# Evidence that the Amino Acid Composition of the Particle Proteins of Plant Viruses is Characteristic of the Virus Group 

I. Multidimensional Classification of Plant Viruses

C. Fauquet, J. Dejardin, J.-C. Thouvenel

Phytovirologie, ORSTOM, Abidjan, Ivory Coast

Key Words. Coat protein • Amino acid composition • Plant virus • Classification • Principal components analysis

Summary. The amino acid (AA) contents of the coat proteins of 134 plant viruses and strains were classified by principal components analysis. The virus groupings that were obtained correlated well with the classification of Matthews. The relationships of each virus were dependent on the number of AA residues (axis 1) and on the percentage composition of each AA in the proteins (axes 2-4). The classification indicated which data were anomalous and needed confirmation. There seemed to be more anomalies in estimates of protein size than of protein composition.

Tremaine and Goldsack [1] attempted, without success, to determine if there was a relationship between the amino acid composition (AAC) of the coat proteins (CPs) of the particles of plant viruses and the shapes of those particles. Tremaine and Argyle [2], using an agglomerative method of sorting strategy and the Euclidean distance metric, could not correlate the AAC of the CPs of plant viruses with groupings based on other classifications [3-5]. Gibbs [6] chose the same criterion in an

Revised: April 9, 1985
attempt to classify 66 plant viruses by using the nonmetric coefficient of Lance and Williams [7] and the principal coordinates method [8]. The analysis distinguished only tobamoviruses and tymoviruses. Nevertheless, a hierarchical agglomerative classification of those viruses not separated by the ordination, using a nonmetric coefficient and flexible sorting [9], showed a general clustering of viruses belonging to the same group, e.g., bromoviruses and sobemoviruses.

Similarly, Gibbs and Harrison [10] studied tobamoviruses and found a close correlation between a classification based on the AAC of the CPs and the groupings proposed by $T s u$ gita [11] and Van Regenmortel [12]. They also demonstrated a close correlation (0.832) be-

Fonds Documentaire ORSTO蹱
tween a computer classification based on the amino acid (AA) sequences of the CPs of 6 tobamoviruses and one based on their AAC. Gibbs [13] and Paul et al. [14] showed that for tobamoviruses there is a linear correlation (0.833) between similarities based on the AAC of the CPs and those based on serological relationships. Consequently, for tobamoviruses it seems clear that groupings based on biochemical criteria are correlated with serological relationships; such groupings are related to those based on sequences of the AAs of these CPs. By contrast, in a study of the tymoviruses, Paul et al. [14] concluded that, although there is a general similarity between the classification based on the AAC of the CPs and that obtained from serological relationships, the coefficient of correlation (0.369) is poor. Moghal and Francki [15], working with potyviruses, concluded that: 'the AAC of antigenically closely related viruses were very similar, but similarities of those distantly related were no greater than those of the apparently unrelated viruses'.

We have reexamined the potential uses of these methods, using new data on the AAC of the CPs and improved methods of statistical analysis. Several classification methods were tested, and the results obtained by the method that gave the best correlation with classifications obtained by other methods using different data are presented here. Our aim was to compare all known data on the AAC of the CPs to discover how well the classification obtained correlated with that of Matthews[16], which is now widely used.

## Materials and Methods

We collected all published data on the AAC, as well as some new AACs obtained for viruses isolated in the Ivory Coast [17]. If the amount of a particular

AA was unknown (e.g., cys or trp), we replaced it either by the average amount in the CPs of the other strains of the same virus or by the average amount in the CPs of the other viruses belonging to the same group. When it was not possible to estimate values in this way, it was assumed that one residue of the AA was present. The AAC data used, expressed in numbers of AA residues per molecule and grouped according to the usual accepted classification, are given in table I.

The classification method used was a principal components analysis by the ANCOMP program from the ADDAD library. ${ }^{1}$ The estimated numbers of AA residues in each protein were the quantitative variables, and the principal components analysis was done with a Euclidean metric of the data after standardizing them to zero mean and unit variance, i.e., the Eigenstructur was searched in the correlation matrix [18].

The objective of a principal components analysis is to find a small number of linearly independent combinations (principal' components) that keep the maximum information of the original variables. The results can be expressed graphically by representing the cluster of individuals as 3-dimensional diagrams that have a minimum of anomalies. The total variation is expressed by a few components without any great loss of information: the first principal component is that which accounts for most of the information (variability) and corresponds to the longest axis of the total cluster of individuals; the second component is orthogonal to it (uncorrelated) and takes a maximum of the residual variability; etc.

