values of over 40 % in contrast to the majority with values of under 40 %. The distributions by port area show three out of the four areas - those with the greatest quantities of small boats -to exhibit the same bimodal distribution. This is important as it indicates the possibile existence of two rather contrasting attitudes towards fishery management to be catered for in these ports. The mean values by port and by degree of profitability are given in Table 6. Ports A, B and C which are almost completely dedicated to nephrops fishing and have smaller boats than port D, have somewhat higher mean values, but the differences are not significant. As is to be expected, low profitability boats including lossmakers quote higher values than medium profitability boats, but it is of interest to note that the most highly profitable boats also a mean have value slightly higher than those of medium profitability.

### *4.2 Fish*

To test the applicability of the reasonable hypothesis to which a large majority have been shown to assent, to the effect that reduced catches in the immediately future could lead to permanently improved catches later, respondents were presented with the diagram in Figure 4, simplified to indicate two years of reduced profits, followed by two years of profits at their current level followed by profits at a permanently increased level ; they were asked to specify how much of a reduction in catch they would agree to if the permanent increase (B in the diagram) were respectively : 100 % ; 50 % ; 25 % and 10 %. In theory, the 'rational' respondent would calculate the relative value of two income streams :

(a) continuation of present average catch levels

(b) a reduction in periods 1 and 2, followed by a permanent increase of the specified amount in periods 5 to infinity.

The discounted present value of the latter income stream for a fisherman presently catching on average of 100 units is :

$$100 \sum_{i=0}^{i=3} 1/(1+r)^i - (A + A/(1+r)) + (100 + B) \sum_{i=4}^{i=\infty} 1/(1+r)^i$$

On this basis, Table 7 shows the percentage reduction that a 'rational' individual should be willing to make in his catch to obtain the benefit specified. The calculation is carried out for various hypothetical discount rates from 5 per cent to 50 per cent. The last column but one of the table shows the actual average reduction that respondents said they would be willing to make to achieve the gains specified. Thus, when promised a doubling of catch from year 5 on, respondents said they would be willing to reduce catch by 10.8 per cent in periods 1 and 2. If the expected increase were 10 per cent, then the average reduction would only be 1.4 per cent. The last column gives the implicit actual discount rates, obtained by extrapolating rational reduction rates on Gaussian paper to the actual average level. Results were very close, at 52-54 % except for those corresponding to 100 % anticipated eventual increase, which were 60 %. An approximate average value of about 55 % would appear to be applicable.

The actual values of the reductions which respondents said they would be prepared to make have been average for the four levels used in the question and the results appear in Table 6 together with the percentages of people willing to make any reduction at all. Sorted by port, they show port A to have a much greater willingness to reduce than ports B, C and D and a correspondingly higher mean value of percentage reduction contemplated. Sorted by profitability category the contrast is less (i.e. values are less influenced by profitability than by inherent inter-areal differences in outlook). However, as with discount rates for money, the least profitable are the least inclined to short-term sacrifice, with however the moderately profitable more strongly inclined thereto than the highly profitable.

To demonstrate the effect of fishermen's discounting rates, they were applied to an example of predicted recovery levels of a fish stock after an improvement in conservation (nephrops after an increase in mesh size, Anon 1985). The two plots show predicted recovery assuming natural (non-fishery-related) mortality rates of M = 0.2 and M = 0.3 ; the value of this difficult-to-assess parameter is believed to lie in the region of M = 0.26. In both cases an immediate fall in yield of 22.8 % from which recovery is quite rapid leads to a permanent increase above former status quo of 18.4 % assuming M = 0.3 and 4.1 % assuming M = 0.2. The worthwhileness of the conservation operation being dependent on the

costs/losses quantified as the space below zero and down to the line of the plot on the left-hand part of the graph being less than by the benefits, the space above zero and up to the plot line in the right hand area. The use of time discounting reduces values below and above zero to an increasing extent with the passage of time and hence reduces the gains to a greater extent than the losses ; the higher the rate of time discounting the stronger this effect is bound to be.

In addition to zero discount rate, the rates shown are 12 %, approximately real rate of interest in Ireland applicable to normal commercial cost benefit analyses, 25 %, the approximate time discounting rate of fishermen applied to money, and 55 %, the time discounting rate of fishermen implicit in their views on accepting immediate catch reductions to achieve long-term benefits.

Figure 5 and Table 8 demonstrate graphically how apparent gains in conservation are whittled away by application of time discounting due to the downgrading of long-term gains to a much greater extent than short term losses ; using M = 0.2 the commercial 12 % rate reduces 20 year gains at 0 % discount rate by about 80 %, and with M = 0.3, 12 % discounting turns the small gain at 0 % into a loss about 3.5 times greater. At 25 % discount rate the M = 0.2 result is approximately a break-even, while for M = 0.3 it is a loss, as is the case for both values of M at the 55 % fishermens 'fish' discount rate.

## 5. DISCUSSION

The depressing conclusion is that from the fishermen's standpoint, reducing catches now to allow the stock to recover is simply unacceptable, as even with the fishermen's 'money' discount rate, future gains are far enough away to fall below the level of short-term losses. A point that may possibly have some significance is that while the unwilling to contemplate reduction of catches as they feel they cannot afford it, the high profitability boats are slightly less willing to reduce catches, possibly because they feel that for them personally, the problem of dwindling catches is not serious to warrant acceptance of any constraints. Looking over the coast however, there are signs of considerable variation, and it is possible that by investigating different attitudes and their bases some way forward might become apparent. Otherwise the only way to make such stock rehabilitation measures acceptable would appear to involve some form of grant/subsidy program to mitigate the effects of initial losses ; if it were certain that implementation would take place, such mitigation of initial losses would become a sensible subject for commercial style loans from financial institutions. However, many responses displayed confidence with present management measures and the strictness of their enforcement, hence there are indications that such loans could be highly risky. However, if conservation can be made more effective, if funds can be found to mitigate initial losses and if such a recovery programme can be implemented in a cheat-proof fashion, the chances are that the Irish fishery in the north-west Irish Sea, as well as many others, can be made reasonably profitable.

# Hysteresis et comportements adaptatifs des pêcheurs artisanaux

**Hélène Rey**

IFREMER 155, rue J.J. Rousseau 92138 Issy les Moulineaux Cedex, France

RÉSUMÉ

*The concept of hysteresis, originally used in the field of physics, has been introduced into social sciences. It helps explaining some of the adjustment gaps in the economy not only as a delay effect between variables, but also as a memory effect of the system. As a new step in our research about economic and social flexibility, adaptative processes in response to "shocks" are questioned here. Flexibility is generally studied as a process of adaptation to changes, for which the memory effects plays an important role. Are considered as "shocks", changes in the system that take place within unexpectable, because unexperienced previously, time frame and variability range. As complex systems are concerned here, the response is highly depending on the initial position of the system at the time of the impulse. Under these conditions, the degree of vulnerability of a fishery facing a shock might depend upon such variables as its life time or the length of the exploitation cycle.*

*The concept of foreseeability of uncertainty is introduced and the main determinants of the expectation ability are discussed. The introduction of effort mobility, depending on entry/exit costs, helps us to consider the succession of factor allocation decisions and thus to improve the deterministic perception of time. The analysis shows that investment decisions depend as much on the actors behaviour as on the steps in the evolution of the fishery or the very impact of the shock, that on the state of stocks, the level of pressure on the stock,...*

## 1. INTRODUCTION

Avec la crise économique la notion d'adaptabilité est devenue une préoccupation majeure des économistes. L'instabilité de la demande et l'allongement de la durée de réversibilité des décisions de production conduisent à une réflexion sur l'introduction de l'incertitude dans le processus de décision et sur la flexibilité des unités de production (Cohendet et Llerena, 1989 Guerrien, 1989 ; Walliser, 1985). Parallèlement les halieutes et les océanographes envisagent les conséquences de l'instabilité de la ressource en montrant le caractère "chaotique" de la dynamique des systèmes

halieutiques (Cury et Roy, 1991). Confrontées à la non applicabilité des modèles traditionnels, les recherches se réorientent vers des modélisations systémiques et pluridisciplinaires qui ne se limitent plus à la dynamique ressource-investissement mais qui tentent d'appréhender l'ensemble des interactions entre les systèmes naturels et les systèmes sociaux. Il en découle un changement de représentation théorique. Contrairement aux modèles déterministes prédateurs-proies, où les variables pertinentes sont définies *a priori*, les modèles systémiques mettent en jeu des interactions multiples où le temps et l'espace sont des variables à la fois spécificatives et explicatives (Chaboud et Fontana, 1991 ; Quensiere, 1992).

Ces approches nécessitent non seulement de nouveaux outils mais aussi de nouveaux concepts. L'intégration des phénomènes de mémoire (Atlan, 1979) et la multidimensionnalité des échelles de temps et d'espace (Lestienne, 1990) font référence à une propriété physique : l'hystérésis. Celle-ci offre un cadre conceptuel de réflexion sur le rôle du temps dans le processus de décision au sein d'un système complexe et ouvert. Il ne s'agit plus seulement d'analyser des effets retard entre variables, mais d'appréhender un effet mémoire du système.

Prolongeant une réflexion sur la flexibilité des unités de pêche artisanale (Dabat *et al.*, 1990 ; Rey, 1991-b), l'objectif de cette communication est d'analyser si la flexibilité est liée à une échelle de temps donnée qui serait le court terme. Le changement d'échelle de temps modifie le niveau d'interrogation : il ne s'agit plus d'aborder la flexibilité du point de vue productif comme la propriété d'un système mais plutôt la flexibilité décisionnelle comme processus d'adaptation dans le cadre d'une transformation du système.

## 2. L'ANALYSE DE LA FLEXIBILITE DES UNITES ARTISANALES RENCONTRE DES LIMITES

(i) Le caractère dispersé des débarquements, la multiplicité des techniques le plus souvent individuelles, la multispécificité des stocks exploités, l'hétérogénéité des niveaux d'activités, font des pêcheries artisanales un objet d'étude qui se caractérise par sa complexité et qui est doté de ce fait d'une propriété d'autorégulation (Atlan, 1979) permettant une adaptation à la variabilité de l'environnement. Ainsi ces pêcheries longtemps considérées comme archaïques, sont à présent étudiées sous l'angle de la flexibilité. Celle-ci induit des spécificités dans les fonctions de production qui relèvent d'une stratégie d'adaptation à un environnement incertain. Sans détailler les formes d'organisation que peut recouvrer cette recherche de flexibilité, on peut noter le caractère familial de la main d'oeuvre, l'existence de formes particulières d'embauche et de rémunération, la pluriactivité et la diversification des techniques et des espèces cibles (Rey, 1991-b). Fréquemment, la flexibilité est assimilée à la diversification de l'appareil productif. Ainsi en Languedoc-Roussillon 13 % seulement des unités de pêche aux petits métiers sont spécialisées tandis que certains pêcheurs pratiquent jusqu'à 15 techniques différentes au cours de l'année. De même 40 % des unités ont une activité complémentaire extérieure au secteur halieutique (Rey, 1989). D'un point de vue dynamique cependant, une fois définie une composition dite flexible des facteurs de production, on observe une stabilité du mode de production dans le temps et dans l'espace. Ainsi 76 % des pêcheurs petits métiers de Méditerranée n'ont pas modifié leur stratégie depuis qu'ils ont débuté leur activité et 72 % n'ont jamais changé de zone de pêche (Rey, 1989).

