Abstract

Introduction

In France, combination prevention tools, particularly antiretroviral treatment for HIV prevention has been available for several years. We described the knowledge of these antiretroviral treatments among immigrants from sub-Saharan Africa, who are particularly affected by HIV, and the factors associated with this knowledge.

Methods

The data come from the Makasi study, which was conducted between 2019 and 2020 among precarious immigrants from sub-Saharan Africa recruited through a community-based outreach approach in the greater Paris area ($n = 601$). We described levels of knowledge of HIV treatment effectiveness (HTE), treatment as prevention (TasP), post-exposure prophylaxis (PEP), and pre-exposure prophylaxis (PrEP), by sex with chi2 test. We investigated factors associated with their knowledge with logistic regressions adjusted for sociodemographic characteristics, living conditions and sexual behaviors ($p \leq 0.2$).

Results

Respondents were mostly men (76%), from West Africa (61%), in precarious situation: 69% were unemployed, 74% were undocumented and 46% had no health coverage. Among this population, knowledge of HIV preventive treatments was heterogeneous. While HTE was well known (84%); TasP was known by only half of the respondents (46%), and PEP and PrEP were hardly known: 6% and 5%, respectively. Multivariate regressions models showed that these antiretroviral treatments for the prevention of HIV was better known by

to the public. All relevant data can be requested by researchers who meet the criteria for access to confidential data from the data access committee: ceped.appui@listes.ird.fr.

Funding: The MAKASI study was sponsored by the French Agency for Research on AIDS and Viral Hepatitis (ANRS), the Agence Régionale de Santé (ARS) Ile-de-France, the French Collaborative Institute on Migrations, the Université Paris Cité (ANR-18-IDEX-001) and a PhD grant from Sidaction (AO 2019- 12276 and 2022- 13327). This article was published with the support of Faculté Sociétés & Humanités of Université Paris Cité and the French Institute for Research on sustainable Development (IRD). The sponsors had no role in the design or conduct of the study; in the collection, analysis, or interpretation of data; nor in the preparation, review, or approval of the manuscript.

Competing interests: The authors have declared that no competing interests exist.

people with a higher level of education (PEP: aOR = 3.33 [1.09–10.20], $p = 0.03$; HTE: aOR = 4.33 [1.87–10.04], $p < 0.001$), those who had a social network in France (TasP: aOR = 1.90, [1.33–2.73], $p < 0.001$), those who had access to the health system and those who were exposed to sexual risks (TasP: aOR = 3.17, [1.03–9.69], $p = 0.04$; PrEP: aOR = 2.60 [0.72–9.34], $p = 0.14$).

Conclusions

There is a need for specific communication on antiretroviral treatment for HIV prevention that targets sub-Saharan immigrants, particularly those who have no access to the health-care system and those who are less educated.

Introduction

Immigrants from sub-Saharan Africa living in Europe are particularly affected by HIV infection [1]. In France, around 37% of new HIV diagnoses in 2018 were among immigrants born in sub-Saharan Africa [2]. Studies have shown that these infections are linked not only to epidemic situations in the countries of origin but also to infection in the country of immigration. In France, it is estimated that between 35% and 49% of Africans living with HIV acquired the infection after their migration [3]. The ANRS-Parcours survey showed that social hardship encountered in France is an indirect factor of exposure to HIV infection since being without stable housing or a residence permit increases the risk of having unprotected sex, sex with casual partners and experiencing sexual violence for women [3–5].

Since several years, HIV combination prevention tools have been available to prevent new infections. These prevention tools include condoms use, HIV testing and the use of antiretroviral preventive treatments such as postexposure prophylaxis (PEP) [6], pre-exposure prophylaxis (PrEP) [7] and treatment as prevention (TasP) [8]. PEP was adopted in France as an HIV prevention tool in 1998. It is a combination of antiretroviral drugs taken by HIV-negative persons who have been exposed to the risk of HIV contamination in the professional environment, through unprotected sex or through the use of a dirty needle. It must be taken within 48 hours after exposure to the virus, then every day for up to a month [9]. PrEP, available in France since 2016 [10], refers to antiretroviral drugs taken by HIV-negative persons before potential exposure to the virus to reduce the risk of HIV infection. TasP has been described in 2008. It refers to the fact that people living with HIV who are on antiretroviral treatment and who achieve and maintain an undetectable viral load beyond six months do not transmit HIV to their sexual partners [11]. In France, it is promoted as a tool of HIV prevention since 2010 [12].