## Results

The first four axes obtained with the principal components analysis accounted, respectively, for $39.6,14.8,7.6$ and $6.1 \%$ of the total information available in the AAC of the CPs of the viruses. In other words, axes 1,2

1 ADDAD (Association pour le Développement et la Diffusion de l'Analyse des Données) library is available at the CIRCE (Centre Interrégional de Calcul Electronique), CNRS-Orsay (Centre National de la Recherche Scientifique).
and 3 (fig. 1) account for $62 \%$ of the variability and result in clusters that correlate well with the currently accepted groups; only the bromoviruses seem to be intermingled with the potexviruses. Axis 1 correlates with 12 of the 18 AAs , and the relative contribution of any one AA does not exceed $10 \%$ (table II). This axis mostly represents the molecular weights (MWs) of the CPs, which range from $17,500(17.5 \mathrm{~K})$ for tobamoviruses to 45 K for tombusviruses. Axes 2, 3 and 4 correlate to particular AAs. For example, axis 3 is statistically correlated only to tryptophan (trp) content, which represents $42 \%$ of the variability in this dimension (table II). Axes 2,3 and 4 (fig. 2) represent only $28.5 \%$ of the total information, but clearly differentiate the viruses into groups, although they are less well separated. Whether considering figure 1 or 2 , most of the virus groups are clearly separated from one another; however, the potexviruses are very close to the bromoviruses, comoviruses, and nepoviruses.

## Viruses with Rod-Shaped Particles

The tobamoviruses ( 23 data sets) were all situated in a restricted part of the ordination and showed great homogeneity. The exception was CCV (No. 052), a tentative member of the tobamovirus group [13].

Tobraviruses (1 data set; No. 061) were classified very close to Chara corallina tobamovirus (No. 052).

The hordeiviruses, represented only by barley stripe mosaic virus (No. 182), and the furoviruses [19], represented by beet necrotic yellow vein virus (No. 046) and peanut clump virus (No. 034-039), were distinct from the tobamoviruses and the single tobravirus (No. 061). Peanut clump virus seemed to be the most clearly differentiated from all the rodshaped viruses.

All the rod-shaped virus groups were relatively close together in the ordination, showing that the AAC of their CPs is homogeneous.

## Viruses with Filamentous Particles

The carlaviruses were represented by 4 data sets: potato virus $S$ (No. 074) and 3 viruses related to cowpea mild mottle virus (No. 162, 169, and 176). These 3 viruses have properties similar to those of carlaviruses, but they are transmitted by whiteflies instead of aphids and their intracellular inclusions are different [20]. Except for No. 074, all are clustered and are close to the potyvirus group.

Potexviruses were represented by 12 data sets ( 4 of potato virus $X$ and 2 of white clover mosaic virus). This group was the most scattered, perhaps because of the difficulty in determining the MWs of their CPs; estimates range from 103 AAs for data set No. 184 to 463 AAs for No. 183. Gibbs and McIntyre [21] suggested that the AA number for potexviruses is around $210-215$, which agrees with that published by Miki and Knight (No. 073) and by Short (No. 226-232). Because the differences are very large and would unnecessarily complicate the figures, we avoided representation of the value 133 AAs for white clover mosaic virus (No. 076) and of the values 103 and 463 AAs for potato virus X (No. 184 and 183). Nevertheless, the AAC of these data are not wrong, and their position in figure 2 is accurate. Except for the last 3 examples, the cluster of potexviruses is clearly delimited in space and close to several virus groups with isometric particles (fig. 1, 2).

The potyvirus group (29 data sets) was the best represented group. Just as for potexviruses, there is uncertainty in the MWs of their

CPs, with estimates ranging from 21 K to 37 K . The sizes of these proteins have not been tested by the Fitmol method [21], but it is recognized that the MW of the CPs of potyviruses is about 34 K [22]. As for the potexviruses, we avoided the representation of the values corresponding to low MWs of CPs (No. 071, 075, 083, 084, and 089). Nevertheless, the AAC of these data are possibly quite accurate, because in figure 2 (which does not take into account the MW factor) they would integrate well into the potyvirus cluster. This suggests that the main error may be in MW rather than in percentage AAC. The potyvi-
rus group was always strictly differentiated from other viruses. (fig. 1, 2) and filled a volume of $1 / 8$ th of the ordination.

Closteroviruses were represented only by 3 analyses; nevertheless, they were similar and were separated from the other viruses.

When only the filamentous viruses are considered, they separate into subclusters that do not overlap.