(ii) Le manque de mobilité constatée à moyen terme ne signifie pas pour autant absence d'innovation. Au contraire la pratique de la pêche s'effectue dans un contexte d'innovation technique continue. L'absence de changement concerne la nature des métiers pratiqués, elle n'exclut pas des modifications tactiques ou technologiques au sein de ces métiers. De même lorsque nous parlons de stabilité des zones de pêche nous faisons référence aux territoires des juridictions prud'homales de Méditerranée. S'il est vrai que peu de pêcheurs dépassent ces limites, cela ne doit pas obérer le fait qu'à l'intérieur de ces espaces, leurs terrains de pêche sont très diversifiés (hormis pour les pêcheries fixes). Dans de nombreuses pêcheries l'exploitation est structurée par les migrations. Cependant là encore il convient de caractériser ces déplacements selon qu'ils s'accompagnent ou non d'une stabilité des lieux concernés. Dans le Delta central du Niger, la réduction des superficies en eaux consécutive à la sécheresse s'est traduite par un déplacement des terrains de pêche qui a conduit certains pêcheurs à s'installer une partie de l'année, dans des campements proches de leurs agglomérations d'origine. Dans d'autres cas, on observe des migrations traditionnelles liées aux comportements de certaines espèces. Là encore, on note une stabilité des zones d'accueil : les campements, dont certains ont tendance à devenir permanents, sont organisés selon des affinités villageoises ou familiales souvent stables d'une année sur l'autre. La variabilité de la crue se traduit plutôt par un ajustement du temps passé dans les campements que par une modification des sites. De même en Côte d'Ivoire Delaunay (1990) observe des flux réguliers et organisés de pêcheurs ghanéens. Dans sa typologie des migrations de pêcheurs en Afrique de l'Ouest, Diaw (1992) montre qu'il s'agit pour la plupart de mouvements régulés.

## 3. L'APPROCHE DE LA FLEXIBILITE COMME PROCESSUS

(i) Les stratégies de flexibilité précédemment décrites relèvent de l'adaptation à une variabilité intra ou inter-annuelle de la ressource dans le cadre d'horizons temporels et d'amplitudes de variation attendus. Cette notion de variation attendue, bien qu'incertaine, nous oblige à nous interroger sur la prévisibilité de l'incertitude. Le concept de risque fait référence à des situations aléatoires mais dont la répétition permet des probabilités conditionnelles *a priori*. Par opposition toute situation où l'on ne dispose pas de statistiques relève de l'incertitude. Selon les cas on distinguera la flexibilité statique et dynamique (Cohendet et Llerena, 1990). La flexibilité statique relève d'une stratégie de diversification qui se traduit par des surcapacités productives mais qui permet une adaptation au risque. La flexibilité dynamique se définit comme la capacité de réagir continûment dans le temps aux incertitudes liées à l'environnement. Cette flexibilité repose sur les notions de délais de réaction (Cohendet et Llerena, 1990) et de capacité d'anticipation.

(ii) Face à l'incertitude, la capacité d'anticipation de l'individu est commandée par sa faculté de mémorisation. On se réfère ici à la notion de flèche du temps qui conduit à une perception du présent comme prolongement du passé et comme racine du futur : *"si les événements accomplis ont laissé des traces, il est vraisemblable d'imaginer que les événements à venir ont leur racine"* (Balzac). Une perception de l'incertitude peut être proposée selon le cadre introduit par Jankelevitch (1974) à propos de l'irréversibilité. Cet auteur distingue en effet quatre niveaux d'approche selon que la mémorisation ou non du passé est associée à une anticipation prospective ou non du futur. La capacité d'anticipation de l'incertitude ne peut intervenir que dans le cas d'une conscience à la fois rétrospective et prospective où il y a pressentiment intuitif du futur en fonction du ressentiment du passé (Jankelevitch, 1974). La théorie économique distingue deux mécanismes. Dans un contexte de stabilité, les anticipations extrapolatives appréhendent l'avenir par une simple projection des tendances passées. Les anticipations adaptatives sont quant à elles censées résoudre le problème de l'appréhension du futur dans un contexte instable. Elles relèvent d'un processus procédural qui raisonne sur une décomposition séquentielle de la décision. L'intégration des observations présentes permet une révision continue de ces anticipations. Dans tous les cas cependant on raisonne hors rupture majeure de l'évolution économique (Malinvaud, 1991). La flexibilité, même dynamique, est conditionnée par la perception des limites du système en fonction de la mémorisation de ses transformations passées et ne peut donc permettre une adaptation instantanée à des chocs.

(iii) La flexibilité se définit donc par rapport à une période (périodisation et historicité liée à la faculté de mémorisation) et par rapport à un cadre spatial (territorialisation liée au caractère déterminant du milieu et aux contraintes d'accessibilité (réglementation, savoir faire...)). Au delà de ces limites, (Cury (1991) parle de frontières) il se produit un changement de dimension du système qui est assimilable à un choc. Le processus d'adaptation doit alors faire intervenir d'autres paramètres et conduit, selon les principes de la dynamique des systèmes vivants, à la transformation du système (Atlan, 1979). Il y a une succession de systèmes dont les paramètres se transforment dans le temps selon les contraintes du milieu.

(iv) Notre définition des chocs fait référence à des faits de nature diverse, tant écologique qu'économique, aussi bien positifs (nouvelles opportunités) que négatifs. Leur origine peut être endogène ou exogène puisque le système pêche est appréhendé ici comme un système ouvert. Le dénominateur commun à tous ces facteurs est que leur impact suffise à engendrer une transformation du système. Cependant, s'agissant de systèmes complexes, les chocs ont des origines multiples. Ainsi la crise de la pêcherie péruvienne en 1973 (la production passe de 13 millions de tonnes en 1970 à 3,8 millions en 1974) est généralement attribuée à un changement hydrologique. Chaboud (1991) montre qu'elle s'explique aussi par des décisions de politique sectorielle. De même, les difficultés rencontrées dans le Delta central du Niger ne sont qu'en partie dues à la sécheresse de 1973. Le changement de réglementation qui attribue à l'Etat en 1963 une souveraineté sur les eaux jusqu'alors régulées de façon coutumière, a aussi eut un rôle perturbateur. De même la construction de barrages sur le fleuve Niger s'est traduite par une réduction des prises évaluée à 5000 tonnes, soit 10 % des captures annuelles (Lae, 1992). Par ailleurs certains chocs génèrent des processus d'autorégulation. Ainsi les phénomènes de malaïgue dans les étangs languedociens se traduisent par d'importantes mortalités et un arrêt temporaire de la pêche. Cependant les comportements grégaires des poissons quelques jours avant permettent des pêches miraculeuses. De même lors du réchauffement de l'upwelling péruvien, on a observé dans un premier temps des prises importantes (170 000 tonnes journalières) liées à des rassemblements d'anchois près des côtes (Chaboud, 1991). Dans ces cas, la possibilité de compenser les pertes futures dépend de la capacité de pêche des unités. On peut supposer que celle-ci, bien que difficile à définir, soit proportionnelle à l'investissement. En l'absence de contingentement, ces pics conjoncturels de capture bénéficient donc aux unités qui ont le plus investi et leur permet une réduction partielle des coûts de sortie de la pêcherie.

(v) Face à un choc, le concept d'adaptation doit être appréhendé de façon particulière. S'agissant de systèmes complexes, il est montré que les réponses dépendent de la position du système au moment de l'impulsion (Cury, 1991). La vulnérabilité d'une pêcherie pourrait donc être fonction de sa durée d'existence et de la phase du cycle d'exploitation auquel elle est soumise. La flexibilité n'offrant pas un cadre suffisant pour appréhender les stratégies d'adaptation à des chocs il convient de rechercher un cadre d'approche plus approprié.

## 4. TRANSFERABILITE DU CONCEPT D'HYSTERESIS A L'HALIEUTIQUE

(i) A l'origine le concept d'hystérésis est utilisé pour l'étude des phénomènes de ferromagnétisme (Bertin, Faroux et Renault, 1984). Après une aimantation portée à saturation, on observe des écarts des courbes de désaimantation qui définissent une aimantation résiduelle : le système ne revient pas à son point de départ et ne retrouve sa valeur originelle qu'après un certain délai. L'importance du phénomène est fonction de la vitesse de variation.

(ii) Dans le domaine des sciences sociales, la transposition de ce concept a permis d'éclairer les écarts d'ajustement observés dans les relations entre l'emploi et les salaires (Cotis et Mihoubi, 1990 ; Le Page, 1991) et entre le taux de change et le solde de la balance commerciale (Ducos et Lecointe, 1991). Dans les deux cas il s'agissait d'expliquer la persistance d'un déséquilibre. En effet au plan théorique, l'hystérésis réfute le postulat classique d'unicité et de stabilité de l'équilibre : Le Page (1991) parle d'analyse des équilibres fragiles. Le concept d'équilibre est au coeur de la science économique. Dans un premier temps, il est abordé de façon statique : on parlera successivement d'équilibre (Walras), d'équilibre général (Marshall), d'équilibre de sous emploi (Keynes). Dans tous les cas il s'agit de systèmes fermés, souvent bidimensionnels. Par la suite, l'introduction d'une dimension temporelle donne naissance au concept d'équilibre intertemporel appréhendé comme une suite d'équilibres temporaires. Là encore cependant, l'hypothèse implicite sous jacente est celle d'une régularité des phénomènes (Malinvaud, 1991).

(iii) L'hypothèse de phénomènes d'hystérésis rompt avec les modèles traditionnels de type récursif, pour lesquels chaque équilibre temporaire dépend des valeurs des équilibres temporaires précédents. Elle ne remet pas cependant totalement en cause le concept d'équilibre mais montre qu'il existe de multiples équilibres et qu'ils dépendent de l'ampleur de la variation, c'est à dire du chemin temporel qui mène à l'équilibre. L'hystérésis met en évidence une dérive qui s'incrémente à chaque période et qui tient compte de phénomènes dont les effets perdurent alors que leur cause originelle est dissipée (Amable *et al.*, 1990 ; Cotis et Mihoubi, 1990). Analyser le processus d'adaptation d'un système complexe et ouvert revient à étudier la dynamique d'un système par rapport à un environnement qui est lui-même en évolution. Selon les auteurs, de multiples images sont évoquées. Cury (1991) fait référence à une pièce de théâtre où le jeu des acteurs et les décors se modifieraient au fil des représentations. Le Page (1991) cite l'exemple d'une balle sur une surface accidentée développé par Blanchard et Summers (1988). Le point d'équilibre dépend de la forme de la surface, avec deux situations extrêmes : s'il s'agit d'un bol, il n'existe qu'un point d'équilibre ; si au contraire la surface est extrêmement plate, la position dépend du choc imprimé à la balle.

(iv) Tester l'hypothèse d'un effet d'hystérésis dans le domaine des systèmes halieutiques, revient à s'interroger sur l'existence d'une dérive temporelle des pêcheries qui résulterait de modifications structurelles liées aux chocs reçus. L'étude de la dynamique de l'investissement paraît être une entrée pertinente. Les observations témoignent généralement d'un trend orienté à la hausse. Il s'agit donc d'affiner l'analyse en envisageant comment cette augmentation peut être fonction des chocs reçus et de la situation de la pêcherie au moment où ils interviennent. Pour ce faire, nous envisagerons tout d'abord les délais de réaction aux chocs au niveau des unités, puis, en fonction des différentes phases d'investissement, les mécanismes de réaction du système dans son ensemble.

## 5. TYPOLOGIE DES DELAIS DE REACTION AUX CHOCS DANS LES SYSTEMES HALIEUTIQUES ET MOBILITE DE L'EFFORT

(i) L'introduction du temps dans les modèles bio-économiques ne s'effectue que par la prise en compte d'un taux d'actualisation qui pondère les valeurs futures du profit. On retrouve ici la même limite que dans les modèles économétriques où le temps est appréhendé d'un coup jusqu'à l'horizon temporel (Malinvaud, 1991). Il s'agit donc d'une

perception déterministe du temps où l'enchaînement des conséquences des décisions d'allocation des facteurs de production n'est pas considéré (Gilly, 1989).