The prescription of these prevention tools, which are reimbursed by social security, is recommended by the French health authorities in populations most vulnerable to HIV acquisition, mainly men who have sex with men (MSM) and people born in sub-Saharan Africa [10]. However, to date, limited research has been conducted to assess the state of knowledge of these treatments among immigrants from sub-Saharan Africa, both in France and in other Western countries [13].

In France, available quantitative studies have focused on HIV testing and condom use in this population. The Knowledge, attitudes, beliefs and practices (KABP) survey [14] conducted in 2005 among 1874 immigrants from sub-Saharan Africa aged 18 to 49 living in the greater Paris area showed that 65% of respondents had been tested for HIV a least once in their

lifetime. In 2016, another survey conducted in the same population showed similar results: 66% of respondents had been tested for HIV in the 12 months prior to the survey and 15% more than 12 months ago; condom use was 57% in the past 12 months among sexually active individuals [15]. Regarding antiretroviral preventive treatments, the studies are exploratory, mainly qualitative and focused on the dissemination and acceptance of PrEP and the difficulties associated with it, but they did not measure the level of knowledge of these prevention methods [16–18].

Using data from the Makasi survey, this study aimed to measure the level of knowledge of these prevention tools and to study the factors associated with knowledge of HIV antiretroviral preventive treatments among immigrants from sub-Saharan Africa living in precarious situations in the greater Paris area.

Materials and methods

Study design and participants

The data used were collected at baseline during the Makasi project, a community-based participatory research that was designed and conducted by researchers and two community-based organizations (Afrique Avenir and ARCAT) as well as a peer groups [19]. The CBO members were part of the steering committees and involved in all aspects of the project. The project aimed to reduce social vulnerability and improve sexual health empowerment among immigrants from sub-Saharan Africa to reduce the risk of HIV infection.

Participants were recruited from intervention sites of the community-based organization Afrique Avenir, which offers rapid outreach testing and health sensitization. Participants were born in sub-Saharan Africa, were 18 years of age or older, HIV-negative and met at least one of the following vulnerability criteria: no stable housing, unemployed, have experienced food deprivation in the last month, have no residence permit or short-term residence permit, are or have been victims of violence, have no health coverage, feel isolated and do not know where to go to see a doctor. Participants received 10 € vouchers for their participation. The survey was conducted in French and English. At inclusion, all participants completed questionnaires administered face-to-face by trained health mediators. These questionnaires included questions on sociodemographic characteristics, living conditions, sexual behavior, and knowledge of combination prevention tools. The study protocol is registered on Clinicaltrials.gov (NCT04468724) and a description of the project has been published [19].

Ethical consideration

The Makasi study was approved by the French Data Protection Authority (Commission Nationale de l'Informatique et des Libertés, CNIL, déclaration n° 2215270) and the Committee for Persons' Protection (Comité de Protection des Personnes, CPP, Sud-Ouest et Outre-Mer, ID RCB 2018-A02129-46). All participants provided written informed consent.

Variables of interest

First, we studied variables related to knowledge of the health-care system and HIV prevention practices such as knowledge of sexual health services, HIV testing, ability to decide how to protect oneself against HIV, condom use at last occasional sex, and perceived risk of HIV infection (for more details, please see [S1 Table](#)). Next, the knowledge of four variables of antiretroviral treatment for the prevention of HIV was studied in detail; these included knowledge of HIV treatment effectiveness (HTE), knowledge of treatment as prevention (TasP), knowledge of pre-exposure prophylaxis (PrEP), and knowledge of post-exposure prophylaxis (PEP).

