Length-weight Relationship of Fishes from Coral Reefs and Lagoons of New Caledonia - An Update

Y. Letourneur, M. Kulbicki and P. Labrosse

Abstract

Length-weight relationships of 316 reef and lagoon fish from New Caledonia (SW Pacific Ocean) belonging to 68 families are computed. A total of 43 750 individuals was used for this purpose. Fish were sampled by different techniques, such as rotenone poisoning, handline and bottom longline fishing, gill and trammel nets, and trawling in various biotopes (coral reefs, lagoon bottoms and mangroves).

Introduction

For the last 15 years, the ORSTOM Centre of Nouméa has conducted stock estimates of lagoon fish in New Caledonia. For most of these studies, underwater visual censuses (UVC) are used to estimate densities and biomasses of a large spectrum of fish species (Kulbicki 1988, 1997; Letourneur et al. 1997a; Wantiez et al. 1997). In order to make biomass estimates it is necessary to know the length-weight relationships of the species studied. These relationships are es-

timated from specimens obtained by experimental fishing in various biotopes.

The present work is an update of the work presented by Kulbicki et al. (1993). The previous work on New Caledonian reef and lagoon fish gave length-weight relationships for 279 coral reef and lagoonal species based on data from New Caledonia. This work had also cited literature on relationships for 56 species occurring in New Caledonia but based on data from other Indo-Pacific locations. The present update takes into ac-

count 9 300 new specimens (on a total of 43 700 individuals). The aim is both to improve previous length-weight relationships of reef and lagoon fish, and to add relationships for a number of species for which no previous information was available from New Caledonia. Most of this new information comes from the northern lagoons of New Caledonia which had previously never been sampled (Labrose et al. 1996, 1997; Letourneur et al. 1997b), and from studies on juvenile fishes (Rossier and Kulbicki, unpublished data).

Materials and Methods

Fish were caught by different methods: rotenone poisoning, handline and bottom longline fishing, gillnet and trammel nets and trawls. Spearfishing was also used in some circumstances, mainly on coral reefs. Nets were mainly used in mangrove areas, whereas handlines were mainly used near the reefs, and both longlines and trawls on the bottom of the lagoon.

Fork length was the measure taken for all species, except for some particular cases: total length for sharks, standard length for Anguilliform fish, and disk width for rays. The sexes are not differentiated here, although we are aware that males and females may have different length-weight relationships.

The parameters **a** and **b** of relationships of the form

$$W = a \cdot L^b \quad \dots 1)$$

were estimated through logarithmic transformation, i.e.,

$$\ln W = \ln a + b \ln L \quad \dots 2)$$

with **a** and **b** estimated by ordinary least squares regression; **L** and **W** are length in cm and weight in g, respectively.

Results and Discussion

The results are presented in Table 1. The identifications are essentially based on Rivaton et al. (1989) with recent updates in the literature being taken into account. Species are arranged by families according to Eschmeyer (1990), and species within each family are presented alphabetically. The present data set covers 316 species, which represents an addition of 37 species compared to the previous work of Kulbicki et al. (1993). This updated data set also gives additional information on 191 out of

the 279 species from the previous study, resulting in a larger range of fish size and better values of the correlation coefficient (**r**) for the log-transformed L-W pairs.

Our present knowledge suggests that the ichthyofauna of the New Caledonian lagoons comprises approximately 1 500 fish species in the 0-80 m depth range (Kulbicki and Rivaton 1997). Thus, despite the relatively high number of species for which L-W relationships are now available, still much needs to be known on the smaller species, mainly from coral reefs. These species are probably not major contributors to total biomass, but might play a significant role in trophodynamic processes and fish production. Additional sampling is underway to complete this data set. Those interested in information at the family or genus level should contact the second author directly.

Table 1. Length-weight relationships of 306 species of fish occurring in New Caledonia. Fish names in parentheses indicate previous misidentifications in Kulbicki et al. (1993).