(ii) La mobilité de l'effort est supposée immédiate, parce que gouvernée par le principe de maximisation du profit sous tendu par la rationalité néo-classique des modèles. Le mécanisme de stabilisation est conditionné par cette hypothèse de mobilité totale. Or la prise en compte des coûts d'entrée et de sortie peut expliquer des écarts d'ajustement. Une mesure de la mobilité peut être proposée en fonction de l'amortissement ou non des coûts d'entrée et de la décomposition des alternatives de sortie selon des critères spatiaux-sectoriels. En effet, les possibilités de reconversion externe à la sphère halieutique sont limitées par la spécificité de l'appareil productif qui tend à privilégier une mobilité intrasectorielle dépendant du marché d'occasion. Cependant, pour les pêcheries artisanales, des degrés de mobilité partielle peuvent être introduits avec le redéploiement d'une partie de l'effort sur d'autres pêcheries, ou avec la réaffectation du facteur travail au profit d'une activité complémentaire.

(iii) Le centrage de l'analyse ici sur le concept de coût d'entrée et de sortie relève de notre volonté de nous situer dans un cadre formel en fonction du temps et de l'histoire de la pêcherie Néanmoins il convient, en raison de la faiblesse des investissements initiaux, de relativiser ce concept pour certaines composantes de la pêche artisanale. L'hétérogénéïté des situations ne permet pas une définition universelle de la pêche artisanale. Sa délimitation est contingente à des situations, des espaces, voire des périodes. Elle se définit généralement de façon négative par rapport à la pêche industrielle (Chauveau et Weber, 1989). En France la discrimination s'effectue à partir d'une taille maximum fixée à 25 m. Sous le vocable pêche artisanale sont donc regroupés par exemple les pêcheurs artisans boulonnais dotés de bateaux de 20 à 25 m équipés de matériel de navigation perfectionné et les petits métiers méditerranéens dont l'actif brut est pour les trois quarts d'entre eux inférieur à 50000 F. De même le raisonnement en terme d'optimalité bute sur la pluralité des finalités poursuivies par les unités de pêche artisanales, notamment lorsqu'elles sont familiales. Parmi ces objectifs on relève la valorisation du statut social dans la communauté, la recherche d'autonomie, la minimisation du temps de travail, le désir d'un maintien dans la communauté et la région d'origine. (Rey, 1991-a).

(iv) Le croisement des degrés de mobilité dans le temps et dans l'espace peut être synthétisé par un tableau à double entrée (cf. tableau 1). Il existe un éventail de situations entre la mobilité et la fixité totale de l'effort qui correspondent à la possibilité de sortie immédiate ou au contraire à une obligation de maintien dans la pêcherie. Lorsque les coûts d'entrée ont été amortis, la mobilité est décomposable en fonction des opportunités. Ainsi on parlera de mobilité d'innovation lorsque l'unité de pêche recherche des opportunités d'exploitation de nouvelles espèces ou de nouvelles zones de pêche tout en continuant à titre complémentaire l'exploitation initiale. Cette continuité peut avoir pour objectif de maintenir des droits historiques, de profiter d'acquis technologiques ou de savoir faire ou résulter de l'impossibilité de réaliser les immobilisations correspondantes. Inversement la contrainte peut venir de ce que les alternatives de reconversion ne permettent pas à elles seules la rentabilisation des facteurs de production, ou, s'il s'agit d'activités nouvelles, du désir de minimiser les risques avec une autre activité maîtrisée. De la même façon la mobilité partielle peut concerner le facteur travail. On parlera alors de mobilité de diversification. A l'extrême la fixité de patrimoine correspond à la situation courante en zone défavorisée ou en situation de crise, où la valeur de revente des investissements se détériore. L'absence de possibilité de reprise oblige alors au maintien de l'activité même dans des conditions de rentabilité défavorables.

Le non amortissement des coûts d'entrée sous entend l'existence de coûts de sortie. Plusieurs possibilités peuvent aussi être distinguées. S'il existe des possibilités de reconversion, la sortie peut intervenir après un délai qui réduit les coûts de sortie. La durée de celui-ci résulte des arbitrages entre les pertes relatives attendues et la rentabilité escomptée des opportunités envisagées. Comme précédemment les alternatives peuvent être partielles et ne concerner que le capital ou le travail. Ainsi la mobilité partielle spatiale ou spécifique correspond au cas d'exploitation partagée entre plusieurs stocks ou plusieurs zones de pêche. Elle suppose par rapport à la mobilité d'innovation de pouvoir s'effectuer sans transformation importante des facteurs de production, ceux-ci n'étant pas amortis. La mobilité partielle temporaire correspond à une réaffectation d'une partie du travail à d'autres activités sans que, à la différence de la mobilité de diversification, cela remette en cause la continuité de l'exploitation initiale.

## 6. CONSEQUENCES SUR LA DYNAMIQUE DE L'INVESTISSEMENT

(i) En premier lieu, il convient de préciser le processus d'investissement. Les facteurs déterminants sont multiples mais les résultats antérieurs et l'accès au financement sont bien évidemment déterminants. En Languedoc Roussillon le niveau

d'investissement varie selon les zones et les types de pêche. Il est corrélé avec le mode de financement et l'existence d'un travail extérieur de l'épouse qui apparaît comme la possibilité d'une caution bancaire et d'un revenu minimum fixe (Rey, 1989).

(ii) L'analyse des comportements des pêcheurs en matière d'investissement nous conduit à distinguer plusieurs situations correspondant à des rationalités différentes. Nous retiendrons quatre catégories principales : des investissements de productivité, de modernisation ou d'opportunité, de flexibilité et de mimétisme (cf. tableau 2).

(1) Les investissements de productivité permettent d'adapter les conditions de rentabilité à l'évolution technologique ou économique du secteur. De ce fait, ils relèvent sauf cas particuliers de l'autofinancement ou du financement bancaire.

(2) Les investissements de flexibilité offrent une souplesse de réponse à des variations anticipables (cf. infra). Ces investissements sont donc dimensionnés en fonction des frontières maximales préssenties du système. Les analyses économiques s'accordent à montrer qu'ils se traduisent par des surcoûts (Cohendet et Llerena, 1990 ; Boussard, 1990). Une mesure de ces investissements peut être tentée en confrontant le matériel de pêche possédé avec le niveau habituellement utilisé et les besoins de rotation. Ainsi en Languedoc-Roussillon les pêcheurs calent en moyenne seulement 27 % de leurs capéchades, 30 % de leurs filets maillants et 32 % de leurs trémails (Rey, 1989).

(3) L'accès aux investissements de modernisation ou d'opportunité dépend fréquemment de l'attribution de crédits ou de subventions et relève souvent des acteurs leaders. Ceux-ci se démarquent souvent par un meilleur savoir faire, lié à une tradition de la pratique de la pêche ou à une plus grande aptitude. Dans certains cas ils peuvent avoir des droits particuliers sur la ressource. Il en est ainsi des maîtres des eaux dans le Delta central du Niger qui reçoivent un tiers des prises des pêcheurs allochtones. Les leaders ont une influence sur l'attribution des subventions voire sur l'orientation des mesures de réglementation édictées par les pouvoirs publics. Moricet et Reveret (1989) pour le Canada et Feral et Berger (1987) en Méditerranée mettent en évidence de tels phénomènes de lobbying où les pêcheurs dynamiques deviennent les interlocuteurs privilégiés de la puissance publique dont ils inspirent la politique d'intervention souvent à leur bénéfice. De même les règles de fonctionnement des prud'homies témoignent d'un corporatisme lui aussi inducteur de discriminations : ainsi dans les étangs languedociens, il faut disposer d'un équipement minimum pour postuler à l'attribution des postes de pêche fixe (Feral, 1976). L'existence de leaders génère une croissance de l'investissement qui se diffuse par mimétisme.

(4) Les investissements de mimétisme se font généralement à la suite de bonnes pêches. Comparativement au niveau d'équipement moyen, ils relèvent jusqu'à un certain seuil d'une rationalité ostentatoire. Par la suite lorsque leur diffusion à l'ensemble du secteur engendre un différentiel de compétitivité, ils deviennent des investissements de productivité pour les unités qui les réalisent tardivement. Les décisions d'investissement de mimétisme étant sensibles au concept de "bonne pêche", c'est moins le niveau global des résultats passés qui est déterminant que sa dispersion dans le temps. Ainsi en Languedoc-Roussillon les achats de matériel de pêche ne sont pas programmés en fonction des besoins mais des résultats (Rey, 1989).

(iii) L'hypothèse d'existence d'un effet d'hystérésis suppose que le taux de croissance de l'investissement est influencé par les successions de chocs et la nature des réactions d'adaptation qu'ils ont entraînées. L'intégration des phénomènes de lobbying et de mimétisme conduit à une approche de type insiders-outsiders où le niveau d'investissement qui est directeur est déterminé par les acteurs qui sont au coeur du système. Il se diffuse ensuite par mimétisme selon un rythme aléatoire lié à la réalisation de "bonnes pêches". La figure n° 1 tente de synthétiser ce processus. On observe la succession de phases d'investissement de modernisation et de productivité chez le groupe des leaders et de mimétisme et productivité pour les non leaders. La diffusion par mimétisme étant aléatoire, les paliers d'investissement et la durée de diffusion (symbolisée par les flèches entre les groupes sur le schéma) sont irréguliers.

Que se passe t-il lors d'un choc ? En cas de persistance d'une crise le nombre d'unités qui va quitter la pêcherie sera fonction des différentiels de coût marginaux, donc des phases d'investissement. Le moment où intervient la crise est déterminant des réactions. Quatre éventualités (cas n° 1 à n° 4 sur la figure) sont possibles quant à l'articulation des situations des deux groupes, leaders et non leaders (cf fig. 1). Selon les phases d'investissement, c'est à dire selon l'histoire de la pêcherie au moment où intervient la crise, les unités relèveront d'une des catégories de mobilité de l'effort et auront donc des réponses différenciées en terme de délais et de degré. Hormis si la crise paraît sans issue (cas où les leaders vont profiter de leur situation pour négocier au mieux leurs conditions de départ), on peut supposer que les acteurs leaders auront une propension plus forte à se maintenir dans la pêcherie (stratégie de confortation de leur avantage liée à leur position d'insiders). L'effort sera donc globalement réduit mais son niveau moyen unitaire s'élèvera du fait du

maintien des leaders. La dynamique des investissements de mimétisme se fondant sur une différenciation de statut l'accroissement du niveau moyen de l'effort unitaire lié à l'augmentation du poids relatif des leaders va accélérer la croissance de l'investissement, et ceci d'autant plus s'il y a attribution de subventions compensatoires, celles-ci étant généralement octroyées proportionnellement au niveau d'investissement.

## 7. CONCLUSION

L'analyse de ces différents mécanismes montre que la décision d'investissement relève autant des comportements d'acteurs, des phases d'évolution de la pêcherie et de la date d'apparition d'un choc que de l'état des stocks et du taux de prélèvement de la ressource. Les quelques éléments développés ici semblent attester d'un effet d'hystérésis. Néanmoins ils reposent pour l'instant sur de nombreuses hypothèses simplificatrices et n'ont pour prétention que d'offrir des orientations de recherche. Ainsi il conviendrait d'établir un modèle pour tester ces hypothèses. De même une exploration systématique du champ des comportements possibles est nécessaire à la généralisation des mécanismes présentés ici qui se basent sur des pêcheries particulières (Méditerranée, Delta central du Niger). Ainsi si les leaders quittent la pêcherie de façon préférentielle (Gates, 1990), les conséquences des chocs seront différentes. Par ailleurs, s'agissant de systèmes complexes, l'attention devra être portée sur les interactions en introduisant par exemple des différentiels d'effets selon les cadres réglementaires et l'impact des processus de substitution capital-travail.

ABSTRACT

*Reliable prediction of financial distress is of great value to both shareholders and lenders. By "financial distress" we will in this paper mean bankruptcy. Nine models have been constructed consisting of various combinations of financial key ratios. These models are tested for their power to predict banckruptcy from one to five years before actual bankruptcy take place. Two statistical methods are used and compared ; the linear discriminant method and the probit method. For all the models the predictive power is significant up to three years before bankruptcy. Two of the models have the ability to predict significantly up to five years before bankruptcy.*

## 1. INTRODUCTION

During the period 1977 to 1990 the North Norwegian fish processing industry experienced a dramatic and turbulent time. The total number of companies declined from about 520 to 240. At the same time the landings of fish decreased from nearly 400 000 tons to 185 000 tons in this area. The main reason for the more than 50 % decline in the total population of processing companies, is financial distress, caused by insufficient capacity utilization, fluctuating marked prices and low productivity.