For HTE and TasP, participants were asked to say whether they completely agree/more or less agree/do not really agree/completely disagree with the following statements, “I think that thanks to treatments, a person who has HIV can have a normal life” (HIV treatment effectiveness); “I think that someone who has HIV and takes his or her medicine does not transmit HIV when having sex” (TasP). For the analyses, responses were coded “Yes” for those who responded that they completely agreed or more or less agreed and “No” for those who responded that they did not agree or completely disagreed.

Questions related to PEP and PrEP were formulated as follows: “Have you heard about post-exposure prophylaxis (or emergency treatment) that you take very quickly AFTER sex to prevent HIV transmission?” (PEP: yes/no), and “Have you heard about pre-exposure prophylaxis (PrEP), a treatment that you take BEFORE sex without condoms and that protects you from HIV?” (PrEP: yes/no).

Independent variables

The association between the variables of interest and the independent variables was tested. The independent variables were sociodemographic characteristics: sex, age (18–29, 30–39, and 40+), educational level (none/primary, secondary, superior), region of birth (West Africa, other parts of sub-Saharan Africa), main reasons for coming to France (work or study, family, medical and other, threat), and duration of stay in France in years (0–2, 3–6, 7+). Variables related to contacts with the health system were used: health insurance coverage (no health insurance coverage; state medical assistance (SMA), i.e., social aid mainly intended to cover the medical expenses of undocumented foreigners living in France; universal health insurance coverage (UHC)), and children (yes/no). Living conditions and social situation in France were captured by occupational status (unemployed, employed (informal/formal/student)), housing situation (own housing, associations, housed by family/friends and no stable housing), residence permit (undocumented, short-term permit (less than a year) and long-term permit (1 year or more), having someone close you can rely on in times of hardship (yes/no) and empowerment in sexual health scores (4 quartiles). This score was constructed from 16 questions and was validated (Cronbach’s $\alpha = 0,71$) [20]. Sexual behavior variables included having a stable partnership (yes/no); having a stable or occasional same-sex sexual partner (yes/no); having transactional sex, i.e., having unwanted sex in exchange for money, papers, or other goods (yes/no); and having forced sex (yes/no).

Statistical analysis

First, we described participants’ sociodemographic characteristics, living conditions and social situation, contact with the health-care system, and sexual behaviors by sex. We compared levels of knowledge of the health-care system, HIV-related preventive practices, and antiretroviral treatment for the prevention of HIV by sex using proportion test and displaying 95% confidence interval. Missing data were around 5% on average for some variables of interests. We performed the analysis only on the complete cases data.

Descriptive analysis using chi2 test was performed to identify variables with a $p \leq 0.2$ that was considered for bivariate and multivariate analysis. The descriptive analysis was made on participants’ sociodemographic characteristics, living conditions and social situation, contact with the health-care system, and sexual behaviors to check whether or not they know each antiretroviral treatment for the prevention of HIV (see [S1 Table](#)). Finally, we performed bivariate analysis and multivariate nested logistic regression models to investigate factors associated with knowledge of each type of treatment. Multivariate logistic regression models were

adjusted for sociodemographic variables as well as all other variables with a $p \leq 0.2$. Multivariate logistic regression models were nested as follows:

- Model 1: sociodemographic characteristics
- Model 2: sociodemographic characteristics + contact with the health-care system
- Model 3: sociodemographic characteristics + contact with the health-care system + social situation in France
- Full model: sociodemographic characteristics + contact with the health-care system + social situation in France + sexual behaviors

The receiver operating characteristic (ROC) curves [21] were used to perform sensitivity and specificity analysis for each of the models. The goodness-of-fit of the models was also investigated using the Hosmer and Lemeshow goodness-of-fit test [22]. The analysis were performed in Stata 15 (Stata Corporation, College Station, TX, USA).