## Viruses with Isometric Particles

The bromoviruses were represented only by 3 viruses, but the results were closely similar and the cluster was compact.

[^1]

Fig. 1. Three-dimensional diagram showing the first three factors of a principal components analysis of 122 data sets of plant virus CPs compared by their AAC. The three axes contain $62 \%$ of the information. The key for the code numbers is given in table I. The positions of the viruses on axis 1 are indicated by the sizes of the circles.

The comoviruses were illustrated by bean pod mottle virus (No. 011) and squash mosaic virus (No. 022). They have 2 capsid proteins ( 22 K and 42 K ), but the correspondence of the AAC used here is unknown and the results are tentative. The 2 AACs are always very close and are near the centroid of the general cluster.

The cucumoviruses were represented by cucumber mosaic virus ( 5 data sets: No. 002-005 and 218) and by peanut stunt virus (No. 204). They cover a large space along axis 1, again revealing possible inaccuracies concerning the MW (185 AAs for peanut stunt virus and 261 AAs for some estimates for cucumber mosaic virus). In the other axes

Table II. Correlation coefficients (COR) between the axes of the ordination and the AA contents of the viral CPs , and percentage of contribution $(\% \mathrm{C})$ of the AA considered in the total variance of the axis

(fig. 2) the AACs are homogeneous. As the MW of cucumber mosaic virus has been revised to about 287 AAs [23] and 235 AAs [24], the real position of the group is probably much closer to the cluster of data sets 002-005. However, the cucumoviruses are well separated from the other groups of spherical viruses.

The sobemoviruses were represented by 5 data sets: 2 strains of southern bean mosaic virus (No. 019 and 020), rice yellow mottle virus (No. 001), sowbane mosaic virus (No. 021), and cocksfoot mosaic virus (No. 216). Only data sets 001,019 , and 020 were always related, and hence probably indicate the position of the group. Data set 216 is remote from the others, and No. 021 is probably not a sobemovirus, insofar as the AAC of the CPs is concerned, which seems to be correct [21].

Four of the five tombusviruses are situated within one subcluster and clearly indicate the position of the group. The tombusvirus group is the most distant from the center
of the ordination. The cluster is determined by factors other than the MW of their particle protein, because it is also quite distinct in figure 2. In fact, the tombusvirus group is represented by one definitive member, tomato bushy stunt virus (No. 028), and by 4 tentative members (No. 014, 017, 030, and 203) [25, 26]. Three of those tentative members (No. 014, 017, and 203) reveal apparent affinities with tomato bushy stunt virus, providing a supplementary element for their classification in the tombusvirus group.

The tymovirus group ( 17 viruses) is the best represented group of viruses with isometric particles and shows the greatest homogeneity along each axis. It is well separated from the other groups, and its body forms a reference mark for the others. It is noteworthy that erysimum latent virus, which is a tentative member of the group, is contained in the tymovirus cluster.

Only 2 nepoviruses represented this group: tomato ringspot virus (No. 027) and

Fig. 2. Three-dimensional diagram illustrating factors 2,3 and 4 of a principal components analysis of 122 data sets of plant virus CPs compared by their AAC. The three axes contain $28.5 \%$ of the information. The key for the code numbers is given in table I. The positions of the viruses on axis 2 are indicated by the sizes of the circles.
tobacco ringspot virus (No. 029). These were always associated and placed near the center of the ordination. The MW of their CPs had been determined to be $53-60 \mathrm{~K}[27,28]$ and was then revised to $13-19 \mathrm{~K}$ [29]. We used the AAC corresponding to about 20 K ; consequently, if the value of $53 \cdots 60 \mathrm{~K}$ is verified, the position of this group will have to be revised.

Other groups were represented by only 1 or 2 individuals, and consequently their posi-
tions in the diagrams are uncertain, i.e., tobacco necrosis virus group (No. 024 and 026), pea enation mosaic virus group (No. 018), dianthoviruses (No. 015), and ilarviruses (No. 200 and 201). Most of these groups are found near the center of the ordination, as is the satellite virus of tobacco necrosis virus (4 data sets; No.023, 025, 185, and 186). Three of these data sets are clustered (No. 025, 185, and 186).

When spherical viruses only are considered, they are spread through a large proportion of the ordination, and some of them, e.g., tombusviruses and tymoviruses, occupy relatively large volumes in the diagrams.