A few companies were able to rewind their operations in an orderly fashion. A Government scheme have been in operation, allowing a selected few to pay the creditors in full and still have some equity intact. Various conditions have been linked to this Government support program, which main aim has been to reduce overall capacity.

However, for most of the companies that have retreated from business the creditors and the owners have had to bear a loss.

We have divided the companies in this study into two groups : one group of companies consisting of those in good financial shape, and the other group consisting of companies under financial distress. As there are no accepted criteria for what should be considered a "good" or a "bad" financial position, we have decided on the following operational dichotomous definition : the companies that went bankrupt during our study period have been grouped as "bad", the rest are "good". Some problems with this definition will be discussed later in the paper.

The purposes of the paper are three-fold. First we will study methods to make prognoses of whether a company will end up as a "good" or as a "bad" company. The linear discriminant model and the probit method will be used to develop testable prediction models. The models are based on published data for the companies from one to five years before bankruptcy. Second, financial key ratios are chosen that best predict bankruptcy. Third, from these results policy concideration are drawn.

Perhaps the seminal article dealing with the problems covered in our paper is Beaver (1966). Beaver studied data bases with annual accounts from a large number of companies for many years. The companies were grouped into two subgroups ; bankrupt companies and non-bankrupt companies. He constructed a model based on the exact year of bankruptcy and calculated financial key ratios from several years before bankruptcy for the two groups. He developed profile analysis based on the financial ratios, and he also developed a method of classification based on the ratios. He demonstrated that substantial differences existed between the two groups regarding values of the individual key ratios many years before bankruptcy. Missing from his study was a formal method (statistical or other) to test the predictive strength of his selected ratios.

David Altman (1968) introduced the discriminant method to bankruptcy prediction problems. From 1968 to present a large number of articles have been published using discriminant prediction models based on financial ratios. The articles focus on statistical problems with discriminant methods, see Eisenbeis (1977), as well as the methods predictive ability. Prominent among the latter articles seems to be Edmister (1972), Altman and Eisenbeis (1978), Joy and Tollefson (1978), Collins and Green (1982), Richardson and Davidson (1983) and Inman (1988).

Another, and perhaps somewhat dissenting line of view, has focused on the methods lack of foundation in theory. Articles in line with this are Wilcox (1971), Scott (1981), Mensah (1984) and Barnes (1987).

Discriminant analysis has been compared with other methods. Lo (1986) and Press and Wilson (1978) compared discriminant analysis with logit regression. Rubin (1990) compared linear programming approaches with linear discriminant and quadratic discriminant models. Our study has compared the linear discriminant function with the probit method. As is well known, the probit method and the logit method will give very similar results when used to discriminate between two groups, and our results from using the probit method could easily be transferred to the logit method.

The rest of the paper will unfold as follows. In section two the data will be presented, and the results will follow in section three. Finally, conclusions and discussions will end the paper in section four.

Statistical methods used in the study are documented in Dreyer and Vassdal (1991), Dreyer (1991) and Vassdal (1991).

## 2. THE DATA

The data used in the study originates from "Driftsunderskelsen i Fiskeindustrien", a yearly, ongoing study of fish processing plants in Norway, see Bendiksen and Dreyer (1989). The companies taking part in this study are a sample of 86 companies from the total population of firms mentioned in the introduction. The sample size have been kept stable even if the total population has decreased. The companies in the sample are situated from mid Norway ("Nord-Mre") in the south, and continuing north to the Russian border. The processors are mainly producing white fish. Thus many of the producers of herring, capelin and shrimp are excluded from this study, as are all types of aquaculture. Some producers with mixed production have remained in the sample.

The part of the norwegian industry we are analysing in this study have their main activity in processing fish.

The same sample of 86 companies are studied each year. Being the same cross-section of companies each year for many years, the data is a so called "panel data" set. From the panel data we have extracted a sub-set of data used particularly for the bankruptcy study. This sample consists of a group of companies which went bankrupt in the periode, and a control group consisting of companies which remained in financial good shape the same period.

The table 1 shows the number of bankrupt companies and the number of companies in the control group for year one until year five before bankruptcy in our study.

Each company, both bankrupt and non-bankrupt (the control group), have been followed five consecutive years. This has been fully possible for the control group. As the data started in 1977, we have not been able to follow all the bankrupt companies up to five years before bankruptcy. As a consequence, of the 24 bankrupt companies in our study, only 13 have a full five years data set, increasing to 23 two years before bankruptcy.

We have excluded from the control group companies that have been refinanced with loss to the creditors or have undertaken other reorganizations with similar economic effects, like a composition or a private arrangement with the creditors. The control group is therefore intended to consist of financially sound companies.

## 3. THE RESULTS

### *3.1 Results from the probit model*

Detailed results from the probit study are reported in Vassdal (1991). This section is a brief summary of the results therefrom. The results from the discriminant study are presented and discussed (in Norwegian) in Dreyer (1991). Those papers are available from the authors.

In the probit part of the study, six different financial ratio models are tested for predictive power. The models originate from various sources. Combinations of financial key ratios suggested from other published studies have been tested. We have constructed ratios which take into account that we are dealing with a spesific industry.

The models are named "Model A" to "Model F" in what follows. The definition of the models are [1] :

Model A :

- Changes in stocks/Gross revenues ($X_1$)
- Interest charges/value added ($X_2$)
- Gross Revenues/Insurance value of assets ($X_3$)
- Profit before year-end adjustment/production value ($X_4$)

Model B :

- Total liabilities/Insurance value of assets ($X_1$)
- Gross Revenues/Insurance value of assets ($X_2$)
- Total indirect costs/Costs of Raw material ($X_3$)

Model C :

- Total liabilities/Insurance value of assets ($X_1$)
- Operating profit/Value of production ($X_2$)
- Contribution margin/Total direct wages ($X_3$)
- New investments/Insurance value of assets ($X_4$)

1. Detailed definitions of the variables are available (in Norwegian) from the authors on request

Model D :

- Current assets/current liabilities (Current ratio) ($X_1$)
- Total debt/total assets ($X_2$)
- Profit before extraordinary Items + Financial expences/Financial expences ($X_3$)

Model E :

- Operating revenues/Total assets ($X_1$)
- Changes in stocks/Sales revenues ($X_2$)
- New investments/Insurance value of assets ($X_3$)
- Financial expences/Value of production ($X_4$)
- Total cash flow generated from operations/Sales revenues ($X_5$)

Model F :

- Conditional tax-free allocations/Total assets ($X_1$)
- Total direct production costs/Costs of raw materials ($X_2$)
- Financial revenues/Gross revenues ($X_3$)

Model G :

- Value of stocks/Sales revenues
- Equity/Total assets
- New investments/Equity
- Total revenues fish production/Gross revenues
- Cash Flow/Insurance value of assets

Model H :

- Long term debt/Total assets
- Sales revenues/Total assets
- Financial expences/Value added
- Extraordinary revenues/Gross revenues
- Quick assets/Short term debt

Model I :

- Total debt/Total assets
- Total indirect cost/Cost of raw materials
- Sales revenues/Insurance value of assets
- Total revenues white-fish production/Total revenues fish production
- Financial expences/Total debt

We have tested model A to F in the probit study and modell E to I and compared results from the two methods by testing modell E and F.

It will be noted that some of the financial key ratios have been included in several models. This is no incidence. The purpose is to test the various ratios in different combinations. It turns out that the combination of ratios in some cases are just as important as the ratios themselves.

The predictive power of the models are tested with the "log likelihood ratio test" (LRT), defined as

$$C = - 2(\ln L(0) - \ln L(\beta^*))$$

where ln L(0) is the log of the likelihood function evaluated at the null hypthesis (i.e. all $\beta_k = 0$, except the constant, which is the ratio of observed $Y_i = 1$ to the total observtions. ($\beta^*$) is the log of the likelihood function when using the optimal estimated values of $\beta$.

The test observator, C, is chi-squared distributed with K-1 degrees of freedom. The following table gives the critical value of the test observator for a few combinations of degrees of freedom and levels of significance. As $R^2$ tests for probit models do not mean the same thing as for standard regression models, we will restain from using $R^2$ test in this section. "Pseudo $R^{2}$" tests are presented in Hensher and Johnson (1981). Similarly the standard F-tests are invalid for a probit model (see table 2).

The table 3 summarizes the results from applying the log likeliood ratio test for testing the predictive power of the selected models.

The null hypothesis is rejected one, two and three years before bankruptcy for all six models. This means that the models significantly increases the ability to predict bankruptcy up to three years before it happens. The predictive power of Model A is clearly less than the other models. Four and five years before bankruptcy only Model E and Model F are able to reject the null hypothesis. The implications are that these two models have satisfactorily predictive power from one to five years. The identification of the last two models we will call one of the major findings of the study.

One method to appraise the success of predictive models, could be to compare the actual number of bankruptcies and non-bankruptcies with the predicted numbers. The success rate in percentages are close to 90 % for the best models, and may even be more than 70 % when the models are not significant according to the log likelihood ratio test. Model A, which clearly have low predictive power four and five years before failure, actually has a success rate of 68 % four years before, and of 63 % five years before. What such a success rate does not show, however, is that almost all the correct predictions are of the type non-bankruptcy, whereas there are very few correct predictions of the bankruptcy cases.

### *3.2 Results from the discriminant model*

In this section, we will present five financial ratio models that have been selected by the discriminant model to give the best score. The models presented 4 years and 5 years before financial distress, have formerly been called Model E and Model F, respectively. The models 1, 2, and 3 years before distress are new, and have not been compared with probit models (see table 4).

The results from the discriminant study, as well as in the probit study, indicate that the modells perform well as far as separeting the two groups of companies.

There is a clear tendency that differences in the ratios between the two groups of firms are decreasing the further away from the time when the firms go bankrupt. The function which best classify the two groups is based on accounts one year before failure, and this function classified only 1.2 % of the firms wrongly. The function which classified most firms incorrect is based on accounting five years before failure. In this case, the function classified 18.4 % of the firms wrongly.

The model shows that the path towards bankruptcy consists of several steps, indicating that different ratios have different meanings as indicators of failure at different steps of the path against failure. This also explains why the functions, in terms of which ratios that are put together, are different. It also indicates the importance of knowing on which step the firm is, when analysing the ratios as indicators of bankruptcy. In our search for good indicators for separating the groups, our experience is that one should select ratios that show differences in value in between the two groups of firms, but they must also show small variance within the group. In the study of the fish processors it has been shown that the most common financial ratios often are poor indicators. Therefore they are avoided in our models due to great variance within the group and lack of stability over the years.

In the present study ratios that are composed for this spesific industry are frequently used. This approach has been useful in our struggle for finding indicators which may separate the two groups of firms well. First of all these ratios are not strongly correlated with other more common financial ratios, and therefore contribute the indication of whether a firm is doing well or not. Secondly these ratios incorporate factors that are essential and spesific for success among fish processors.

In the literature it is often discussed which capability discriminant models have to predict failure, and how to measure such capability. The conclusion of these discussions have been that the best test is to use the model on a different period of time and/or differrent firms than from which the model is developed. As far as the model is concerned in predicting failure, it has been emphasizied that the model should be tested in a period which comes after the years from which the model is developed. At the same time it is also stressed that the model should be tested on firms which are as identical as possible in terms of size, nationality and business.

It is difficult to know how well our models are able to predict distress, as we have only been able to test it for a period of two years on Norwegian fish processors. However, our experience so far indicate that the models are quite sensitive to which period of time analysed. This also indicates that further develpoment of the models by incorporating a longer period of time, may create changes in the functions as far as which ratios and the discriminant coefficients are concerned.