Results

Between February 2019 and December 2020, of the 1854 individuals who were eligible for participation in the Makasi project, 1566 (84%) received a proposal to participate, 990 (53%) agreed to participate and 635 (34%) participants were included (Fig 1). Some respondents were lost between acceptance and inclusion because the project took place in public spaces and on trucks. On busy days, people had to wait in a tent to be received in the inclusion truck after they accepted to participate, and some refused to wait. 34 individuals were excluded from the analyses because of several missing values. The analyses were based on a sample of 601 participants. We compared those included in the study to those eligible but not included. Those included were similar to those not included in terms of region of birth. They differed significantly on other socio-demographic characteristics such as sex, age, duration of stay in France and living conditions (see S2 Table). Those included in the study were more often men (76.2 vs 66.5; $p < 0.001$), arrived in France in the two years before the study (50.1 vs 30.8, $p < 0.001$) and they were more precarious: unemployed (69.2 vs 59.6, $p < 0.001$); undocumented (73.9 vs 48.6, $p < 0.001$).

Sociodemographic characteristics and knowledge levels of combination prevention tools

A predominantly male population and many precarious situations

The characteristics of the study population are described in Table 1. It was a predominantly male population (76.2% were men), largely young (30.6% are under 30 years of age) and educated (51.2% had secondary schooling and 18.5% had superior education). Half of the participants had arrived in the two years preceding the survey (50.1%), often to work (including to study): 47.2 of men; 47.6 of women; or to flee their country: 40.8 of men; 35.7 of women.

The survey concerns a population that often faces precarious situations. One person out of two was housed by family or friends (50.4%), and only 27.8% of the respondents had their own housing. There was also a large proportion of people who were unemployed (69.2%), undocumented (73.9%) and without health insurance coverage (46.1%).

Nearly half of the respondents had a stable primary partner (43.6%), and this was more often the case for women than for men (60.8% vs. 38.2%). Most of these partners were of the opposite sex, with only 4.2% of participants having had stable or occasional partners of the same sex in the past 12 months. 49.6% of respondents had sexual relations with occasional partners in the 12 months preceding the survey. Some respondents had transactional sex (8%)

Fig 1. Recruitment flowchart.

<https://doi.org/10.1371/journal.pone.0287288.g001>

and forced sex (2.7%), with higher levels among women (21% had transactional sex and 8.4% had experienced forced sex).

Heterogeneous levels of knowledge of prevention tools. Knowledge of sexual health and testing practices was high in the study population. This suggests that the study population is aware of the risk of exposure to HIV (Table 2). 70% of the respondents were aware of sexual health services, and 80% had already been tested for HIV during their lifetime, with more women than men being tested (89% vs. 78%, $p = 0.003$). Regarding the ability to decide how to protect oneself, 81% declared that it was fairly easy or very easy to decide how to protect oneself, with men giving this answer more than women (83% vs. 75%, $p = 0.03$). This result appears to be consistent with protection at last occasional sexual encounter: more men reported using a condom at last occasional sexual encounter (57% vs. 47% among women). We also noted that 41% of respondents reported having a perceived risk of HIV infection equal to or more than the rest of the population.

Knowledge of antiretroviral treatment for the prevention of HIV was very heterogeneous (Table 2). While 84% of the respondents knew about HTE and nearly half knew about TasP (46%), only 5% and 6% knew about PrEP and PEP, respectively.

Factors associated with knowledge of antiretroviral treatment for the prevention of HIV. We presented the results of the full multivariate logistic regression models in the article (Figs 2 and 3). Results on Models 1, 2 and 3 are in the supplemental supporting information (see S3–S6 Tables). Goodness-of-fit tests and areas under the ROC curves showed that the multivariate logistic regression models had good properties (see S3–S6 Tables).