## Viruses with Bacilliform Particles

There were 3 data sets for alfalfa mosaic virus (No. 177-179), but its MW is uncertain. No. 177 has 297 AAs and correlates well with the Fitmol analysis [21]; in contrast, No. 178 and 179 were assessed to have 172 and 177 AAs, respectively. The primary structure of the coat protein [30] has been shown to have 217 AAs , and consequently we must imagine a migration of the group (No. 178,179) in the positive direction of axis 1 to get the correct position of this virus in figure 1 .

## Discussion

The analysis of principal components used in this work is a reliable method for representing the relationships of individuals and clusters of individuals, when there is no evidence to indicate that they are phylogenetically related, for which a more realistic classification is a hierarchical one. This method enables a multivariate analysis to be represented in multidimensional space, thus giving a precise picture of the relationships of the viruses [2, 6].

The hyperspace filled by plant viruses in an ordination of all proteins represents only $5 \times 10^{-4}$ of the total hyperspace [2]. The CPs of plant viruses therefore constitute a very dense subcluster of all known proteins. This cluster is not organized at random, and the most important conclusion of our study is that subclusters within it correlate well with currently accepted virus groups [16] that are
formed on biochemical, structural, biological, and serological criteria. Thus, the product of one gene of each of these viruses provides classificatory information which is closely similar to that provided by all genes of the viruses.

It is noteworthy that, despite the great range of sources of information and of analyses used in our study, the classification obtained is close to the currently accepted classification [16]. There are some exceptions, and it is not known whether these are real or a result of experimental error. Our study showed that axis 1 correlates most closely with the MW of the CPs and consequently must be determined precisely. Nevertheless, the MW is not the sole discriminatory element; figure 2 , which represents $28.5 \%$ of the information and excludes the MW axis, provides the same clustering pattern. Obviously, more data sets of the AAC of these and additional viruses would bring a greater precision to the ordination and would increase the density of the clusters.

Only $28.5 \%$ of the total information included in the AACs is needed to provide a meaningful classification, and there is a similarity of CPs of plant viruses within the protein hyperspace. These apparent similarities may reflect a common origin in evolution, with only small, but real, differences. Our classification does not correlate only with the shape of virus particles; within one part of the diagram, viruses can be found whose particles are filamentous, rod-shaped, or isometric. Serologically related viruses are grouped in clusters, but the distances between the clusters do not reflect distances in serological relationship. The AAC of the CPs of plant viruses seems to contain information derived from several sources that may be diverse and may interfere with the AAC of
the CPs. Nevertheless, there is a basic similarity of all plant virus CPs; this is presumably because the CPs protect the nucleic acid genomes and form large soluble macromolecules. Plant virus CPs also have a structure that is related to biological factors (e.g., transmission mode), and they have a specific basis reflected and measured by serological relationships [31].

The principal components method of classification, like hierarchical methods, shows close relationships clearly. Unlike the latter, it also gives a measure of the relationship between subclusters. Therefore, as the close groupings within our classification correlate well with currently accepted groupings of viruses, it is worth examining the correspondence between the higher-order relationships (inter-cluster) shown by our classification and the recently discovered 'intergroup' or 'inter-genus' relationships indicated by nucleotide sequence analysis. Distant relationships of this sort have been found between viruses with RNA and DNA genomes [32], between plant and animal viruses [33], among those with rod-shaped, isometric or bacilliform particles, and between those whose particles have a lipid envelope and those that do not [34].

Such sequence homologies indicate, for example, that at least some of the genes of alfalfa mosaic virus, brome mosaic bromovirus, cucumber mosaic cucumovirus, tobacco streak ilarvirus and Sindbis alphavirus have homologous sequences [34-37] and hence probably have a common ancestor. Thus, it is of interest that all these viruses (except Sindbis alphavirus, which was not included in the classification) are close to one another in the central region of the ordination (fig. 2). A similar distant relationship has been found among cowpea mosaic comovirus and polio-
and encephalomyocarditis picornaviruses [33]; each of these viruses has a divided RNA genome and a $5^{\prime}$-linked protein (VPg) [38-40]. Other viruses of this type are the nepoviruses [41] and pea enation mosaic virus [42]. It is noteworthy that the single comovirus and nepovirus in our classification group close to pea enation mosaic virus (fig. 2). However, other viruses that have a $5^{\prime}$-linked VPg but an undivided genome, e.g., potyviruses [43], sobemoviruses [44], and luteoviruses [45], are widely dispersed in our classification. Thus at least some of the relationships between subclusters that are illustrated in figures 1 and 2 may correlate with more distant, possibly more ancient, relationships between the currently accepted groups.

## Acknowledgments

The authors thank Dr. A.J. Gibbs and Dr. B.D. Harrison for help and advice in the preparation of this paper.