Whether the model is able to predict distress among fish producers, depends on whether the relationships between the different ratios in the discriminant functions are the same in the future as in the period of time from which the model was developed. This is the main issue of all kind of predictions. The issue of a certain stability among the ratios over the years, is difficult to ensure among the fish processors. This is connected to the turbulent contingency factors with which these firms are working. There is a vast uncertainty connected to the quantity of fish available at a given time, what price they will have to pay for it and what price they will get for their finished products. At the same time, the difference between the price of the raw materials and the price of their products is the main factor for their profitability. Importantly, this factor is not under the control of the single firm as the Norwegian processors often do not have their own fishing vessels integrated in their company.

The prediction of failure or success amongst fish processors are therefore more dependent of external changes, than the information which is recorded in their accounts. Since the changes in these external factors are rather radical and frequent, it is difficult to predict if a fish processor will fail or not in the near future based only on last years accounting.

This, of course, is a general problem with any prediction, but the problem is less among other industries which are working under more stable conditions than Norwegian fish processors. It also illustrates the importance of limitting the use of such prediction models to one spesific industry and also the importance of knowing the business thoroughly on which the model is applied. This restriction is also well illustrated by the fact that the ratios contstructed spesific for this industry, are of great importance in the modells which are developed in this study.

This study, both the discriminant and the probit study, indicates that there at two sucess factors among in this industry in the period we have studied which the single firm itself are able to controll. The two factors are cost controll and capacity utilization.

## 4. CONCLUSIONS

In this paper two statistical methods have been presented and applied. The methods have their advantage in situations when the dependent variable is binary, that is represented by two mutally exclusive events. The probit model and the linear discriminant model have been used for model building purposes.

Both methods made it possible to construct very reliable predictions of financial distress. We have also identified two models which could predict coming financial distress up to five years before its occurance. We are in addition in the position to tell which variables in the models that are most important in the explanation. The variables can be tested using the standard student t-test. The elasticities of the probabilitry of bankruptcy as a function of changes in one of the variables can also be calculated. The elasticity is a valid measure of the relative importance of the financial key ratios in each model.

Our experience with discriminant models on Norwegian fish processors is that their capability to classify correctly drops when there are dramatic changes in the external factors. The predictions are therefore strongly dependent on periode of time analysed and also on which periode of time the model is designed.

The results from this analysis show that the strength of the model is not in predicting failure or sucess. The contingency factors of the selected industry are too turbulent and unstable for that. The lack of stable external factors makes the indicators fluctuate widely from one year to another. The model might preform better if it is developed on a longer period of time, but we will never get away from the problem of frequent and dramatic changes in the external factors which the single producers neither can foresee nor contoll and which are essential for the firms profitability.

The findings in this study also emphasize that using such modells as reported in this study is restricted to the industry from which the modells are developed.

# Unemployment Insurance and the Length of the Fishing Season

**Noel Roy, Eugene Tsoa, William E. Schrank[a] and Leigh Mazany[b] ***

ABSTRACT

*The standard economic theory of labour supply suggests that a worker's budget constraint is piecewise-linear in the presence of income taxes or subsidies such as unemployment insurance. Estimation of labour supply functions when the budget constraint is piecewise-linear have been commonplace for more than a decade. Such studies have been used, for example, to investigate the effect of income taxes and unemployment insurance on the willingness to work and the length of the average work spell.*

*Virtually all existing studies assume that workers are subject to a given wage in the work-leisure choice model. While appropriate for industrial workers, fishermen usually do not work for a fixed wage. Seasonal differences in resource availability imply a non-linear relationship between fishing income and the length of the fishing season. As a result, the budget constraint of a fisherman in a work-leisure choice model is non-linear, and with the presence of unemployment insurance benefits the fisherman would be facing a kinked non-linear budget constraint.*

*The paper consists of three parts. First, the basic structure of the Canadian unemployment insurance program as it affects inshore fishermen is outlined. Second, a theoretical model is developed which analyzes the length of fishing season decision in the presence of an unemployment insurance plan essentially similar to the one described in Part I. Third, some econometric difficulties encountered in the statistical estimation of these theoretical relationships are described. Fourth, the model is subjected to a series of numerical simulations, to determine its sensitivity to parameter changes.*

* The analysis underlying this paper was supported by a research grant from the Institute of Social and Economic Research, Memorial University ; a Donner research fellowship from the Canadian-American Center, University of Maine ; and a Science Subvention from the Department of Fisheries and Oceans and the Natural Sciences and Engineering Research Council of Canada. We wish to thank the Department of Fisheries and Oceans and the Employment and Immigration Commission of the Government of Canada for providing us with the data used in this paper.

## 1. INTRODUCTION

The Canadian unemployment insurance program was established to enable government to insure employees against the consequences of job loss. It has been a fixture of the Canadian social welfare system since 1940. The present Unemployment Insurance Act has been in force since 1972.

In order to qualify for unemployment insurance benefits, a claimant must necessarily have been involved in an employment contract with an employer. Self-employed persons, in other words, normally do not qualify for coverage.

There is one exception to this. Section 146 of the Act enables the Canada Employment and Immigration Commission to operate a scheme of unemployment insurance for "self-employed persons engaged in fishing." Such a scheme has been in existence since 1957.

Section 146 is found in a part of the Act labelled "Transitional and Repeal Provisions," and contains a sub-section stating that "this section shall be repealed on a day to be fixed by proclamation." However transitional this provision was intended to have been when it was established, the Special Seasonal Fishermen's Benefits Program, as it is called, has since taken on a political life of its own, and has become a fundamental element of and support mechanism for inshore fisheries on the Atlantic coast of Canada.

The present Unemployment Insurance Act was passed by Parliament in 1971 and replaced somewhat less generous legislation. After an initial period of stability, perceived difficulties with the Act led to a series of amendments, mostly in a more restrictive direction, over the period between 1976 and 1980. Other than amendments passed in 1983 in response to recommendations by the Kirby Task Force on the Atlantic Fisheries, the Act has remained essentially unchanged since then, at least insofar as it affects inshore fishermen in Newfoundland.

The purpose of this paper is to examine how the 1971 Act and subsequent amendments have influenced the behaviour of inshore fishermen. This influence could potentially have been felt in three ways :

i) by altering the attractiveness of fishing relative to other forms of economic activity, unemployment insurance can affect the number of people engaging in fishing as a full-time or part-time occupation ;

ii) by modifying the returns to fishing, it can change the length of time that fishermen engage in this activity over the fishing season ; and

iii) it can also change the intensity with which fishermen are prepared to fish at any particular time.

This paper is primarily concerned with changes of the second kind, that is to say, with changes in the length of time spent fishing over a season as a result of the unemployment insurance program.

The basic structure of the Canadian unemployment insurance program as it affects inshore fishermen is outlined in Part II of the paper. Part III develops a behavioural model of the decision to fish in a particular week within the season, which we subsequently use to evaluate the impact of seasonal fishermen's benefits on the length of the fishing season. Some econometric difficulties are discussed in Part IV. The simulation possibilities which exist with a fully specified model are illustrated in Part V.

## 2. THE UNEMPLOYMENT INSURANCE PROGRAM

The Canadian Unemployment Insurance program works in the following manner. Employees who earn income in excess of a predefined minimum in a week are deemed to have insurable earnings in that week. Both the employee and the employer then contribute premiums at a given rate to an Unemployment Insurance Account. If the employee works a sufficient number of insured weeks, then upon an interruption of earnings (s)he may, after a two-week waiting period, obtain weekly unemployment insurance benefits equal to a percentage of the average weekly insured earnings received during the qualifying period. The level of weekly earnings which is insurable is subject to a ceiling, which limits the level of both the premiums which must be contributed and the benefits which can be received.

The length of the period over which benefits can be received depends on the number of insured weeks in the qualifying period, and on the national and regional rates of unemployment. Earnings received during the benefit period may be kept if they are less than 25 percent of the weekly benefit ; earnings in excess of this result in a dollar-for-dollar reduction in benefits.

Most inshore fisheries in Atlantic Canada are organized as a co-adventurer rather than an employer-employee relationship. In the co-adventurer system, the boat owner receives a predefined share of the value of the catch net of operating costs. The remainder is shared evenly among the crew of the vessel. The structure of the unemployment insurance program is not well suited to this arrangement. It is not obvious who should be considered to be the employer ; what should be treated as insured earnings ; and when an interruption of earnings is deemed to take place.

Usually, the fish buyer is deemed to be the employer ( *Regulations*, s.76). The insured earnings of a crewman consist of the crewman's share. For the boat owner (or lessee), insured earnings are deemed to be the net value of the catch after deducting (a) his/her crewmen's shares and (b) 25 percent of the value of the catch to account for operating expenses. If the boat owner's earnings fall short of the minimum level of earnings required for a week's earnings to be insurable under the Act, these earnings are deemed to be at that minimum level (*Regulations*, s. 78). This implies that even a minimal level of fishing activity qualifies a boat owner for unemployment insurance, and qualifies him or her at an artificially high rate.

Fishermen are permitted to arrange their affairs with buyers in such a way as to accumulate their catches over more than one week, and to average the accrued value over that number of weeks (*Regulations* , s. 79(5)). This means that earnings in weeks during which catches are high can be applied to weeks in which earnings are lower. This enables fishermen to obtain increased benefits from weeks during which earnings exceed the ceiling, and to include as an insured week one in which earnings are below the minimum level. This practice became more widespread after 1986, when Revenue Canada released a statement which gave a broadened interpretation to this section of the *Regulations*. As landings have declined as a result of resource depletion, this characteristic of the program has increased in importance.

Fishermen are categorized into year-round fishermen and seasonal fishermen for unemployment insurance purposes. The requirements for classification as a year-round fisherman are extremely stringent (*Regulations* , s. 84), and almost all inshore fishermen in Newfoundland, which is the primary focus of our analysis, are classified as seasonal fishermen. A seasonal fisherman can receive benefits only during the 'off season', which for most fishermen is the period between November and May (*Regulations*, s. 85(7)). For this reason, potential claimants regard entitlement to fishing benefits as inferior to entitlement to benefits from regular employment, which can be taken at any time in the year, and usually for a longer period of time.

To qualify for regular benefits, regular employment must be obtained for a minimum number of weeks during the qualifying period. For the most part, fishermen in Newfoundland, especially full-time fishermen, have not been able to obtain sufficient regular employment to avail themselves of regular benefits. Table 1 presents a breakdown of the UI dependence of Newfoundland fishermen actively fishing in 1984, based on a survey conducted by the Department of Fisheries and Oceans. [1]

## 3. A MODEL OF THE LENGTH OF THE FISHING SEASON

Fishing is a seasonal occupation, and boat owners, if they are rational, will decide whether to fish in a given week on the basis of a comparison of the marginal benefits and costs of doing so. We model this decision-making process on the basis of a theoretical analysis similar to that formulated by Ferris and Plourde (1980, 1982).

The model is based on the supposition that fishing income varies over the year because of changes in resource availability. As a result, fishing income is subject to diminishing returns as the fishing season is extended past the peak season. The longer a fisherman continues to fish, the smaller the incremental returns from fishing an additional week. This relationship between fishing income and fishing weeks can be represented as a concave function similar to the FF curves in Figures 1(a) and 1(b).[2]

The factors that determine whether a fisherman will fish in a particular week depends on the nature of the alternative activities available to him or her. In Canada, fishermen are classified by the regulatory authority into full-time and

1. Source : Department of Fisheries and Oceans, *1984 Survey of Atlantic Fishermen*, unpublished data. In Newfoundland, 65 percent of active fishermen held full-time status in 1984.
2. The weeks in Figure 1(a) and 1(b) need not be consecutive ; there may be alternating periods of fishing and inactivity over the year, in response to variations in resource availability over time.

part-time categories. Part-time fishermen typically have other employment activities available to them ; they usually fish only during the peak of the season.[3] When incremental fishing income falls below the wage that could be earned in alternative employment, they discontinue fishing. This choice decision is represented in Figure 1(a), where the slope of the tangent line WW equals the wage rate obtainable in alternative employment.