Factors associated with knowledge of HTE and TasP. Men were twice as likely as women to be aware of HTE (aOR = 2.12 [1.22–3.69], $p = 0.007$) (Fig 2). Those with secondary education (aOR = 2.98 [1.71–5.18], $p < 0.001$) and superior education (aOR = 4.33 [1.87–10.04], $p < 0.001$) were more likely to have this knowledge than those with primary education. Having children and having an SMA or UHC increased the probability of knowing about HTE (aOR = 2.37 [1.38–4.09], $p = 0.002$; aOR = 1.89 [1.04–3.44], $p = 0.03$ and aOR = 1.93 [1.05–3.53], $p = 0.03$, respectively). The same was true for having a stable partnership (aOR = 1.93 [1.14–3.26], $p = 0.01$). Having someone to rely on in France was significantly associated to

<https://doi.org/10.1371/journal.pone.0287288.t002>

knowledge of HTE in the bivariate analysis (OR = 1.73 [1.11–2.70], $p = 0.01$) but this association was no longer significant in the multivariate analysis.

In the multivariate model 1 adjusted for participants' sociodemographic, we saw that those with a secondary or superior education levels were more likely to know about TasP than those with a primary education level (aOR = 1.52 [1.01–2.30], $p = 0.043$ and aOR = 1.71 [1.00–2.91], $p = 0.048$, respectively). This results is also confirmed in the full model, even less significant (aOR = 1.51 [0.99–2.32], $p = 0.055$ and aOR = 1.66 [0.95–2.89], $p = 0.070$, respectively) (Fig 2). Having a stable partner or having experienced forced sex also increased the probability of knowing about TasP (aOR = 1.90 [1.33–2.73], $p < 0.001$) and aOR = 3.17 [1.03–9.69], $p = 0.04$, respectively).

Factors associated with knowledge of PEP and PrEP. Those with a secondary education were three times more likely to know about PEP than those with a primary education (aOR = 3.33 [1.09–10.20], $p = 0.03$) (Fig 3). This probability was also higher for those who were unemployed than for those who were employed (aOR = 4.97 [1.62–15.18], $p = 0.005$). In addition, having someone to rely on in France increased the probability of knowing about PEP (aOR = 3.34 [1.30–8.59], $p = 0.01$). People with a high intermediate level of sexual empowerment had a significantly higher probability of knowing about PEP than those with a low intermediate level of sexual empowerment (aOR = 4.51 [1.30–15.60], $p = 0.01$). Having transactional sex significantly increased the probability of knowing about PEP (aOR = 5.72 [1.51–21.57], $p = 0.01$).

In the full model on the factors associated with knowledge of PrEP, none of the variables were significant at the 5% level. However, we observe certain trends. For example, having