Full-time fishermen must fish on a consistent basis throughout the fishing season in their area in order to maintain full-time status for licensing purposes. They cannot work longer than 30 days at other employment within the fishing season, and can pursue only limited self-employment in specified primary industries outside the fishing season. Alternative employment is not a major consideration for such fishermen.[4] Their behaviour can be modelled as selecting the level of fishing activity which places them on the highest possible indifference curve between work and income. This choice is represented in Figure 1(b).

Let us represent net fishing income $F$ in a season as a concave function of the number of fishing weeks $L$.

$$F = f(L), \tag{1}$$

where $f\,' > 0, f\,'' < 0$.

In this model, part-time fishermen divide their working weeks between fishing and non-fishing employment so as to maximize income earned in the work period. If non-fishing employment is available at a weekly wage $w$, income during the working period is maximized when fishing income in the marginal fishing week equals this wage.

$$f'(L) = w. \tag{2}$$

Full-time fishermen,[5] on the other hand, seek to maximize the value of a utility function $U(F,L)$, where $U_F > 0$ and $U_L < 0$. This occurs where

$$f'(L) = -\frac{U_L}{U_F} = \mathrm{MRS}_{LF}. \tag{3}$$

For both groups of fishermen, the seasonal fishermen's benefits program alters this pattern of incentives. The benefits received supplement earnings from fishing, and in so doing alter the incentives to fish, through both income and substitution effects.

The income effects are discussed first. If leisure is a normal good, then the higher income from unemployment insurance leads to an increase in the demand for leisure. In the case of full-time fishermen, this would result in a reduction in the number of weeks spent fishing, in order to enjoy this additional leisure. Part-time fishermen would also reduce their work activity, while still maintaining the equilibrium condition $f'(L) = w$. However, any reduction in fishing weeks $L$ would result in an increase in $f'(L)$ (since $f'' < 0$), so that this condition would no longer be satisfied. It must be the case then that *all* the reduction in work effort must be outside fishing. There is thus no income effect on fishing weeks in the case of part-time fishermen with alternative employment opportunities[6].

The substitution effects are more complex, and are best represented through formal modelling. The amount of unemployment insurance income $S$ earned in a benefit period is the product of three factors :

- the benefit-earnings or replacement ratio $r$, which is the proportion of average weekly insured earnings during the qualifying period which is returned to the claimant as benefits during a week of unemployment ;

3. In 1984, active full-time fishermen fished an average of 19.1 weeks in Newfoundland ; active part-time fishermen, only 11.8 weeks. (Source : Department of Fisheries and Oceans, *1984 Survey of Atlantic Fishermen*. Economic and Commercial Analysis Series, Surveys and Statistics Report 37. Ottawa, 1987. Tables 4.8 and 4.9.)
4. In 1984, active full-time fishermen in Newfoundland earned an average of only $664 in non-fishing employment income, as opposed to $6,798 in net fishing income and $3,421 in seasonal fishermen's benefits (Source : Department of Fisheries and Oceans, *1984 Survey of Atlantic Fishermen*. Economic and Commercial Analysis Series, Surveys and Statistics Report 37. Ottawa, 1987. Table 9.8.)
5. We are using the terms part-time and full-time here rather loosely, to distinguish between fishermen who have, or do not have, alternative employment opportunities within the fishing season. This distinction may not strictly correspond to the licensing classification used by the Department of Fisheries and Oceans.
6. For a further elaboration on this point, see Ferris and Plourde (1980), chapter 4.

- the average level of weekly insured earnings $E$ during the claimant's qualifying weeks, which is the basis on which the level of weekly benefits is calculated ; and
- the number of weeks $B$ over which the claimant is entitled to draw benefits.

This can be written as

$$S(L) = rE(L)\ B(L). \tag{4}$$

The benefit-earnings ratio $r$ is a constant, which was equal to 2/3 over the period 1972-1978 and to 60 percent thereafter.[7]

Until 1983, the average value of insured earnings was calculated over qualifying weeks in either the entire qualifying period (which usually begins in April), or in the last 20 weeks of this period, whichever was to the fisherman's advantage. We have assumed (equation (1) above) that fishing income increases at a diminishing rate as the number of fishing weeks increases. If weekly earnings are below the insurable ceiling, this implies that average weekly insured earnings decline as the number of fishing weeks is increased. This would have a negative effect on the level of unemployment benefits, which would act as a disincentive to extend the number of fishing weeks. Thus, we can specify that $E'(L) \leq 0$, with the strict inequality holding where $f'(L)$ is below the maximum level of weekly insurable earnings.

In 1983, this provision was modified so that those fishermen with at least 15 qualifying weeks of fishing would receive benefits based on earnings in the *best* ten weeks of fishing. This would render $E(L) = E(10)$ for $L \geq 15$, which would remove the disincentive to extend the number of fishing weeks for those fishing at least 15 weeks.

The relationship $B(L)$ between the number of benefit weeks and the number of insured weeks during which income was earned can be separated into four stages. In Stage 1, the number of insured weeks $L$ is less than the minimum number of qualifying weeks required to entitle a claimant to benefits, denoted by $q$. In Newfoundland, this minimum level of insured weeks was 8 until 1978, when it was raised to 10 weeks. In this stage, obviously, there are no benefits ; i.e.,

$$B(L) = 0 \text{ if } L < q. \tag{5a}$$

Once a claimant qualifies for benefits, the number of weeks in which he can claim benefits increases with the number of insured weeks, up to some maximum. In Stage 2, this maximum has not yet been reached, so there is a positive relationship between the number of benefit weeks and the number of insured weeks. This positive relationship creates an incentive to extend the number of fishing weeks in order to qualify for a longer period of unemployment benefits. In other words, $B'(L) > 0$ in this stage. Specifically, claimants are entitled to 5 weeks of benefits for every 6 qualifying weeks, so $B'(L) = 5/6$. As well, since 1976 fishermen have been entitled to a certain number of weeks of so-called "extended benefits", $B_{ext}$, which is independent of the number of qualifying weeks they have worked. Thus, in Stage 2 the number of benefit weeks can be written as the linear relationship

$$B(L) = 56\,L + B_{ext} \tag{5b}$$

In Stage 3, the maximum number of benefit weeks $B_{max}$ has been reached. Additional fishing does not increase the period over which a fisherman is entitled to benefits. The positive incentive to extend the number of fishing weeks which exists in Stage 2 is removed. In this stage we have $B'(L) = 0$, and

$$B(L) = B_{max}. \tag{5c}$$

Ultimately, as the number of fishing weeks is extended further, fishing takes place during the 'off-season', when seasonal benefits could be claimed. Obviously, in this stage, every additional week spent fishing is a week in which unemployment benefits could have been received. This is Stage 4, where there exists an incentive to *reduce* the number of fishing weeks. Here we have $B'(L) = -1$, and so (allowing for the two-week waiting period)

$$B'(L) = 50 - L. \tag{5d}$$

7. There was a special 3/4 rate for low-income claimants with dependants over the period 1972-74. However, this rate appears to have been almost irrelevant to fishermen in Newfoundland. In a 10 percent sample of fishing UI claimants over this period, only 31 out of 1350 claimants had insured earnings below the level required to qualify for this rate.

Overall, then, the relationship $B(L)$ is piecewise linear, with 4 distinct segments, and can be expressed as

$$\begin{aligned} B(L) &= \min\left[\frac{5}{6}L + B_{ext},\ B_{max},\ 50 - L\right], \quad L \geqslant q, \\ &= 0, \quad L < q. \end{aligned} \tag{6}$$

An example is presented in Figure 2 ; this is the relationship which prevailed over the period 1972-75. The relationship was altered by amendments in 1976 and in 1977, which modified the $q$ , $B_{ext}$, and $B_{max}$ parameters. These changes are summarized in Table 2 and illustrated in Figure 3. They are considered in greater detail in Roy, Tsoa, Schrank and Mazany (1992).

When income from seasonal fishermen's benefits is added to earned fishing income, total fishing income $F$ becomes

$$\begin{aligned} F(L) &= f(L) + S(L) \\ &= f(L) + rE(L)\,B(L). \end{aligned} \tag{7}$$

An example of such a relationship, appropriate to the period 1972-75, is provided in Figure 4. This figure shows a typical pattern for earned fishing income $f(L)$, seasonal fishermen's benefits $S(L)$, and total fishing income $F(L)$. The shape of these relationships are obviously dependent on that of the $f(L)$ function, which affects the average insured earnings function $E(L)$ and therefore the $S(L)$ and $F(L)$ functions as well.

The optimum conditions can then be written as

$$F'(L) = f'(L) + S'(L) = w \tag{8a}$$

for part-time fishermen, and

$$F'(L) = f'(L) + S'(L) = \mathrm{MRS}_{LF}(F, L) \tag{8b}$$

for full-time fishermen.

The slope of $S(L)$ can be derived as

$$S'(L) = r[E(L)\,B'(L) + E'(L)\,B(L)]. \tag{9}$$

As was explained above, $E'(L)$ is generally negative,[8] since average weekly insured earnings decline as the number of fishing weeks is increased, so this factor will act to algebraically reduce the slope of the $S(L)$ function. The behaviour of $B'(L)$ is more complex, as we have seen, and depends on the stage in which the value of $L$ falls. It is worthwhile to consider each of the four stages separately.

In Stage 1, $S(L) = 0$, so the $F(L)$ and $f(L)$ curves are identical.

Fishermen working in Stage 2 are subject to two conflicting forces. On the one hand, $B'(L) > 0$, which implies that additional fishing increases the number of benefit weeks. On the other hand, $E'(L) < 0$, which implies that additional fishing reduces the level of average insured earnings as fishing becomes less lucrative, and so lowers the size of the unemployment benefit. Under normal circumstances, we expect that the former effect will dominate[9], so that normally $S'(L) > 0$ in Stage 2.

8 Unless the fisherman earns the maximum qualifying income throughout the qualifying period, in which case it is zero.

9. One simple example, reflecting a not particularly favourable circumstance, arises when the fisherman's benefits are based on the average earnings over the qualifying period, and these earnings never exceed the qualifying ceiling. Then $E(L) = f(L)/L$, and so

$S(L) = r\frac{f(L)}{L}\left[\frac{5}{6}L\right] = \frac{5rf(L)}{6}$. *Since* $f'(L) > 0$, $S'(L) > 0$ as well.

In Stages 3 and 4, it remains true that $E'(L) < 0$, but here $B'(L) \leq 0$, so it is necessary that $S'(L) < 0$. The level of seasonal fishermen's benefits, then, must decline as the number of fishing weeks is extended into Stages 3 and 4. Total fishing income inclusive of unemployment insurance F(L) will continue to increase for a while, but we would expect that normally there will be a point at which extending the number of fishing weeks will add less to earned income $f(L)$ than will be lost from seasonal benefits $S(L)$ (i.e., $f'(L) + S'(L) < 0$), so that total fishing income would decline if the number of fishing weeks were extended beyond that point. The value of L at which this happens depends on the slope of the $f(L)$ and $E(L)$ functions.

Let us now examine the implications of these relationships for the behaviour of fishermen. Consider a part-time fisherman with less than the minimum number of insured weeks (Stage 1). Unless (s)he increases his/her insured weeks to at least the minimum level (Stage 2), (s)he will not receive benefits. It may be worth his/her while to extend his/her fishing effort into Stage 2, if the unemployment benefits received, plus the attendant fishing income, exceed the foregone wages. This case is illustrated in Figure 5(a), where the introduction of seasonal benefits leads to a change in the tangency from point E to point $E'$. On the other hand, if the foregone wage income is high enough, as it is in Figure 5(b), the fisherman will not modify his/her behaviour, because it remains optimal to fish less than the number of weeks required to qualify for unemployment insurance. In summary, a fisherman in Stage 1 may not modify his/her behaviour as a result of the unemployment insurance program, but if (s)he does, it will be to increase his/her insured weeks into Stage 2.