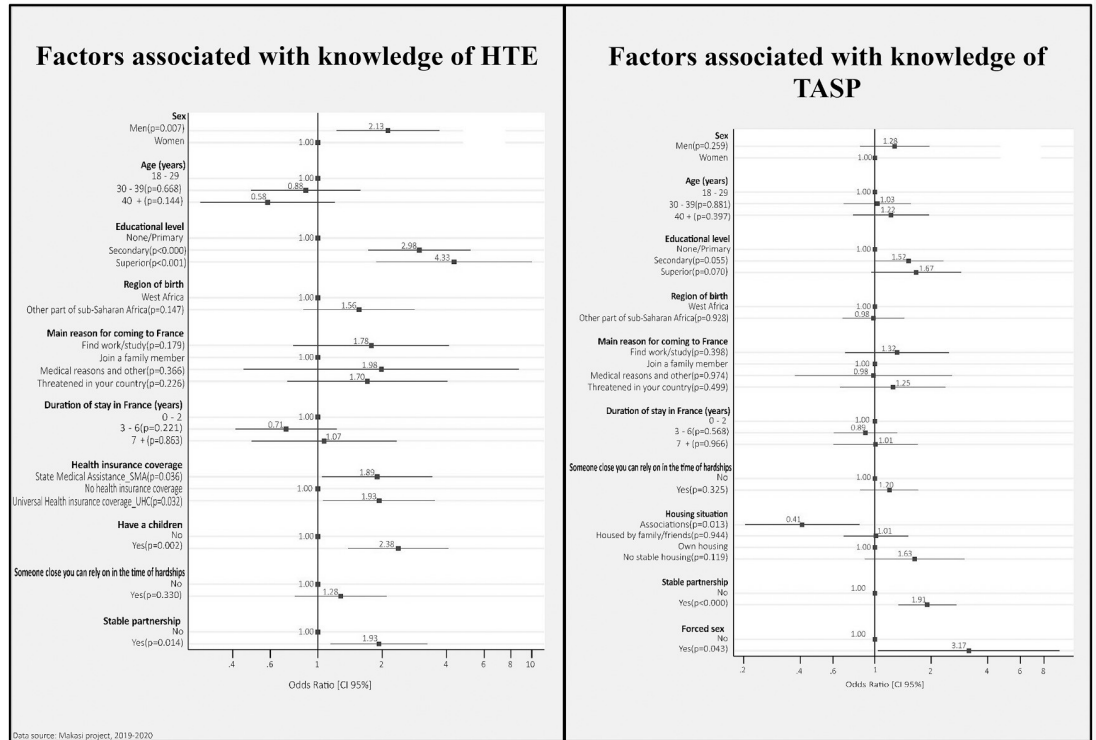

Fig 2. Factors associated with the knowledge of HTE and TASP.

<https://doi.org/10.1371/journal.pone.0287288.g002>

Fig 3. Factors associated with the knowledge of PEP and PrEP.

<https://doi.org/10.1371/journal.pone.0287288.g003>

someone to rely on in France appears to be correlated with the knowledge of PrEP (aOR = 2.28 [0.88–5.90], $p = 0.08$). Similarly, having a stable primary partner and experiencing transactional sex appears to be correlated with the knowledge of PrEP (aOR = 1.96 [0.84–4.54], $p = 0.11$ and aOR = 2.60 [0.72–9.34], $p = 0.14$, respectively) (Fig 3). These trends were consistent with the fact that having someone to rely on in France and having a stable primary partner were more significant in the bivariate analysis (OR = 2.57 [1.06–6.18], $p = 0.03$ and OR = 2.22 [0.99–4.96], $p = 0.050$ respectively).

Discussion

This study population faces several precarious situations. In this study, most participants were young and male, half of them had recently arrived in France. This population is rarely surveyed in other studies [23]. Our results showed that in this population, the levels of knowledge of antiretroviral treatment for the prevention of HIV were heterogeneous: the effectiveness of HIV treatment was widely known, half of the respondents knew about TasP, while less than 10% of them were aware of PrEP and PEP.

We can see from our results three categories of factors that were linked to the knowledge of HIV preventive treatments: access to information, contact with the health-care system, and exposure to sexual risks.

The participants who were informed about antiretroviral treatment for the prevention of HIV were those who had access to information in general: the people with a higher level of education and those who knew someone in France (i.e., they had someone to rely on; this person could also be a partner). As highlighted in work on PrEP in the United States, this information on antiretroviral treatment for the prevention of HIV is generally shared on social media and in interpersonal relationships [24]. Therefore, in France, we found that personal networks and good health literacy play an important role in the exposure to information.

Participants who had UHC or SMA were more likely to have access to the health-care system than others; this is also the case for people who had a child. As expected, this proximity to the health system is associated to the knowledge of antiretroviral treatment for the prevention of HIV.

Finally, people who were exposed to sexual risks (those who reported transactional relationships or those who experienced forced sex) were more aware of antiretroviral treatment for the prevention of HIV, probably because they were more targeted by information campaigns on these treatments, as suggested in the HIV prevention strategies in France [25]. Compared to persons who have no stable partner, people who have a stable partner are also more likely to be more aware of antiretroviral treatment for prevention of HIV. These results suggest that being sexually active is a factor positively correlated with knowledge of antiretroviral treatment for the prevention of HIV.