If a part-time fisherman works enough weeks to qualify for seasonal benefits, (s)he is in equilibrium when $F'(L) = w$. The availability of fishermen's benefits clearly changes the value of $L$ at which this occurs.[10] This value is increased if $S'(L) > 0$, and is decreased if $S'(L) < 0$. Thus, the behaviour of part-time fishermen is governed by the sign of $S'(L)$, so that they fish longer if $S'(L)$ is positive and cut back if it is negative. For full-time fishermen this effect is supplemented by an income effect as well, which if leisure is a normal good would induce a reduction in the number of weeks spent fishing.

In Stage 2 it is normally the case that $S'(L) > 0$, because additional insured weeks permit more benefit weeks. Therefore, part-time fishermen in Stage 2 are predicted to fish longer as a result of seasonal benefits. This is illustrated in Figure 6. For full-time fishermen, this may be offset to a greater or lesser degree by a negative income effect, so that such fishermen may choose to work less as a result of the higher income.

Fishermen working in Stages 3 and 4, whether full-time or part-time, suffer from no such ambiguity. Additional fishing effort lowers the value of insured earnings, as in Stage 2 ; in addition, the number of benefit weeks either does not change (Stage 3) or falls (Stage 4). Therefore additional fishing lowers the amount of unemployment benefits received, and this creates an incentive to fish less, which augments any negative income effect. This effect is illustrated in Figure 7.

To summarize, then : the model predicts that seasonal fishermen's benefits will cause fishermen working in Stages 3 or 4 to reduce the number of weeks spent fishing. Those fishing less than this *may* be induced to increase the number of weeks spent fishing. The effect is one of compaction in the variance in fishing effort from that experienced without unemployment insurance. The basic conclusion of this theoretical analysis is that there is no theoretical presumption that seasonal fishermen's benefits will either increase or reduce the *average* amount of time spent fishing.

## 4. SOME ECONOMETRIC CONSIDERATIONS

The authors have elsewhere (Roy, Tsoa, Schrank and Mazany 1992) examined the impact of the various changes which have taken place in the seasonal fishermen's benefits program on the number of inshore fishermen in Newfoundland and on the number of weeks they have spent fishing over the year. This analysis is based on the application of the theoretical model outlined above to a ten percent sample of seasonal benefit recipients over the period 1972-1981, and a one hundred percent sample over the period 1981-1985. For the most part, the predictions of the theoretical model are reflected in the data.

In the final analysis, however, we would like to use econometric techniques to estimate the optimizing conditions in equation (8). Unfortunately, such estimation poses severe challenges. In rough order of seriousness, these are (1)

10. Throughout this analysis we assume that while alternative employment opportunities are available to part-time fishermen, these opportunities are insufficient to permit such fishermen to qualify for regular unemployment insurance benefits. Fishermen who qualify for regular benefits are ineligible to receive special seasonal fishermen's benefits.

problems of parameter identification, (2) suitable treatment of the piecewise non-linearities and discontinuities in the benefit function $S(L)$, and (3) the adjustments appropriate to the upper and lower limits associated with the number of insured weeks and the level of average insured earnings. We discuss each of these problems in turn.

### *4.1 Identification of parameters*

The number of weeks worked by seasonal benefit recipients varies widely across our sample, from the minimum 8 or 10 weeks needed to qualify for benefits, up to nearly a full year. Such differences can be explained by the model as being due either to differences in the shape of fishermen's catch functions $f(L)$ (i.e., differences in their opportunity sets) or to differences in the shape of their indifference curves (i.e., differences in their preferences). That is to say, one fisherman may work a shorter period than another either because his/her productivity falls off more rapidly as his/her season is extended, or because (s)he has a stronger preference for "leisure" (understood to mean non-market activities generally). We can incorporate these parameters into the optimum condition for a full-time fisherman (8b), which then becomes

$$F'(L_i\,;\,\beta_i) = \mathrm{MRS}_{LF}(L_i,\,F_i\,;\,\delta_i)\,, \tag{10}$$

where $\beta_i$ are the parameters associated with the $i^{\text{th}}$ fisherman's catch function and $\delta_i$ are those associated with his/her utility function.

The difficulty is that neither $\beta_i$ nor $\delta_i$ are directly observable. We cannot infer from the data to what extent differences in the behaviour of fishermen are due to differences in opportunities or to differences in preferences.

This problem is *potentially* less serious for part-time fishermen, whose optimum condition can be written as

$$F'(L_i\,;\,\beta_i) = w_i\,. \tag{11}$$

Since the $w_i$, unlike the preference function parameters $\delta_i$, are observable in principle, we should be able to identify the catch function parameters $\beta_i$. Unfortunately, our data sets do not contain information on alternative wage opportunities, so the identification problem exists in this case as well.

To evaluate the seriousness of this difficulty, we estimated a version of the optimum condition (10) under two alternative specifications : (1) all fishermen have identical preferences (all $\delta_i$ identical), so that all behavioural differences are due to differences in catch functions, and (2) all fishermen have identical catch functions $f(L)$ up to a scalar multiple ($\beta_i$ identical), so that behavioural differences are due entirely to differences in tastes. The sample we utilized was the set of fishermen qualifying for seasonal benefits during 1982 in Newfoundland, meeting the following characteristics :

i) worked between 10 and 23 insured weeks, so that they fall in Stage 3 of the benefit-weeks relationship (8) ;

ii) drew the maximum 27 weeks of benefits, so that they were unemployed throughout the benefit period ; and

iii) earned less than the maximum weekly insured earnings of $350 in their qualifying weeks.

We are left with a sample of 5,631 out of a potential 13,142 claimants. Unfortunately, our data source does not distinguish between full-time and part-time fishermen. The 1984 DFO Income Study reveals that in that year, 77 % of seasonal fishermen's benefit recipients were full-time fishermen, so we feel justified in using the full-time model on this sample.

We use log-linear approximations for both the catch functions $f(L)$ and the utility functions $U(F, L)$. We represent the catch function as

$$f_i = \alpha_i\, L_i^{\beta_i}\,. \tag{12}$$

The elasticity of the seasonal catch $f$ with respect to the number of fishing weeks $L$ is measured by the $\beta$ parameter, which should be between 0 and 1. The greater the curvature of the $f(L)$) curve, the lower is $\beta$.

The $\alpha$ parameter reflects the productivity of the fisherman for a particular value of $L$. This is known to vary considerably from person to person, depending on such factors as experience, location, and innate skills. We assume that $\alpha$ is related to various socio-demographic indicators by a semi-logarithmic relationship of the form

$$\ln \alpha_i = Z_i \gamma + \epsilon_i , \tag{13}$$

where $Z_i$ is the vector of relevant socio-demographic indicators and $\epsilon_i$ captures otherwise "unexplained" variations in $\alpha$. In the regressions, we use the following indicators in $Z$:

1. Age of the claimant (AGE).
2. A binary sex dummy variable (SEX) which equals zero if the claimant is male and one otherwise.
3. A binary occupation dummy variable (FISHER) which equals one if the claimant is classified as a fisherman in the database and zero otherwise.
4. A number of binary dummies for CEIC management areas (AREA) where the claimant has filed his/her claim. [11]

The first three variables are expected to be indicators of experience. The fourth should reflect local fish abundance.

Substituting (13) into (12) gives the catch equation

$$\ln f_i = Z_i \gamma + \beta_i \ln L_i + \epsilon_i . \tag{14}$$

The utility function used is a Cobb-Douglas function in income $F_i$ and weeks of 'leisure' $52 - L_i$,

$$U_i = F_i^{\delta_i}(52 - L_i)^{1-\delta_i} , \tag{15}$$

which implies the marginal rate of substitution function

$$MRS_{FL} = \frac{1 - \delta_i}{\delta_i} \frac{F_i}{52 - L_i} \tag{16}$$

Within the selected sample, $B(L) = B_{max}$ since all claimants are in Stage 3 of the $B(L)$ function. As well, we can reasonably assume that $E(L) = f(L)/L$, since weekly insured earnings are below the maximum. Thus from equation (4) unemployment benefits are

$$S_i = rB_{max} \frac{f(L_i)}{L_i} . \tag{17}$$

Substituting (17) into (7) and differentiating with respect to $L$ gives the slope of the fishing income function

$$F'(L_i) = \left[1 + \frac{rB_{max}}{L_i}\right] f'(L_i) - \frac{rB_{max}}{L_i^2} f(L_i) . \tag{18}$$

The optimum condition (8b) can be arrived at by equating the slope of the fishing income function (18) with that of the indifference curve (16). After simplifying, we can express the optimum condition as

11. The CEIC management areas are coded as follows, with St. John's as datum : AREA40 = Clarenville, AREA41 = Happy Valley, AREA51 = St. John's Central, AREA52 = St. John's West, AREA53 = Harbour Grace, AREA54 = Gander, AREA55 = Marystown, AREA57 = Grand Falls, AREA58 = Stephenville, AREA60 = Corner Brook.

$$\frac{1-\delta_i}{\delta_i}\frac{L_i}{52-L_i}+\frac{rB_{max}}{L_i+rB_{max}}=\beta_i\,, \tag{19}$$

where $L_i$ is shown to be a function of both $\delta_i$ and $\beta_i$. Since neither parameter is directly observable, neither can be identified without further restrictions.

If we assume that fishermen have identical preferences ($\delta_i = \delta$), then we can, by substituting (19) into (14), express the optimum condition as the linear-in-parameters relationship

$$\ln f_i - \frac{rB_{max}}{L_i+rB_{max}}\ln L_i = Z_i\,\gamma + \theta\frac{L_i}{52-L_i}\ln L_i + \varepsilon_i\,, \tag{20}$$

where $\theta = \delta/(1-\delta)$. Since in this sample the replacement rate $r$ is 0.6 and the maximum benefit period $B_{max}$ is 27, we can estimate the parameters $\theta$ and $\gamma$ through ordinary least squares. Values of $\beta_i$ corresponding to various values of $L_i$ can then be obtained from equation (20).

The regression results are reported in the column of Table 5 labelled Run 1. The estimated value of $\theta$ is 0.52, which corresponds to a value of the utility function parameter $\delta$ equal to 0.34. The $\gamma$ parameters are also presented. Age is positively related to productivity, although not significantly. Males are significantly more productive than females, and those classified in the database as fishermen are more productive than those not so classified. There are also significant geographic differences, as reflected in the AREA dummies.

Values of the catch function parameter $\beta$ which are implied by equation (20) are presented in Table 3 for various levels of $L$. The median value of $L$ in the sample is 12.

Suppose now that all fishermen have identical values for the catch function parameter $\beta$, rather than for the utility function parameter $\delta$. We continue to permit the $\alpha$ parameter in the catch equation (12) to differ among fishermen, so only the curvature, and not the position of the catch function is invariant. Then the catch function in equation (14) is linear in parameters and can be estimated directly using ordinary least squares.

The regression results are reported in the column of Table 5 labelled Run 2. The estimated values of the $\gamma$ parameters are similar to those estimated from the identical preferences model in Run 1, although the influence of the age is much greater in the latter model. The estimated value of the catch function parameter $\beta$, however, is 0.91, which is significantly higher than those values implied in the identical preferences model and reported in Table 3. Similarly, the values of the utility function parameter $\delta$ implied by equation (19) for this value of $\beta$ are presented in Table 4. We see values considerably higher than the value 0.34 estimated in the identical preferences model. The implication is that the model specification *does* matter.

It does not necessarily follow that we have to choose between two extreme specifications, those of identical preferences and identical opportunities. We may be able to identify the two sets of parameters on the basis of much weaker assumptions on the distribution of these parameters, through the utilization of maximum likelihood techniques. The existence of piecewise segments in the opportunities set should enhance the possibility of identifying the two sets of parameters, as should the parameter changes to which the unemployment insurance program (and therefore the opportunities set) has been subjected over the years. However, we have not yet solved this statistical problem to our satisfaction.