The results of this research reveal a low level of knowledge of the main preventive treatments for HIV-negative African immigrants living in precarious situations in France. This result is similar to what has been shown in the United Kingdom, where research has also highlighted low levels of knowledge of PrEP and PEP in a population composed mainly of people from Sub-Saharan Africa: Only 19% of respondents had heard of PrEP, and 59% knew about PEP [26]. A recent study in Portugal reported 4.5% of PEP knowledge and 2.3% of PrEP knowledge among immigrants born in Africa [27]. In France, at the time of this study, although there has been no other survey carried out among immigrants from sub-Saharan Africa with which to compare our results, the number of people who were aware of PrEP and PEP in our study was low compared to the data available among MSM [28–31]. Indeed, the EMIS survey reported that among MSM surveyed in France, 59% were aware of TasP in 2017. Knowledge of PrEP

and PEP were 83% and 69%, respectively [30]. In the PREVAGAY study conducted in late 2015, 77% knew about PEP, and 54% knew about PrEP [31]. Despite the differences and possible links between African immigrant, particularly those in precarious situations, and MSM, our results point out an important knowledge gap between this two populations exposed to HIV, as also reported in Portugal [27].

This knowledge gap may be linked to a lack of communication strategies targeting precarious immigrants, as recommended by French health authorities [25]. The information campaigns initially carried out for the implementation of clinical trials and the populations reached by these trials were essentially urban MSM and non-immigrant population [7, 16]. Thus, the conditions under which PrEP emerged and the dissemination of information about this tool contributed to reproducing pre-existing social inequalities in health, class and race [16, 32]. This is consistent with the results from a study conducted in the United States that highlighted a lack of communication about PrEP among nonwhite populations and among non-MSM populations [24]. In France, it is recently that information campaigns on antiretroviral treatments for HIV prevention have been implemented for immigrant populations from sub-Saharan Africa [33–35]. However, it is still early to observe the effects of these campaigns on the level of knowledge of these treatments among precarious immigrants from sub-Saharan Africa.

Our study has some limitations. The study was based on a study sample of 601 people. As a result, low numbers in some of the categories did not allow for stratified analyses, such as analysis stratified by sex. In addition, the low levels of knowledge of PrEP and PEP, although they produced relevant results, impacted the statistical power of the analysis of factors associated with knowledge of these two treatments. Thus, despite the use of tests adapted to small numbers, none of the factors appeared significant at the 5% level for PrEP in the full multivariate model ($n = 27$). As every survey with face-to-face questionnaire, our survey may suffer from social desirability bias. However, sexual indicators (eg same sex relationships) are similar to those obtained in other surveys in this population [36]. Desirability bias does not seem to impact our results in terms of levels of knowledge of antiretroviral treatments for HIV prevention insofar as we find heterogeneous levels of knowledge according to the indicators and that similar results have been observed in the few existing studies. People included in the study were arrived more recently and lived in more difficult socio-economic situations than people eligible but not included. This bias may amplify the poor knowledge of antiretroviral prevention. Furthermore, concerning the variable “having a stable partnership”, given that no distinction was made between a stable partnership in France or in the country of origin, it is possible that some respondents declared stable relationships with partners who do not live in France. It is also possible that the stability of the partner was not understood in the same way by the respondents. Finally, the results presented here cannot be generalized to the entire immigrant population of Sub-Saharan African origin residing in the greater Paris area, since our study population is selected on the basis of precarious situations. Despite these limitations, this study has the merit of being one of the few to describe levels of knowledge of HIV preventive treatments in an immigrant population living in the greater Paris area and to study the factors associated with this knowledge.

Conclusions

Our results show that there is a poor knowledge of antiretroviral treatment for the prevention of HIV among a population of precarious sub-Saharan African immigrants. Approximately one person in twenty knew PrEP and PEP, even though this population is exposed to sexual risk and the risk of HIV infection. These low levels of knowledge of PrEP and PEP suggest that

prevention campaigns must be more inclusive and careful not to increase inequalities in access to information among groups exposed to HIV infection. These results highlight the need for specific communication on HIV preventive treatment for sub-Saharan immigrants in precarious situations, particularly for those who have no access to the health-care system and those with low levels of education.