### *4.2 Piecewise non-linear opportunity sets*

The theoretical structure outlined in Part II demonstrates that the optimum relationship governing the determination of the fishing season can be decomposed into four distinct segments. Linear estimation of this relationship across the entire spectrum of fishing seasons is clearly unacceptable, even as an approximation. This is clear from an examination of the relationships portrayed in Figure 4.

The easiest solution to this problem, and the one used in the early literature on non-linear budget constraints (see Hausman 1985 for a survey), is simply to estimate the relationship for each segment separately from the others.

There are two problems with this procedure. First, it is relatively inefficient in that information from data contained in one segment (on preferences, say) is not utilized in the estimation of the relationship across other segments. Second, optimization errors on the part of fishermen (as a result of uncertainty, for example) can result in behaviour which would introduce bias into the parameter estimates.

The source of this bias is twofold (Pudney 1989, pp. 198-201). First, optimization errors result when a random variable is added to equation (20). Then variable $L_t$ becomes random as well, and therefore regression estimates of equations such as (14) or (20) are subject to simultaneity bias.

The second source of bias is that with optimization errors, the observed and optimum positions of a given data point may lie on different segments. For example, a fisherman who would best locate in Stage 2 mistakenly fishes into Stage 3. When such points are grouped into the "wrong" segment, the resultant estimates are biased.

A problem related to the above is that points whose optimum position is at the corner vertex formed by two segments will generally satisfy a tangency condition for neither segment. Inclusion of these boundary points in the estimation will also bias the results. When fishermen make optimization errors, however, we cannot identify cases with corner optima.

This is not a new problem. There exists an extensive literature (Wales and Woodland 1979 ; Zabalza 1983 ; Phipps 1990 ; Osberg and Phipps 1989) on the impact of piecewise-linear constructs such as progressive income taxes and unemployment insurance on the length of work spells. Maximum likelihood methods have been successfully utilized to resolve these difficulties (Pudney 1989, pp.201-205). The problem, however, is simplified considerably by the assumption usually made that work is available throughout the year at a fixed wage. The challenge is to adopt these techniques to contexts, such as the present one, in which the "wage" varies systematically through the year.

### *4.3 Upper and lower limits and partially observable data*

In the regressions reported above, we removed from our sample claimants whose average insured earnings were at the maximum $350 per week, because we could no longer use the level of insured earnings as a measure of earned income. This required discarding 939 observations, a considerable loss of information. Moreover, there is considerable danger in this procedure of sample selection bias resulting from the removal from our sample of the most productive fishermen. Fortunately, there is an extensive econometric literature on this so-called partial observability problem (Pudney 1989, ch. 4).

We have tested two alternative specifications of the identical opportunities model. The first, labelled Run 3, re-estimates Run 2 using a sample which includes claimants reporting the maximum insured earnings during their qualifying weeks. The second, labelled Run 4, is a Tobit regression analogous to Run 3. The outcome, which frankly surprised us, is that there is only a negligible difference in the estimated values of $\beta$ and most of the components of $\gamma$ among these three runs. The truncation in the value of maximum insured earnings does not appear to be a serious problem, at least in this sample.

## 5. SIMULATION EXERCISES

Successful estimation of the optimal conditions would enable us to simulate the impact of changes in the parameters underlying the unemployment insurance program on the length of the fishing season. For example, let us take the identical opportunities model underlying Run 2 as valid. We can rewrite the optimum condition (19) as

$$\theta_i = \beta \frac{52 - L_i}{L_t} - \frac{rB_{max}(52 - L_t)}{(rB_{max} + L_i) L_i}, \tag{21}$$

which enables us to associate a value $\theta_t$ with each value of $L_i$, for an estimated value of $\beta$ such as the 0.91 in Run 2. The implied $\delta_i$ values are reported in Table 3. Now rewrite equation (21) as

$$(\beta + \theta_i) L^2 - [(52 - rB_{max}) \beta + rB_{max}(1 - \theta_i)] L + 52 rB_{max}(1 - \beta) = 0 , \quad (22)$$

a quadratic equation in $L$. For the given $\beta$ and $\theta$, we can evaluate the value of the number of fishing weeks $L$ which would prevail if either of the unemployment insurance parameters $r$ and $B_{max}$ were modified.

Table 6 presents the simulated outcome of (a) a reduction in the benefit-earnings ratio $r$ from 0.6 to 0.5 ; (b) a reduction in the maximum number of benefit weeks $B_{max}$ from 27 to 20 weeks ; and (c) both changes simultaneously. The first change increases the number of fishing weeks by anywhere from 1.6 to 2.6 weeks, depending on the initial value of $L$. The second change increases the number of fishing weeks by from 2.2 to 3.9 weeks. The two changes together increase the number of fishing weeks by from 3.1 to 5.4 weeks. These are fairly large changes. As expected, the impact of the two changes together is not additive. Note that the simulated changes occasionally go outside Stage 3, and this would have to be taken into consideration in a full simulation.

ABSTRACT

*The major tuna fisheries in the southwest Pacific are the purse seine fishery catching skipjack and juvenile yellowfin, and the longline fishery catching a range of species including albacore, yellowfin, bigeye, marlin, and swordfish. The paper describes studies of three of these fisheries - the eastern longline fishery in the Australian Fishing Zone, and the purse seine and longline fisheries in Papua New Guinea's Exclusive Economic Zone. The studies involve calculating fishing costs and estimating multi-species production functions. An example of the policy application of this work is the question of whether purse seine catches should be restrained to conserve juvenile yellowfin for the longline fishery. The cost of such a policy depends upon whether purse seiners are able to target their fishing effort on particular species. The paper reports evidence that suggests that targeting is possible and shows that a policy of yellowfin conservation will be less costly in these circumstances than otherwise.*

## 1. INTRODUCTION

Bioeconomic modelling of fisheries involves specifying a biological production (or growth) function and an economic production (or harvest) function. Early bioeconomic models (see for example, Schaefer (1967)) adopted a single species approach to both the biological and economic production functions. Later work recognized that biological interactions among species should be taken into account even if the aim of the model was to predict the impact of fishing a single species. The recognition of competition among species for food, as in the case of the Peruvian anchovy and Californian sardine (see Murphy (1967)), or of predator-prey relationships, such as the relationship among capelin, cod and seals in the Barents Sea (see Flaaten (1986)), led to more complete modelling of the biological production process and presumably to more robust management prescriptions.

Recent work has developed a multi-species approach to the economic production relationship in the bioeconomic model. In many cases, such as trawl fisheries, a number of species are regularly harvested by the fleet. Some species may be regarded as major species while others are by-catch. This situation can be modelled within a multi-output/multi-input production function framework. The fact that vessels simultaneously harvest more than one species imposes a constraint on the fishery manager. In an extreme case in which species are caught in fixed proportions, the fishery manager is tightly constrained in his ability to regulate the stock of any individual species. How tight the constraints imposed by the nature of the economic production process are can be ascertained by estimating the inter-relationships among species in the form of a multi-species production function.

The present study uses the multi-species production function approach to estimate the relationships between the harvests of various species in the tuna fisheries of the South West Pacific region. Two fisheries are considered : the longline fishery which harvests seven species - yellowfin, big eye, albacore, swordfish, black marlin, blue marlin, and striped marlin ; and the purse-seine fishery which catches two main species - skipjack and juvenile yellowfin. The longline fisheries studied are located in the North East portion of the Australian Fishing Zone, and in Papua New Guinea's Exclusive Economic Zone (EEZ). In the former area the operations of both Australian and Japanese vessels are analysed, while in the latter area the study is concerned with Japanese vessels only. The purse-seine fishery studied is pursued by Japanese and United States vessels in Papua New Guinea's EEZ.

In Part 2 of the study the multi-species production function approach is outlined and its relevance for fishery management is discussed. Part 3 describes the objectives and approach of the individual studies referred to above. In Part 4 one of the studies is described in more detail and its results are used to illustrate the importance for policy making of understanding the multi-species structure of the economic production function. The example chosen is that of the tuna purse-seine fishery, and the policy issue used as an illustration is the question of reducing the purse-seine harvest of juvenile yellowfin to benefit the longline fishery. The paper concludes with a brief discussion of the importance of the multi-species approach.

## 2. THE MULTI-SPECIES APPROACH TO FISHERY PRODUCTION

The multi-species approach to estimating the technology of the economic production function for a fishery has been adopted in several recent studies. Squires (1987, 1988) uses a translog multi-product restricted profit function to estimate the technology of the New England otter trawl fishery which harvests cod, flounders, haddock, redfish and pollock. Kirkley and Strand (1988) estimate a dual revenue function for the New England, Georges Bank trawl fishery which exploits a similar range of species. Squires and Kirkley (1991) use a generalized Leontief revenue function to estimate input-compensated supply functions for five species - dover sole, thorny heads, sable fish (Alaska or black cod), other flatfish, other rockfish - plus miscellaneous species in the multi-species trawl fishery off the California coast. The Kirkley and Strand (1988) and Squires and Kirkley (1991) studies treat fishing effort as a single composite input, whereas the Squires (1987, 1988) papers consider three inputs - labour, energy, and capital.

The purpose of the above studies is to establish which of those features of the technology of the economic production function should be taken into account in developing fishery management policy. The implications of the multi-input nature of the economic production function for fishery management through gear regulation have been developed by Anderson (1985), Campbell and Lindner (1990), and Campbell (1991). Since the focus of the present paper is on the implications of the multi-species nature of the fishery for management through various forms of output regulation, the single input case will be used for illustrative purposes.

The two main features of the technology of the economic production function can be established by tests for input-output separability and non-jointness-in-inputs (see Squires (1991)). In describing these two characteristics of technology it will be assumed that the firm's short-run behaviour involves maximizing revenue subject to a fixed input constraint. In the long-run the firm varies its input level to maximize profit. Revenue is maximized in the short-run by choosing a point on the product transformation curve where the marginal rate of product transformation is equal to the relative price of the species. Input-output separability implies no specific interaction between any one output and any one input. In the two output, one input case, this means that the marginal rate of transformation between any two outputs is independent of scale. Figure 1 shows product transformation curves for two levels of effort contributed by a vessel in a two-species fishery. The marginal rate of product transformation is given by the negative of the slope of the product transformation

curve. The revenue maximizing output combinations are indicated by the points marked A in Figures 1(a) and 1(b). In Figure 1(a) the product transformation curve exhibits input-output separability as the catch per unit effort of both species is independent of the level of effort. In other words, the product transformation map is homothetic. In Figure 1(b) the proportion of species 1 in the total harvest falls as scale increases because of an absence of input-output separability.

Non-jointness in inputs implies that separate production functions exist for each output. This means that the proportion of each species in total harvest depends only upon the level of effort and is not influenced by price. A technology which is joint in inputs allows vessels some control over the proportions of species in their harvest. They are able to "target" particular species. Figure 2(a) illustrates a production technology which is non-joint in inputs since the catch per unit effort for both species depends only on scale. Figure 2(b) illustrates jointness-in-inputs so that a change in the price ratio from $P_1$ to $P_2$ changes the catch per unit effort of each species, holding effort constant.

The generalized Leontief revenue function for the two output, one input case can be used to illustrate the two main features of the production technology described above. The revenue function is :

$$R(P, E) = \sum_i \sum_j \beta_{ij} (P_i P_j)^{1/2} E + \sum_i \alpha_i P_i E^2 \qquad (2.1)$$

where $P_i$ is the price of output $i$ and $E$ is the level of fishing effort. The supply functions are given by :

$$h_i(P, E) = \beta_{ii} E + \alpha_i E^2 + \sum_{j \neq i} \beta_{ij} (P_j / P_i)^{1/2} E \qquad (2.2)$$

If there is input-output separability, $\alpha_i = 0$ , and the catch per unit effort is independent of the level of effort, although it may be influenced by the relative price of the species. If there is non-jointness-in-inputs, $\beta_{ij} = 0$ for $i \neq j$, and catch per unit effort is independent of the relative price, although it may vary with the level of effort. In this case the harvest of each species is described by a species-specific quadratic function of fishing effort. If both input-output separability and non-jointness in inputs hold, catch per unit effort is a constant.
